The case was treated by strong continuous extension of the head upon the trunk; and under this treatment the symptoms of interference with the cord gradually disappeared. In three months the patient was able to leave her bed, with the head securely supported by a leather cravat. In another month she was sent home in this condition, but returned in eight weeks, when it was found that the head could now be supported without any assistance; the prominence, however, both anteriorly and posteriorly, was persistent.

Professor Küster looked upon this as a case of complete recovery after fracture of a cervical vertebra, contrary though such an opinion was to all previous experience. In the discussion which followed the reading of this paper, it was suggested that the case was one of hysteria; but this Professor Küster felt no difficulty in refuting, as the very distinct objective symptoms of fracture were to his mind conclusive proof that such was the nature of the case.

ON INGROWING TOE-NAIL.—Mr. Greig-Smith (*Bristol Medico-Chirurgical Jour.*; *Edinburgh Clinical Jour.*) divides this subject into two classes, intrinsic and extrinsic:

a. *Intrinsic, i. e.*, in the nail, or in the surrounding tissues, or both.

1. In the nail. In some persons the nails are convex, and dip deeply into the surrounding flesh. In such cases, the ordinary nail-cutting is difficult, and

a spicule of bone is often left behind which insinuates itself into the neighboring flesh. The latter swells and conceals it. Irritation is thus set up, and the condition developed.

2. In the flesh. Some people have redundancy of flesh in their toes, overlapping the nails. The confinement in the boot and soddening perspiration starts the condition.

3. In both nail and flesh. The existence of both the above conditions—an arched toe-nail and an excess of soft tissue—will frequently be found associated with the malady.

b. Extrinsic, or from causes lying outside the nail and its surrounding tissues.

1. Flattening of the arch of the foot. When the natural arch is destroyed, the anterior pillar, the ball of the great toe, atrophies, and the patient rests the weight of the body on the whole of the flattened sole. At the end of the step, when the knee is flexed, the weight is transferred to the anterior portion of the foot. This is naturally the pad at the root of the toes, particularly of the great toe; but when the plantar ligaments are relaxed and perhaps painful, this support is not available. Recourse is then had to the only available help, the only tendon which passes from the top of the arch of the foot to its anterior extremity, viz.: that of the flexor longus pollicis. By its contraction the tip of the great toe is brought to the ground, and acts as a substitute for the natural pier. But constant use of the toe in this wise induces hypertrophy of its tissue, and consequent overlapping of the toe-nail. By easily understood stages this hypertrophy becomes irritation, inflammation and suppuration where the flesh is crowded over the edges of the nail, and we thus get the condition fully developed.

It is simple flat-foot, *pes planus*, and not splay-foot, *pes valgus*, which is most likely to start the mischief. If splay-foot causes it, it is more by everting the toe from pressure on its inside in walking, and so squeezing it against the second toe.

2. Eversion of the great toe. This is most frequently dependent either on a habit of walking with the limb much rotated outwards, or on a congenital deflection of the toe itself. This too close proximity may merge into a passing beyond, and then we have the second toe, perhaps with the third, overriding the great toe and evidently causing the complaint.

3. Inversion of the lesser toes. In this case the same result is produced by a deviation inwards of the second and third toes.

Treatment. a. 1. Careful attention to nail cutting. If the granulations are exuberant, the application of a crystal or two of chromic acid, which leaves a hard, dry scab under which the sore quickly heals.

2. Where the cause lies in a superabundance of flesh in the toe, a condition which is usually accompanied with thin, tender skin, which perspires and chafes readily; first, apply chromic acid if necessary, and thereafter, pressure either by strapping or by elastic. Every night the affected toe is to be surrounded tightly from the lip upwards by thin strips of adhesive plaster, taken out of boiling water. This

may be removed in the morning and replaced by an India-rubber cap, such as is worn over a sore finger during a post-mortem examination. The toe is thus rendered and kept anæmic by compression; congestion is removed, and the tissues get more firm and resisting in the course of a few months. Dusting the foot with boracic acid is also good.

3. A judicious combination of the methods just described.

b. 1. Of the extrinsic causes, the most important is flattening of the arch of the foot. Wear a small pad of several thicknesses of chamois leather or flannel under the ball of the great toe. This pad may be put on every morning, and retained in position by a collar of thread or elastic carried around the root of the great toe. After a few months the pad may be gradually given up.

2. When the cause is eversion of the great toe, place a pad between the great and second toes, stopping short of the sore part. This pad, which may be constructed of several layers of flannel or chamois leather, is retained in position by two collars round the great and second toes respectively.

3. In cases where the second and third toes overlap the first, the condition is easily remedied by wearing a double band of tape so arranged as to keep these two toes turned outwards and pushed downwards.

Such is the scientific treatment of the complaint. But in a class that cannot afford to temporize, Mr. Greig-Smith removes the matrix as well as the nail, and scrapes the periosteum off the bone. The operation is a simple one and by the exercise of a little dexterity may be done on both feet while the patient is under the influence of nitrous oxide gas. The knife grazing the bone is carried rapidly round the flesh on the right side of the nail, and, by a change of the same movement, passes under the nail down to the bone, and lifts away nail, matrix, and suppurating flesh. A piece of boracic lint is wrapped tightly round the toe, and need not be removed for a week. In the meantime the patient may get about. At the end of the week the sore will be smaller than the nail removed, for the healthy tissues have been pressed inwards over the sore. In three weeks the wound is cicatrized over; and most likely in a few weeks more a stunted nail is developed, like that usually seen in the fifth toe, from which no trouble ever arises.

The sore from this operation heals as quickly as that from simple avulsion of the toe-nail; and there is no young and tender nail to be guided in its growth, and perhaps cause the old trouble in its maturity. This simple cicatrization is altogether a more rapid and less painful process than the growing of a young nail.

As a plan of treatment he believes that mere avulsion of the toe-nail ought to be abolished from surgery. It gives much discomfort during the growth of the young nail, does not attack the true cause of the mischief, and is most uncertain as a mode of cure. The toe-nail is useless; a firm cicatrix is innocuous, and not more unsightly than the ordinary toe-nail of the adult. The removal of the matrix, and the scraping of the bone is certain to cure the very worst case of the disease.

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 65 RANDOLPH STREET,
CHICAGO, ILLINOIS

SATURDAY, SEPTEMBER 20, 1884.

ILLINOIS STATE BOARD OF HEALTH AND VACCINATION.—At the regular quarterly meeting of this Board, held in Springfield, Ill., July 2 and 3, 1884, the following resolution was adopted:

“Resolved, That the increasing prevalence of small-pox in London and elsewhere, indicating a probable renewal of the epidemic tendency, and its frequent introduction into Illinois from neighboring States within the past few months, make it desirable that vaccinal protection be secured as fully as possible in every portion of the State; and to this end the Secretary is hereby authorized to call the attention of sanitary authorities and others to the subject, and to take the necessary steps to push the further enforcement of the school-vaccination order of the Board, so that all new scholars, and those who have not heretofore fully complied with its provisions, may be properly protected against small-pox before the advent of cold weather.”

The Secretary of the Board, availing himself of the authority here given, has issued the following order and accompanying comments:

“In accordance with this action of the Board, county superintendents of schools, school directors, trustees and teachers, are hereby reminded that the admission of any child to a public school in this State, without presenting satisfactory evidence of proper and successful vaccination, is prohibited.

“In this connection attention is respectfully invited to the following facts, concerning the operation of the school-vaccination order during the winter of 1881-82, and which are compiled from the fifth annual report of the State Board.

“When the school-vaccination order went into effect, January 1, 1882, nearly 69 per cent., or over 490,000, of the enrolled scholars in Illinois were either entirely unprotected against small-pox by vaccination, or had again become susceptible through

failure to re-vaccinate at the proper time. Within sixty days, that is by the 1st of March, 1882, there was less than 6 per cent. of unprotected and susceptible remaining among those in attendance; and the frequency of small-pox and varioloid among public-school children had been lessened more than one-third, while the mortality rate of cases was reduced from 16.5 per cent. to 3.3 per cent. On the one hand, the number of cases was reduced, owing to the general vaccinal protection; and, on the other hand, the cases which did occur were milder and less fatal, because of the modifying effect of vaccination. The small-pox reports made to the Board from all parts of the State during the four years, 1880-1883, show that the deaths among *unvaccinated* school-children were at the rate of 48 in every 100 attacked; while the deaths among *vaccinated* school-children were only in the proportion of *nine-tenths of one per cent.* of those attacked. It is difficult to conceive of a stronger argument than these figures present for the necessity of a thorough enforcement of proper and successful vaccination as a prerequisite to admission to the public school-room.”

The printed circular, just issued from the office of the State Board, from which we have taken the foregoing paragraphs, also gives full instruction as to what constitutes “proper and successful vaccination,” and all necessary instructions to school authorities and teachers to enable them to execute the orders of the Board efficiently. Experience has fully proved that without some strong compulsory influence, large numbers of both children and adults will be allowed to accumulate in every populous community, without any protection against variola, and are, consequently, ever ready to become its victims, and to aid in spreading the disease to others.

As a very large proportion of all the children in the State desire admission to the public or other schools supported wholly or in part by public taxation and controlled by public officers, the making of proper vaccination a prerequisite for such admission becomes one of the most efficient methods of securing a near approach to the complete protection of the whole population. If the same method was adopted and enforced in every State, it would greatly lessen the danger of having the disease gain a foothold anywhere.

MEDICAL EDUCATION AND MEDICAL SOCIETIES.—

The stand taken by the Nebraska State Medical Society in regard to the admission of members, as indicated in the letter of Dr. Mansfelde in the preceding number of this journal is highly commendable. If it were taken by every State and local medical society in our country, and the conditions named faithfully exacted, it would soon bring a marked im-

provement, more especially in the preparatory or general education of those who propose to enter upon the study of medicine, which is really more important so far as regards the standing and usefulness of the profession than any other one item connected with its education. Forty years since we urged this subject upon the attention of State and local medical societies with all the ardor of youth. We then claimed that it was the duty of the profession at large to erect and enforce a proper standard of general education for those who might propose to study medicine, by having every medical society provide a board of censors for making the necessary preliminary examinations, and no member of said society should receive a young man or woman as a student of medicine who had not first obtained a certificate of proper qualifications from such board. We have not changed our views on the subject since, but we have lived long enough to learn that members of the medical profession are no more exempt from inconsistencies than other classes of people.

We have seen parties, who in medical society meetings and addresses, would advocate the most rigid exaction of a fair standard of general education, take students into their own offices who had not even a respectable common or district school education, and then advise them to attend medical colleges, where not only no standard of general education was required, but where a diploma could be obtained for an expenditure of the smallest amount of time and money. We have no doubt, however, but that the Nebraska State Medical Society is in earnest, and its Secretary is doing a good work in the office he holds.

CHOLERA IN EUROPE.—In Marseilles the epidemic seems to have spent its force. Under date of Sept. 14 but two cases are reported. The total number of fatal cases in that city, from the outbreak of cholera up to the present date, has been 1,445. Of these, 1,140 were Frenchmen; 247 Italians; 19 Spaniards; 11 Greeks; 6 Austrians; 5 English; 11 Swiss; 3 Germans; 2 Americans, and 1 Swede. From Toulon the last reports are favorable. Fourteen cases are reported during the two days ending Sept. 14.

The malignant scourge seems, however, to have lost none of its virulence. The theatre of action is transferred to Naples, where, during the past week, its ravages have been terribly severe. Nor is this surprising.

If any city on the continent was in favorable condition for the pestilence to do its worst, that city

was Naples. Its tenements literally swarm with inhabitants, filthy beyond description.

Its narrow tortuous streets, shut in by high buildings, into which the sun can scarcely pierce, damp and reeking with filth, its drainage neglected, its sewers discharging their foul pollutions all along the base of the hills, until the bay is contaminated with the accumulations of years, such are the conditions joined with the intense heat of the city in summer, which conspire to produce the alarming fatality of the present visitation.

Our dates from Naples are up to Sept. 14. During the previous two days 1,229 cases had been reported in the city, of which 687 had been fatal. During the same period 129 other cases are reported at various points in Italy, of which 43 were at Genoa. With less of poetic inspiration than when it was uttered, but with far more truthfulness it may *now* be said "See Naples and die."

The warnings from Toulon and Marseilles—and now repeated with such terrible emphasis at Naples, should not fall idly upon the ears of those who, in the old world or in the new, are responsible for sanitary conditions.

To be unprepared for the epidemic, so far as human agencies can avail, is to be criminal. With a rigid surveillance of our cities and thoroughfares, the courage of the people will be maintained, and if the pestilence shall make its appearance upon this continent, it will doubtless be shorn of its terrors if wise and efficient counsels shall prevail.

THE AMERICAN PUBLIC HEALTH ASSOCIATION, which will hold its next annual meeting in St. Louis, Mo., on the 14th of next month, has met with serious losses by deaths during the past year.

Five members of the Advisory Council of the Association have died within the past year, viz.: Dr. Elisha Harris, of New York; Dr. Charles W. Chamberlain, of Connecticut; Dr. Robert J. Farquharson, of Iowa; Dr. John Taylor Gilman, of Maine; and Dr. Hillary Ryan, of Texas.

Dr. Harris was one of the founders of the Association and its President at the session of 1878. He was Secretary of the State Board of Health of New York at the time of his death. Dr. Chamberlain was also Secretary of the State Board of Health of Connecticut; and Dr. Farquharson, an ex-medical officer of the United States Navy, Secretary of the State Board of Health of Iowa.

THE AMERICAN GYNÆCOLOGICAL SOCIETY is to hold its next annual meeting in Chicago, commencing on the 30th inst.

The local committee of arrangements have made preparations to give the members of the Society from other parts a cordial reception, and to obtain for them a generous hospitality during their stay. A full attendance and profitable meeting is expected.

DR. J. G. KIERNAN, of this city, has been appointed by the County Commissioners, Medical Superintendent of the Cook County Asylum for the Insane.

DR. JOHN G. ADAMS, one of the oldest and most beloved of New York physicians, whose death was announced a few weeks since, left by his will the following bequests:

Five thousand dollars to the Presbyterian Hospital, for a free bed for the sick poor of the Brick Church; \$5,000 to the Academy of Medicine, to pay off the debt on its building (this bequest is revoked by codicil on account of the action of the Academy in reference to the new code); \$2,500 to the Bridgeport Protestant Orphan Asylum and Hospital; \$500 each to the Physicians' Mutual Aid Association, and the Training School for Nurses. His medical library is bequeathed to the New York Academy of Medicine.

SOCIETY PROCEEDINGS.

HYSTERIA, AS AFFECTED BY REMOVAL OF THE OVARIES.

BY G. L. WALTON, M.D., BOSTON.

Read before the Section for Clinical Medicine, Pathology and Hygiene of the Suffolk District Medical Society, April 9, 1884.

It is not the object of this paper to discuss oöphorectomy, as such, either from the surgical or the moral point of view, but to consider the question of hysteria as benefited or not benefited by the operation. This operation having, in the face of persistent opposition, forced itself into recognition on purely gynæcological grounds, the neurological aspect of the subject seems now to attract considerable attention, and its importance is not inconsiderable.

That all sorts of reflex nervous symptoms accompany diseases of the uterine appendages is a well-recognized fact. Similar symptoms appear, to be sure, in women with normal reproductive organs, and even in men, facts which have led to the depreciation of the uterine origin of hysteria to the degree that we sometimes meet with the statement that hysteria is *always* a constitutional disease, having no relation whatever to the pelvic organs. Now, although this

is undoubtedly the usual character of the disease, there are certainly many cases in which hysteria occurs in persons possessing no constitutional tendency to nervous trouble, the symptoms dating accurately from disease of the pelvic organs. In view of these cases we must take a step backwards toward the ancient view that all hysteria arose from uterine disorder, substituting, however, probably here the ovaries for the uterus as the seat of original irritation. It becomes of practical importance to consider this subject carefully, for if hysteria exists in a given case of pelvic disease in which operation is proposed, and if the hysteria is considered to be dependent on the ovarian irritation, there will be an additional indication for removing the offending organ. Indeed, if the hysterical symptoms reach a certain degree in such a case they may alone furnish sufficient cause for the operation. One finds not infrequently among reported cases of Battey's operation the statement that the reflex nervous symptoms were relieved. Detailed accounts of such symptoms are, however, not common, and it seems probable that among these cases typical and measurable symptoms of hysteria, such as hemianæsthesia, would be oftener found if oftener sought. As a rule, however, the nervous symptoms have occupied the background, the important indication for operation being generally the dysmenorrhœa.

The question of removal of the ovaries for hysteria alone has now been broached, and has already been practically tested with results diametrically opposed.

As an example of unsuccessful operation may be cited the case of Landau and Remak¹, in which both ovaries were removed on account of hystero-epilepsy, combined with hysterical hemianæsthesia. The ovaries were found normal, and the nervous symptoms were not alleviated in the least. These writers express, therefore, the opinion that the operation for hysteria is unjustifiable, and that the tenderness existing over the ovaries in this disease is merely a hyperæsthesia symptomatic of the general nervous irritability rather than pointing to the source of the nervous trouble. On the other hand, a large number of cases have been reported in which hystero-epilepsy and similar symptoms have disappeared after removal of the ovaries. In the collection of 218 cases made by Battey of the operation between 1872 and 1881 epileptic attacks were present in twenty-six cases, and were relieved in over two-thirds of the number. A number of cases have been reported since this collection was made in which hystero-epilepsy has been the chief indication for removal of the ovaries, and has disappeared or been greatly mitigated by the operation.

As examples of such cases may be mentioned two of Carstens',² whose histories were briefly as follows:

CASE I. The patient, twenty-four years old, single, had been a sufferer about five years from dysmenorrhœa, leucorrhœa, and severe hystero-epilepsy, coming on at the menstrual periods. There was no hereditary nervous tendency. Examination showed retroversion of uterus, slight endometritis, internal stenosis of uterus, and ovarian tenderness. The left ovary (adherent) was removed, together with a small cyst

¹Zeitschrift f. klin. Med. Berl. 1883. VI. 437-454.

²American Journal of Obstetrics, March, 1883.

from the left Fallopian tube. The operation was followed by disappearance of the menses, and by permanent relief of the hystero-epilepsy and the leucorrhœa, at least neither had recurred a year after operation.

CASE II. The patient, twenty-four years old, married, has no nervous family history. Severe ovaralgia came on four years ago, accompanied by pain in the vetex and attacks of hystero-epilepsy, occurring sometimes daily. Examination showed retroflexion of the uterus and exquisitely tender left ovary. This was removed, and found diseased. Perfect cure followed, without remission up to the time of second report, made four months after operation. The conclusions drawn by Carstens are as follows: "In general I might conclude that Battey's operation is not only justifiable, but really we might say it is criminal neglect not to perform it in cases which fail to be benefited, by other treatment. It is a last resort after every other proper treatment has failed in cases which are caused by ovarian disease, such as hystero-epilepsy, dysmenorrhœa, and menorrhagia due to fibroid tumors, and which either endanger the life of the patient or make life a burden to her.

These views are certainly justified by experience, and the difference between these results and those of E. G. Landau and Remak seems to lie in the selection of cases. That operated on by the latter writers was one of the large class of hystero-epileptics in which the nervous condition is independent of the uterine appendages. The fact was established by examination of the ovaries after operation that in this case the ovarian tenderness did not result from disease of those organs, but was only indicative of general sensitiveness of the nervous system. As regards this class of cases, which is to say, probably, as regards the large majority of cases of hysteria, the conclusions of Landau and Remak are undoubtedly correct. Such cases, however, as those operated on by Carstens come under quite another category, in that the hysterical symptoms were manifestly secondary to and dependent on ovarian irritation. It is only with regard to the latter class of cases that the question of operation should ever have been considered for a moment, and the first question to be asked is, Into which class does the case in hand fall?¹

It may be well at this point to consider briefly the probable physiological relation between hysteria and the ovaries in the two varieties of hysteria, idiopathic and symptomatic.

Hysterical symptoms, mental, paralytic, and convulsive, arise probably from perverted function of the cortical cells of the brain, the final centres of sensation and motion, and the seat of the mental processes. This may be considered the accepted view of neurologists at present. Just what pathological state obtains in those cerebral cells is still a matter of conjecture. Post-mortem examination reveals nothing. Whether the disturbances arise from vaso-motor irregularities, to minute changes in structure, or to mere alteration

in reflex irritability without anatomical basis we need not question at present. All that interests us in this discussion is the fact that the connection is a close one between these perverted cerebral states and disordered visceral organs, and that, whatever the *modus operandi*, cerebral and abdominal irritability generally, if not always, co-exist in cases not only of hysteria, but of the allied nervous conditions, as hypochondria and neurasthenia. Now the link through which the connection is established between brain and viscera can be none other than the sympathetic nervous system. From this system the ovaries are richly supplied from the renal plexus, whose connection with the brain is anatomically a very direct one, although this is by no means an important factor, inasmuch as the physiological relation between all parts of the sympathetic nervous system is so close, and the transit so rapid, that the most distant portions of the body are always in intimate and immediate connection.

In cases of hysteria the cerebral disturbance is evidenced sometimes by *loss* of activity motor and sensitive, as in paralysis, and sometimes by *increased* activity, as in convulsions and hyperæsthesia. Again, both classes of symptoms often co-exist in the same patient, some cerebral functions being abnormally active, while others are depressed. Among the symptoms illustrating the former no one is more constant than hyperæsthesia. Spots of hyperæsthesia are sometimes found on the scalp and sometimes on the spine, but rarely fail in the region of the ovaries. The opinion is, to be sure, held by many distinguished writers, as, for example, by Westphal, that this tenderness is in connection with the abdominal wall, not the ovaries. But this view seems clearly disproved by the fact that the spots of tenderness rise during pregnancy with the uterus and fall again after childbirth.¹ The ovarian tenderness arises probably from the peculiar irritability of the rich sympathetic nervous supply of the ovaries, an irritability greatly increased at certain periods by the congestion to which the female reproductive organs are subject. In the ordinary case of hereditary hysteria, this tenderness being merely a local symptom of excessive excitability, the removal of the ovaries will have no more effect on the disease than the removal of a sensitive spot of skin over the spine.

In the acquired form of hysteria, as in that secondary to peritonitis, cellulitis, or cystic degeneration of the ovaries, the symptoms may be much the same as in hereditary hysteria, but the whole train is probably started by mechanical irritation as by the pressure of an exudation upon this same ovarian nervous supply, the line of transmission of irritability being from the ovaries to the brain and thence to the various parts of the body. In such cases the hysterical symptoms may not only furnish an additional indication for the removal of the source of irritation, but they alone may make life such a burden to the patient as to render the operation not only justifiable but imperative. Certainly when the cerebral irritability culminates in persistent hystero-epilepsy with its usual accompaniments, mental and physical, any

¹ Cases of *insanity* accompanying menstruation have indeed been relieved by the removal of normal ovaries and tubes, merely by establishing the menopause, and perhaps analogous cases of hysteria exist. I should hesitate, however, at present, except in a most aggravated case, recommending the operation for hysteria unless organic disease were suspected.

¹ Féré.

measure which promises a chance of relief is worthy of careful consideration.

Until a comparatively recent date the symptoms of hysteria have received so little systematic study that it is only in the latest reports that we find accurate accounts of the nervous manifestations in individual cases. Recent investigations have, however, enabled us not only to classify more or less satisfactorily the seemingly incoherent symptoms of this protean disease, but have brought to light a new symptom whose importance cannot be overestimated, in that it gives us when present a comparatively accurate measure of the severity and progress of the disease. I refer to unilateral loss of sensation.

Hemianæsthesia should, then, always be sought in cases of functional nervous disease, whether idiopathic or secondary to disease of the visceral or other organs, and the clinician who follows this plan will be surprised by the frequency of its occurrence in a marked degree unsuspected even by the patient.

The following cases, which have come under my observation, and in one of which the ovaries have been removed with a (so far) successful result, will serve to illustrate the presence, among other hysterical symptoms, of a typical hemianæsthesia secondary, probably, to disease in the pelvic region.

CASE. The first patient, Mrs. H., was sent to Dr. H. W. Bradford on account of indistinct vision. Dr. Bradford attributed the ocular disturbance to the nervous trouble, and requested me to examine the case.

The patient, thirty-two years old, married, without issue, belongs to a family with no mental or nervous history excepting that the father died of apoplexy. The mother is living and well. During the past ten years the abdomen has been excessively tender, especially in the right side, pressure there causing pain for days afterward. Within two years she is said by her family physician to have had an abscess in right iliac region with an offensive discharge per vaginam. For about ten years the patient has suffered from severe headaches, accompanied sometimes by vomiting, and sometimes by ringing in the ears and vertigo, with tendency to step up and to fall forward. The headaches begin about a week before the menstrual period, and disappear a week after. During this time her sight, at other times fair, is very indistinct. During this period, also, the patient is forgetful, incapable of mental exertion, and makes such mistakes as bringing a plate when she goes for a fork, often enough to cause her anxiety. Between the periods her mind is perfectly clear and vigorous. She has suffered from cramps in the right arm and leg, and from temporary loss of power, having, for example, dropped a plate from weakness of the right hand. She has herself noticed that the sense of smell is much better on the left side than on the right, and she always uses her smelling bottle on that side. The appetite is fair, the bowels constipated. The menstrual flow is moderate in quantity and very painful. The headaches are seated principally at the vertex and temples, and are accompanied by coldness of the vertex, dilated pupils, and by paleness of the face.

Physical examination. The heart and lungs are

normal. The pupils are large, alike, and react sluggishly to light. Patellar reflex exaggerated on both sides. Extreme tenderness of the scalp is found, especially at the vertex, and there are tender spots on the temples. There is no tenderness elsewhere excepting over abdomen. The abdomen is full and tympanitic everywhere. The left ovarian region is somewhat sensitive to pressure, and on the right side the tenderness is so excessive as to preclude careful palpation, the lightest percussion causing pain over a large area. No vaginal examination was made. The report of a previous examination contains the information that anteversion of the uterus existed, that the cervix was normal, and that there was slight vaginismus.

Motion. There is no special loss of motion in any muscle or group of muscles, but the strength is greater as a whole on the entire left side.

General sensation. There is loss of all forms of sensation on the entire right side to the median line; only moderate heavy pressure being perceived on this side, while on the left the lightest touch is everywhere felt.

Special senses. The sense of *smell* is greatly impaired on the right, also that of taste. The smell of menthol and the taste of sugar, both distinct on the left side, being barely perceived on the right. The *hearing* through the bone is wanting on the right, and that through the air is greatly impaired, the watch which is heard at 50 centimeters on the left being heard on the right at only 15. The hearing for high tones was not tested. The membranes are normal; the Eustachian tubes quite free.

The report of the *ocular* examination, kindly given me by Dr. Bradford, is as follows: Vision with right eye $\frac{7}{10}$ (Monoyer) emmetropic. With the left eye there is perception of light only, with lateral fixation. No visual field for form or color to be obtained. The field for form in the right eye is concentrically retracted excepting downwards, where the apex of a triangle reaches the normal limit. The fields for color in this eye are all concentrically limited, with reduction of the field for blue (outside) to nearly the degree of red and green, the fields of the latter colors being about one-third of the normal, that of blue one-sixth. The fundus on the right is normal. On the left, upon continuous exposure, the arteries seem to contract to one-third their diameter, and the patient becomes unable to continue. (This result was several times repeated). The pupils retract normally to accommodation, sluggishly to light, and are one-third or more larger than normal.

The diagnosis was that of hysteria, probably secondary to abdominal disease. The coldness of the head, dilatation of the pupils, and ischæmia of the retina (left) pointed to irritation rather than paralysis of the sympathetic, and nitro-glycerine in drop doses of the one per cent. solution was advised, in the hope of at least relieving the headaches. Operation on the ovaries was in this case not considered, but if the symptoms should become so severe (to use Carstens' expression) as either to endanger the life of the patient or to render it a burden, and if careful local examination should reveal a pathological lesion involving the ovary, and if, again, all other treatment, local and

general, should prove useless, the operation should certainly be taken seriously into consideration. The headaches and general condition were reported some time after as benefited, apparently by the nitro-glycerine.

It seems a pertinent inquiry, foreign to the question under discussion, but bearing on the pathology of hysteria, whether anæmia of the surface of the left hemisphere, resulting from spasm of the blood-vessels, may not have been the cause of the anæsthesia and weakness of the opposite side. It is certainly an interesting, and, as far as I know, unique phenomenon that the visual defect in the right eye was typical of central disturbance (amblyopia, with concentric retraction of the field), while the blindness of the left eye was that of retinal ischæmia.

CASE. The second patient, Miss A., was one operated upon by Dr. Barss, of Malden. The nervous symptoms being pronounced, Dr. Barss kindly gave me the opportunity to examine the patient before and after operation. The case will be reported by him in detail later, but a brief sketch of the important facts will be of interest in this connection.

January 2, 1884 (before operation). The patient, aged 29 years, single, belongs to a family free from nervous and mental trouble. She had suffered from excessively painful menstruation, and more or less constant pain in the back since puberty. Both these symptoms have increased in severity, and of late years various nervous symptoms have been superimposed. The patient is now unable to leave the bed, on account of pain and weakness. She has been for some years subject to frequently-recurring convulsive attacks, in which she is sometimes rigid, and sometimes shakes violently. No distinct opisthotonos has been observed. Examination reveals marked diminution of all sensations on the entire right side of the body to the median line. Taste (sugar, quinia) and smell (lemon, vanilla) are entirely wanting on the right. The hearing by the air is less acute on the right, and that by the bone is wanting. The sight is above normal on both sides without glasses, and there is no retraction of the field of vision, nor loss of color perception. The tendon reflex is greatly exaggerated on both sides, the tap causing a violent twitch of the whole body, and great distress. There is some loss of strength in the right arm and leg. There exists a wax-like rigidity of both feet, most marked in the right, the foot resisting forcible movements, but yielding gradually to pressure. Once placed in an awkward position the foot remains so for some minutes without causing the least distress, or even attracting the patient's notice. Attempts to flex the right leg upon the thigh are met by tonic contraction of the quadriceps femoris. The ovarian region is excessively tender on both sides, most markedly so on the left. Palpation shows the left ovary twice the size of the right (Dr. Barss). The patient is anxious for immediate operation, although its nature and dangers are fully understood, the patient being unwilling to undergo the pain of another menstrual period. Both ovaries were removed, without the tubes, January 18, 1884. They were found cystic degenerated. Recovery was rapid, and the patient

expressed herself within a week as feeling better than for many years.

My second examination was made March 21, two months after operation. The hemianæsthesia was much lessened, the lightest touch being felt over the entire right side, though not quite so plainly as on the left. The substances which were not perceived at all by smell and taste on the right side before operation were now recognized on that side, though not so easily as on the left. The watch on the temple, previously heard only on the left, was now heard on both sides, best on the left. There was no trace of the wax-like rigidity in the left foot, and that in the right was much diminished, the right foot when bent into an awkward position now falling back directly to a natural one, though not so completely as the left. The reflex spasm of the quadriceps femoris on the right still persisted. The tendon reflex was normal on the left, but still exaggerated on the right, causing a twitch of the whole body, but less marked than before, while the distress caused by the tap was comparatively slight.

The most marked improvement was with regard to the convulsions, previously so severe and frequent, only two light attacks having appeared since the operation. There had been considerable pain in the back and abdomen at the menstrual period, and at this time the patient, at others up and about, was confined to her bed for some days. We cannot, of course, assume that the improvement will be permanent, but the case well illustrates the role which hysteria may play as an indication for operation, and the result up to this time has certainly been most satisfactory.

BOOK REVIEWS.

INJURIES AND DISEASES OF THE JAWS. The Jacksonian Prize Essay of the Royal College of Surgeons, England, 1867. By CHRISTOPHER HEATH, F.R.C.S., Professor of Surgery in University College, Surgeon of University College Hospital, Dental Hospital, etc. Third edition. Philadelphia: P. Blakiston, Son & Co. 1884. Pp. 480. Price, \$4.50.

The third edition of this standard treatise is not markedly changed in form or in size. It is, upon the whole, more carefully written, and contains a chapter on Diseases of the Temporo-Maxillary Articulation, which is a new topic. Tumors of the jaws are far more intelligently and satisfactorily classified in this edition, and this whole important subject is revised in the light of recent pathological research. In other words, microscopical study of the various new growths of the jaws is made the basis of their classification. Chapters XIV to XXV—nearly one-half the entire work—are devoted to the various tumors of the gums and jaws.

This constitutes the portion of the book to which the general surgeon would turn for special information. Specialists in oral surgery, aside from mere

dentistry, are now to be found in the larger cities. This is not a work on dental surgery.

A chapter on Fracture of the Lower Jaw, another on its treatment, another on the complications, and separate chapters on fracture of the upper jaw, and also on dislocations, occupy 100 pages in the beginning of the book.

This will serve as an indication of the fulness with which these topics are treated. It is needless to add that not even Hamilton's standard work on Fractures and Dislocations gives the injuries of the jaw one-half this space. We commend this work to general practitioners.

E. W. A.

STATE MEDICINE.

HEALTH IN MICHIGAN, AUGUST, 1884.

Reports to the State Board of Health, Lansing, by observers in different parts of the State, show the diseases which caused most sickness in Michigan during the month of August (4 weeks ending Aug. 30), 1884, as follows:

Number of Weekly Reports Received, 205.		For Preceding Month.	
Diseases Arranged in Order of Greatest Area of Prevalence.	Per Cent. of Reports Stating Presence of Disease.	Per Cent. of Reports Stating Presence of Disease.	
Diarrhœa.....	88	72	
Intermittent fever.....	72	93	
Rheumatism.....	68	68	
Neuralgia.....	60	66	
Consumption of lungs.....	60	63	
Cholera morbus.....	50	39	
Bronchitis.....	49	47	
Dysentery.....	48	29	
Remittent fever.....	44	45	
Cholera infantum.....	42	27	
Tonsillitis.....	35	34	
Erysipelas.....	32	28	
Influenza.....	30	28	
Inflammation of bowels.....	26	20	
Whooping-cough.....	23	27	
Typho-malarial fever.....	22	10	
Inflammation of the kidney.....	20	24	
Diphtheria.....	14	8	
Typhoid fever.....	12	7	
Scarlet fever.....	11	11	
Pneumonia.....	10	15	
Inflammation of brain.....	10	9	
Puerperal fever.....	9	7	
Cerebro-spinal meningitis.....	8	6	
Membranous croup.....	5	5	
Measles.....	5	8	

For the month of August, 1884, the reports indicate that diarrhœa, cholera infantum, typho-malarial fever, cholera morbus, and dysentery increased in area of prevalence.

Compared with the average for the month of August in the six years, 1877-1882, erysipelas, rheumatism, and bronchitis were more prevalent, and remittent fever, intermittent fever, dysentery, and cholera morbus, were less prevalent in August, 1884.

For the month of August, 1884, compared with the average of corresponding months for the six years, 1879-1884, the temperature was lower, the absolute, and the relative humidity, and the day ozone were less, and the night ozone more.

Including reports by regular observers and others, diphtheria was reported in Michigan in the month of

August, 1884, at 27 places, namely: Alamo, Armada, Alpena, Au Sable, Bloomfield, Birmingham, Berlin, Detroit, East Saginaw, Flint, Grand Rapids, Groveland, Holly, Ishpeming, Kalamazoo, Leland, Maple Rapids, Manistee, Monroe, McBride, Northville, Oakland, Pontiac, South Haven, Summit, Vassar, and Warren; scarlet fever at 20 places,—Albion, Au Sable, Armada, Bridgetown, Cadillac, Columbiaville, Clayton, Detroit, Dorr, Fairfield, Grand Rapids, Hastings, Hazleton, Ionia, Jasper, Kalamazoo, Novi, Stanton, Swartz Creek, and Sand Beach; and measles at 10 places,—Detroit, Grand Rapids, Grand Haven, Kalkaska, Kalamazoo, Ludington, Manistee, Muskegon, South Haven, and Whitehall.

HENRY B. BAKER, Secretary.

Lansing, Sept. 12, 1884.

NECROLOGY.

GERRISH, JAMES W. F., M.D., was born in Monmouth, State of Maine, February 12, 1831, and died at his residence in Seymour, Ind., August 4, 1883, and was, therefore, at the time of his death, in the 52nd year of his age.

His father was successively a teacher and a physician. Dr. Gerrish received his early education in a school taught by his father in his native town, and when, with the tide of emigration that set in for the great West, his father moved to Indiana, he accompanied him. It was not until about 20 years of age that he decided to adopt the medical profession as his life-work; but the decision once made, with that promptness, energy and industry that were distinguishing characteristics of his after-life, he applied himself to study in the office of his father some two years, and then entered college in Cincinnati, Ohio, where he graduated in 1855.

Upon the completion of his studies he located in Paris, Ind., and at once entered into practice. A man of his talent and skill could not long remain unknown, and when the war of the rebellion broke out he was doing a large and lucrative practice. Dr. Gerrish was not wanting in patriotism. When the State equipped and sent to the front the Sixty-seventh Regiment Indiana Volunteers, a regiment holding a high and honored position in the annals of the war, he accompanied it as Assistant Surgeon, but was soon promoted to the rank of Surgeon to the regiment. Through that dark and bloody ordeal he shared the varying fortunes of "the boys in blue," holding many positions of honor and trust, being at one time in charge of the General Hospital of the Thirteenth Army Corps, only returning to his home in 1864, when failing health would no longer permit him to do duty in the field. After his return he located in Seymour, and at once entered upon a large and lucrative practice, which continued until his death.

As a physician Dr. Gerrish was very successful, being careful, patient and kind; but it was as a surgeon he was most extensively known. Skilful in a remarkable degree, possessing a most thorough knowledge of his art, a keen discrimination, a steady hand, self-re-

liant, he performed, in his twenty-eight years of constant practice, scores of capital operations, among them some of the most difficult and dangerous. A constant reader, nothing new or useful escaped his notice, and he discarded nothing worthy of a place among the remedies or agencies of the healing art.

He was an active member of the Jackson County Medical Society, the Mitchell District Medical Society, the Indiana State Medical Society, and one of the founders of the Tri-State Medical Society, of which he was in 1877 Vice-President, and a permanent member of the American Medical Association, and an honorary member of the Southwestern Kentucky Medical Association. To the literature of some of these bodies he was a valued contributor, and at all times took a deep interest in their deliberations.

As a man the memory of Dr. Gerrish will long be cherished in the hearts of those who knew him, for his goodness and philanthropy. He possessed in the fullest degree that fellow-feeling for the race that made him wondrous kind.

In the later years of his life he was brought by the force of circumstances to occupy a new and special field of usefulness. He fell in with the current of thought and effort which was carrying forward a popular movement in the temperance reformation. With his characteristic earnestness and decision, "with malice toward none and with charity for all," he espoused this cause. For several years past he was at the head of a strong local organization in the city of Seymour. His presence at their meetings, his wise counsels and sympathetic addresses to his friends and neighbors, soon gathered around him a large and efficient membership in what is widely known as the "Seymour Reform Club." At the time of his death he was the President of this Club, and of the Grand Temperance Council of Indiana, both of which were, in reality, his foster children. About two years ago he decided to go a step further and higher in the scale of reformation. He made a public profession of religion, and united himself with the First Presbyterian Church of his home. From the time of entering the Master's service until his death he was a worthy and consistent member of the church, an untiring worker in the Master's vineyard, a tried and true follower of the banner of the cross, and he died in the hope and full belief of an immortality beyond this world, and a place in that "house not made with hands, eternal in the heavens."

Facts furnished by Samuel H. Charlton, M.D., Seymour, Ind. L.

JULIUS COHNHEIM.—The closing days of the International Medical Congress were saddened by the announcement by Prof. Virchow, in the Section of Pathology, of the death from gouty nephritis, in Leipzig, on August 14, of his distinguished pupil, Prof. Julius Cohnheim. A telegram of condolence was immediately sent to his widow by the Section.

Prof. Cohnheim was born in Demmin, in 1839, and studied medicine from 1856 to 1860 in Berlin, Würtzburg, Greifswald, and Prague. He commenced to practice in Berlin, but was appointed, in 1864, assistant to Prof. Virchow in the Pathological Institute, when he entered upon a new life. In 1868 he was appointed Ordinary Professor of Pathological Anatomy in Kiel. He soon left Kiel, however, to succeed Waldeyer in Breslau. His work here was probably the most brilliant and fruitful of his whole life; so much so, that he was called to the Pathological

Institute, in Leipzig, on the occurrence of the first vacancy. His name will chiefly be remembered for his contributions to the doctrine of inflammation. His discovery of the migration of the white blood-corpuscles through the walls of the capillaries in inflammation is his chief title to fame. It is too early, says the *Deutsche medicinische Wochenschrift*, to estimate the great influence of his work, and we can only know that in his death practical pathology has sustained an irreparable loss, even though in his "Vorlesungen" he has left a work, for him an enduring monument, which combines physiology and pathology to one extent never before attained. Few more important truths have been formulated in medicine than Cohnheim's, "without blood-vessels no inflammation is possible."—*Medical News*.

MISCELLANEOUS.

OFFICIAL NOTICE.

ANNUAL DUES from members of the Association—*Five Dollars* per annum—are payable directly to the Treasurer. Such payment entitles them to receive the JOURNAL of the Association for one year.

SUBSCRIPTIONS TO THE JOURNAL from those who are not members should be forwarded to the office of publication, Chicago.

BACK VOLUMES OF THE TRANSACTIONS may be procured, at reduced rates, by addressing the Treasurer.

THE INDEX to the 33 Volumes of Transactions will be forwarded, postpaid, on receipt of *One Dollar* by the Treasurer.

According to a resolution passed May 9, 1884, at the Washington meeting, continuous payment of Annual Dues is required, to retain permanent membership.

RICHARD J. DUNGLISON, M.D.,
Treasurer.

Lock Box 1274, Philadelphia, Pa.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPT. 6, 1884, TO SEPT. 12, 1884.

Greenleaf, Chas. R., Major and Surgeon, to conduct a detachment of recruits to the Department of the Columbia, and upon completion of this duty rejoin his station, Columbus Barracks, Ohio. (S. O. 210, A. G. O., Sept. 6, 1884.)

Gorgas, W. C., First Lieutenant and Assistant-Surgeon, assigned to duty at Ft. Randall, D. T. (S. O. 98, Dept. of Dakota, Sept. 5, 1884.)

Egan, P. R., First Lieutenant and Assistant-Surgeon, when relieved by Assistant-Surgeon Fisher, to report at Ft. Lowell, A. T., for duty as Post Surgeon. (S. O. 82, Dept. of Arizona, Sept. 2, 1884.)

Fisher, W. W. R., First Lieutenant and Assistant-Surgeon, assigned to duty at Ft. Apache, A. T., relieving Assistant-Surgeon Egan. (S. O. 82, C. S., Dept. of Arizona.)

Ewing, Chas. B., First Lieutenant and Assistant-Surgeon, assigned to duty as Post Surgeon at Ft. Stanton, N. Mexico. (S. O. 177, Dept. of the Missouri, Sept. 6, 1884.)

McCaw, W. D., First Lieutenant and Assistant-Surgeon, (recently appointed), to report in person to the Commanding General Department of the Missouri for assignment to duty. (S. O. 209, A. G. O., Sept. 5, 1884.)

OFFICIAL LIST OF CHANGES IN MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING SEPTEMBER 13, 1884.

Surgeon T. C. Heyl, September 8, 1884, from the "Adams," and to the R. ship "Independence," Mare Island, California.

LACERATIONS OF THE FEMALE SEXUAL ORGANS
CONSEQUENT UPON PARTURITION;
--THEIR CAUSES AND THEIR PREVENTION.

BY S. D. GROSS, M.D., LL.D., D.C.L. OXON., L.L.D.
CANTAB., EMERITUS PROFESSOR OF SURGERY IN THE
JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

Read before the Section on Obstetrics and Diseases of Women, American
Medical Association, May, 1884.

My object in appearing before you, as stated in the programme, is to read a paper on lacerations of the female sexual organs consequent upon parturition. It may seem odd, if not impertinent, to those of you who do not know me intimately, that I should venture to discourse upon such a subject so essentially in the hands of specialists; but they will perhaps pardon me if I tell them that, although I have all my professional life, now extending over a period of fifty-six years, been a general practitioner, yet during the first third of a century of that life I was more or less extensively engaged in obstetric practice; while during the last third I have had more or less to do almost daily with the treatment of female diseases requiring the use of the speculum and operative interference of various kinds. I have performed ovariectomy, and on numerous occasions sutured the perinæum and the vesico-vaginal septum with a degree of success, if not highly flattering, at all events respectable. Within a short time after my entrance into the profession, I translated Hatin's *Manual of Obstetrics*, a small volume which had an extensive circulation in its new dress; in 1839 I contributed several pages in my work on *Pathological Anatomy on Uterine Moles*, founded upon original observations and dissections; and in 1854 I unearthed, after much labor and research, Ephraim McDowell's claims to the fatherhood of ovariotomy, up to that period generally ascribed to other sources. Moreover, as a writer on systematic surgery, compelled to keep abreast with the knowledge of the times, I have embodied in my treatise an elaborate chapter on the diseases and injuries incident to the genital organs of the female sex, reflecting, at least in some degree, an outline of the existing state of the science. I make these remarks, in anticipa-

tion, as a justification for bringing before the Section a subject which, in some of its relations, has been so often and so elaborately discussed by many of the ablest men all over the civilized world. I might have taken my budget before the Surgical Section, but believing that fairer justice would be meted out to it here, I have given it this direction. When I shall have finished my task I trust you may not be able to say with Appelles, "*Ne sutor ultra crepidam*;" but rather incline to Tacitus, "*Nihil scriptum miraculi causa*."

It is astonishing how much has been written on the treatment of these lesions, and how little has been said upon their causes and prevention. Operations almost innumerable have been devised for their relief; volumes have been written upon the subject, and everywhere, in town and city, the gynæcologist is ready to offer his services in sewing up lacerations of the genital organs of maltreated and unfortunate women. Seldom do we hear the voice of any of them raised in behalf of preventive measures, and then only in an indirect or roundabout manner. I am here this evening, not to wrestle with shadows or imaginary demons, but with stern realities, and to speak the truth, the whole truth, and nothing but the truth, as I understand it. The time has arrived when this matter should be met in a bold and fearless manner.

The lacerations of which I desire to speak are those which affect—(1) the perinæum; (2) the vesico-vaginal septum; (3) the recto-vaginal septum; (4) the neck of the womb; and (5) the urethra, or mouth of the urethra and of the vagina. A few remarks under each of these heads will suffice for my purpose.

Laceration of the perinæum is of frequent occurrence, and cannot always be avoided even under the most judicious management. In primiparæ, the fourchette is almost invariably ruptured, especially when the tissues are unusually rigid, and the protruding structures are very large, or very rapid in their descent, or where the perinæum is not properly supported. Fortunately, such an occurrence is of little moment, as it respects the patient's welfare, either present or prospective. But it is very different when the rupture is extensive, involving a large portion of the perinæum, or perhaps extending—as not infrequently happens—through the sphincter muscles of the anus and the lower extremity of the vagina. Then such an accident constitutes a great evil, and demands more or less skill for its cure.

Lacerations of the vesico-vaginal septum are among the saddest of calamities, entailing, if not

successfully remedied, endless suffering upon the poor patient. I know of nothing more calculated to excite our sympathy, or to enlist the noblest qualities of our nature. In the worst forms of such accidents, in which science and skill offer no relief, as occasionally happens even in these enlightened days, death would be a welcome visitor. Equally distressing is a recto-vaginal fistula, or a rent with loss of substance in the urethra.

Lacerations of the neck of the uterus, even when comparatively slight, often entail great suffering, local and constitutional; the former manifesting themselves in various kinds of pains and discharges, and the latter in almost every form of nervous disorders of which it is possible to form any conception, together with more or less derangement of the digestive and assimilative organs. Of the frequency of these accidents, an idea may be formed when I state, what has long been known to most of you, that one of our most distinguished native writers on gynecology has expressed his conviction that rupture of the neck of the uterus, in greater or less degree, is almost inseparable from a first labor. Whether Dr. Emmet is correct in this conclusion is a question which remains to be determined. If it be true, it would inevitably go to prove that God has made woman much less perfect than the world has given him credit for. As childbirth is one of the special prerogatives of woman, designed to perpetuate the race, there is something peculiarly distressing in such an idea. Looking at the matter from a practical standpoint, one would naturally conclude that the Author of our being had constructed the womb with special care to protect the organ, at least as a rule, against the possibility of a contingency fraught with such sad consequences. If we assume the correctness of Dr. Emmet's statement, we may well wonder, without irreverence, why Almighty God did not create simultaneously with woman a competent gynecologist, ready to meet this inevitable evil, for such unquestionably it must be whenever it occurs. If this evil is the outgrowth of civilization, then the sooner we get rid of this civilization the better will it be for our poor wives and daughters, considered as procreating beings.

It was a happy circumstance when, in 1851, Sir James Y. Simpson first called attention to this important subject. It was like the discovery of a new world in human progress. In the *Proceedings of the Edinburgh Obstetrical Society*, for January of that year, he proclaims the important truth, until then unknown, or only guessed at, that fissuring and laceration of the cervix are not, as had been generally believed, rare lesions during labor, but, on the contrary, very common occurrences, especially in primiparæ, and he supports his views, not only by what he saw with the aid of the speculum, but by an appeal to autopsies in which rents and fissures were detected in the mouth and neck of the uterus after natural labor. The facts thus pointed out by the great Scotch professor were afterwards—namely, in 1869, and again in 1874—brought more fully before the profession by Dr. Emmet, in two important papers published in the *American Journal of*

Obstetrics, where they soon attracted general attention. To these two distinguished men, then, are we mainly indebted for the knowledge which we now possess upon this important subject; knowledge of priceless value to suffering woman, and of the greatest consequence to the obstetric practitioner.

If we inquire into the exciting *causes* of these accidents, it will be found that they vary with the situation and structure of the parts involved in them. The great factor in laceration of the perinæum is parturition, either alone or in conjunction with the means employed to effect it. When this wall to the outlet of the pelvis is very rigid, and the action of the uterus unusually vigorous, forcing down the head of the child with great vehemence, it is easy to conceive not only of the possibility, but of the great likelihood of such an accident, especially in the absence of proper support. In such a condition the perinæum is very much, to use a figurative expression, in the position of the door of a room, with a big, burly fellow on the inside, knocking for egress. To carry out the simile, he does not in every case batter down the whole of the opposing obstacle, but only a portion of it, representing a comparatively slight laceration, as where the fissure is limited to the fourchette, or to the anterior portion of the perinæum, while, when the resistance is extreme, the entire wall is torn, the lesion extending, through the sphincter muscles, into the rectum; in other words, the entire door is battered down, and the vagina and bowel are laid completely open.

Of the various kinds of lacerations of the vagina, or of the vagina and the uterus, constituting what are known as fistulæ of the bladder, or of the rectum, those dire calamities which form so prolific a field for operative interference, the most common factor unquestionably is either prolonged or very severe pressure. "This is," says Thomas, in his able work, "beyond all doubt, the most prolific source of the accident, though it may also attend a rapid labor in which the vagina has been pressed against some point of the pelvis with great violence." The active agent of this pressure is generally the child's head, especially when it is disproportionately large or wedged in behind the pubic symphysis, unduly compressing the vesico-vaginal septum, followed by destructive inflammation and sloughing. The accident is generally the result of protracted pressure, as when the child's head has been wedged in in this position for many hours, neither, perhaps, receding nor advancing; or it may be caused in a very short time, as when the pressure is unusually concentrated and severe. If the pains are very violent, the pressure of the presenting parts may be so great as to end in actual rupture of the vesico-vaginal septum, but, as a rule, the opening is the direct result of concentrated pressure, eventuating in inflammation and sloughing, precisely as in an ordinary bed sore. Vesico-vaginal fistulæ are not infrequently produced by the pressure of the child's head upon a distended bladder. How far the maladroit use of the forceps, vectis, or other instruments may be capable of producing such lesions, will form the subject of future inquiry.

The principal causes of lacerations of the cervix

are precipitate labor, labor attended with rigidity of the mouth of the womb, and instrumental labor. Lacerations are not uncommon in breech cases, in which delivery is obliged to be expedited on account of the retained head before the cervix is properly dilated. These are unquestionably the most frequent and efficient factors in the production of accidents in this situation. If to these we add the presence of cicatricial tissue in the cervix, malpresentations, and section of the cervix, as occasionally practised by ignorant obstetricians, we have a complete list of all the causes, active and predisposing, of rupture of the uterus during normal parturition. A premature discharge of the amniotic fluid acts mainly, I presume, as a means of retarding labor than as a cause of laceration of the cervix. I must not omit to allude here to a statement of Dr. Emmet that laceration of the cervix is of frequent, if not common, occurrence in cases of criminal abortion. I do not know that this fact has been noticed or verified by other observers, but of its truth I entertain no doubt. In his tables, Dr. Emmet gives ten cases of this kind, and he declares that he has met with this accident in every instance where the woman admitted the fact of exposure to malpractice.

Having thus briefly discussed the situation and causes of the accidents in question, let us, in the next place, inquire into the best means of preventing them, the chief object which I have had in view in bringing this matter before you to-day. There is more honor in one ounce of preventive midwifery than in one pound of curative gynecology, the outgrowth of ignorant or meddlesome obstetric practice. That many of these occurrences are inevitable without any just blame attaching to the professional attendant is well known to every practitioner of the least experience, but that they may, as a rule, be prevented by the exercise of proper care and skill will, I think, be readily admitted; at all events it is true.

The great remedy, as laid down in the books, for rigidity of the perinæum is manual support during the descent of the child's head, or whatever else the presenting parts may be; this, as a rule, is quite sufficient; but not so when the resistance is very great. In this event, the accoucheur is expected to make use of the hot bath and of hot fomentations, to anoint the parts with oil, and even, in extreme cases, to make slight incisions on each side of the middle line. Nothing is said in these injunctions of the abstraction of blood as a means of relaxing this tense, resisting wall which so obstinately stands in the way of the completion of the parturient process. What are the active agents of this resistance? Unquestionably the muscles of the perinæum, the sphincters of the vagina and anus, the transverse muscles, and the elevator muscles of the anus. The skin and connective tissue offer no obstacle. The whole difficulty resides in the muscles, and its amount is precisely in proportion to their development, great in strong, young, robust women, and comparatively slight in those of an opposite character. If this statement be correct, and no one can doubt it, it follows, as a necessary corollary, that the obstacle is most readily overcome by some measure that will relax the perineal muscles.

Hot water, oil, and medicated unguents will not do this, and no sane man would wait for the tardy and uncertain effect of local bleeding. A far better plan is to take blood at once from the arm from a free orifice in one of the large veins, the patient sitting up in bed during the operation, so as to produce the most rapid and decided impression at the least expense of the system. If there be anything better than this, anything more likely to answer the purpose, I am not aware of it. The loss of ten, twelve, sixteen, or even twenty ounces of blood can do no harm in such a condition of things. A few days under proper treatment always suffice to replace it, while, as a rule, it promotes rather than retards recovery, by rendering the woman less liable to puerperal fever, peritonitis, and pelvic cellulitis.

In regard to lacerations of the vesico-vaginal septum, much may be done in the way of prevention, and so also in regard to rents into the rectum. It is self-evident that anything that lessens the size of the canal through which the child is to pass, or that seriously interferes with the descent of the child's head, must act as an impediment to delivery. All obstetric teachers are aware of this fact, and hence they take special pains to instruct the young practitioner to see that the rectum is well emptied during the latter stages of pregnancy, or, at all events, on the approach of labor, and that the urine is evacuated from time to time as the labor progresses. These precautions are unquestionably most important safeguards, and, if duly attended to, are rarely followed by serious injury. If, on the contrary, they are neglected, as I fear is not infrequently the case, especially among the lower classes of women, it is easy to conceive that the consequences must be of the most direful nature, especially if, superadded to these obstacles, there is an impacted condition of the child's head along with violent uterine contraction. Under such circumstances it is difficult to conceive how the poor patient could escape injury in some form or other. The machinery must break down somewhere. A few hours may suffice to do the mischief. The only remedy, of course, is the forceps or crotchet, and the former cannot be applied too soon. The bladder must be liberated, or a vesico-vaginal opening, if not something worse, will be the inevitable result.

The proper remedy for the relief of the stationary head, whether impacted or simply arrested by the inertia of the womb, is—provided the cervix is sufficiently dilated, or dilatable—the forceps, that "noble instrument," as it was called by Chapman, who, in 1733, published the first account of it, upwards of one hundred years after its invention by Paul Chamberlen, of England. I shall not speak of the numerous modifications which this valuable instrument has experienced in the hands of the obstetricians, or detain you by asking whether the long instrument is preferable to the short, or the short to the long. In the hands of the judicious practitioner, each has a distinct and separate value; but it will be pertinent to the object of this paper to inquire into the reasons which have led to the great changes which have taken place in regard to the frequency of its use.

Beginning with the great Baudelocque, the most

illustrious accoucheur of the last century, we find that he applied the forceps once in 561 cases; Clark in 728; Collins in 617; Lachapelle in 293; Baer in 274; Boivin in 214; Davies in 53; Naëgle in 31; Kluge in 16; Carus in 14, and Siebold in 7.¹ Smellie, who flourished in the middle of the last century, and who was the most famous accoucheur in his day in Great Britain, applied the forceps once in 125 labors; and Merriman, another distinguished English obstetrician, once in 93.

From the late Dr. Churchill, of Dublin, we learn that in Great Britain, until recently, the forceps were employed once in 249 cases; in France, in 140; and in Germany, in 106.

In this country, the present fashion is to apply the forceps very frequently, both in private and in hospital practice. Some of my friends inform me that some accoucheurs resort to the instrument as often as once in four labors; others in 6, 8, or 10. Whether the forceps are employed as often in Great Britain and on the Continent of Europe, I am unable to say; but the difference, if any, must be very trifling.

Dr. William P. Dewees, who was the great Philadelphia accoucheur in his day, and who delivered upwards of ten thousand women, writing in 1843, holds the following language in regard to the use of the forceps: "However strongly I may be impressed with the utility of the forceps, I should not feel myself warranted to use them as often as they appear to be in Great Britain and on the Continent of Europe. The frequency with which they have been employed in some instances is really alarming, and, I had like to have said, must have been too often unnecessary. In my own proper practice, I have not employed them oftener than once in 350 cases, though I have been under the necessity of using them very frequently in the practice of others."²

Notwithstanding that Dewees so seldom employed the forceps in his own cases, we nowhere find that he had any serious lacerations of the genital organs. In the tenth edition of his *Treatise on the Diseases of Females*, published in 1854, "with the author's latest improvements and corrections," not one word is said upon the subject, not even upon rupture of the perineum. Now, if such accidents had occurred under his observation he could hardly have failed at least to mention the fact. If I am told that Dewees did not use the speculum, and could, therefore, not detect them, I reply that he had eyes to see, and fingers to feel. He certainly could tell what the nature of the case was when urine or fecal matter flowed off by the vagina. Philadelphia's great accoucheur, Dr. Ellwood Wilson, has superintended, as he informs me, 10,600 cases of labor at the Lying-in Hospital in that city, without the occurrence of a solitary instance of vesico-vaginal, or recto-vaginal fistula. He, like others engaged in large private practice, has witnessed numerous atrocities in consultations. The testimony of my late colleague, Professor Ellerslie Wallace, is precisely of the same import.

In a discussion of the admirable paper of Dr. Emmet, "On the Necessity for Early Delivery, as Demon-

strated by the Analysis of 161 Cases of Vesico-vaginal Fistula," read before the American Gynecological Society, in 1878, Dr. D. Humphrey Storer declared that, in an experience of several thousand cases of midwifery, he had witnessed only two cases of vesico-vaginal fistula, adding that there was no man in Boston who applied the forceps less seldom than he. He approved of the employment of the forceps in certain conditions of labor, "but the idea," he remarks, "that the forceps is an instrument which must be almost constantly used is, I think, a dangerous one." This sentiment was elicited by the statement of Dr. Emmet that the great factor in the production of vesico-vaginal fistula is impaction and long detention of the child's head, aided by distension of the bladder, and the assertion that instrumental delivery has rarely, if ever, any agency in the production of this sad occurrence.

Dr. H. P. C. Wilson, of Baltimore, on the same occasion, asserted that he had made it a rule for many years, when called to a case of labor, to carry with him a bottle of chloroform and a pair of forceps, adding that he had frequently used the forceps when he was certain that the woman would be delivered safely by nature, simply to shorten the labor and to relieve suffering. Dr. John L. Atlee, in referring to Dr. Wilson, said, "the older I grow the more apt I am to employ the forceps." In opposition to these sentiments, I take leave to cite the views of America's latest writer on obstetric medicine, Dr. Lusk, as expressed in his admirable treatise, *The Science and Art of Midwifery*, the second edition of which was issued only a few months ago. "I can only say," declares this excellent author, "that, with increasing experience, my own practice has grown more and more conservative, and my own belief is that true wisdom requires us to abstain from even trivial operations, so long as nature is able to do her work without our assistance."

Is it not a fact, I would ask, that the forceps are often used merely as a means rather to save the time of the accoucheur, than as a means to prevent the suffering of the poor woman; to enable him to meet another engagement, to visit the theatre, or to attend a dinner or an evening entertainment? Passing along the streets, not long ago, said Dr. Goodell to me a few months since, my eye lighted upon a gentleman walking rapidly on the opposite side, who, the moment he recognized me, shook his green bag at me, exclaiming, "reed-birds for supper," and hurried on.

I take leave here to quote what I deem eminently pertinent to this part of my paper, a passage from a communication that appeared in the *New York Medical Record*, March 8th of the present year, from the pen of Dr. A. E. Dugas, of Augusta, Georgia: "When I graduated in 1875, an old sage in the profession advised me as follows: 'My boy,' said he, 'I am an old man; I have practiced over fifty years, and, as you are aware, have been very successful. In regard to your labor cases, I would give you the following advice: First, as you intend practicing in the city, make it a habit of leaving

¹ Robert Lee's Table, in *Lectures on Midwifery*.

² *Midwifery*, p. 292.

your forceps at your office, for if you ever require them, you will always have ample time to send for them, and your not having them with you may save some women much trouble. Second, do not examine your patient much or often; see that things are right, and then let nature manage the case.' "

The "old man" here alluded to is no less a personage than the great and venerable Dr. Louis Alexander Dugas, a man of vast experience as a practical surgeon and accoucheur, and emphatically one of the sages of our profession. How wise such advice is in contrast with the accursed practice of the day, when every obstetrical fledgeling thinks himself competent to use the forceps, and is anxious to get to his "reed-bird supper," I leave you to judge.

If all accoucheurs were well educated and well versed in the use of the forceps, there might be some justification for the frequency with which they are applied at the present day. There might even be some justification in hitching them on the child's head, when nature is fully equal to her task, to get home in time to a good supper, but to use them on the slightest pretence, as is so often done now-a-days by every sciolist, hardly out of his swaddling-clothes, is, if you will allow me to say it, simply damnable. Surely our obstetric teachers have a great deal to answer for in sending forth every year armies of incompetent young accoucheurs. Surely they commit a grave sin when they teach the frequent application of this "noble instrument," employed far too seldom in former times, as it is certainly employed too often in ours. In conversing recently upon this subject with a distinguished obstetric teacher, now retired, he said to me, "I always enjoined it upon my pupils, after pointing out to them the uses and abuses of the forceps, to carry the instrument with them to every case of labor, adding that it was just as important as it is for the mariner to carry his compass with him to sea." Without wishing to disparage the judicious use of the forceps, which I have no right to do, and which God forbid I should do, I think a careful consideration of the case justifies me in endorsing the opinion of Baudelocque, uttered more than a century ago, that the forceps, as generally used, have done more harm than good, and in this view I am glad to be able to say that I am sustained by many eminent, able, and experienced obstetricians and gynecologists of the present day.

That many accidents happen for the want of a proper use of the forceps, or of their timely application, is proved by the numerous cases of vesico-vaginal and other fistulæ, and by the still not infrequent sacrifice of the child, if not also of the mother; of the former by fatal compression or craniotomy, and of the latter by exhaustion, heart clot, pulmonary obstruction, or other causes. It would be difficult to find in all the records of obstetric medicine a case which more sadly and forcibly illustrates the baneful effects of the want of the proper use of the forceps than that of the Princess Charlotte, whose death, in 1817, threw the whole British nation into mourning. The amniotic liquor had been discharged early in the labor, and although the head had long been in the lower strait, the delivery, which took place at the end

of fifty-two hours, was intrusted entirely to nature's efforts. No wonder that the child was still-born, and that the poor woman, exhausted by her protracted labor, expired soon after her delivery. No wonder that her principal accoucheur, Sir Richard Croft, committed suicide as the best remedy for his sad blunder and consequent mortification!

I come, in the third place, to inquire briefly into the proper preventive treatment of lacerations of the cervix. We have said that these injuries are most common, by far, in primiparæ, especially when pregnancy occurs in women somewhat advanced in life. Spiegelberg found that the average duration of labor in 506 primiparæ was 17 hours, and 12 hours for multiparæ. After the thirtieth year, the duration is materially increased, amounting, according to Hecker, in primiparæ, to twenty-one hours, and, according to Ahlfeld, to twenty-seven hours.¹ If we ask what is the cause of this difference in the duration of labor in primiparæ and multiparæ, we shall find a ready answer in the difference in the pliancy and softness of the genital organs, and in the fact that the way is paved by the previous parturition. In primiparæ, especially in elderly ones, the genital organs are hard, firm, inelastic, unyielding; in multiparæ, on the contrary, they are comparatively soft and dilatable, yielding readily before the advancing head. In the one case the labor is comparatively easy, rapid, and safe, both to mother and child; in the other, painful, protracted, and fraught with danger; the uterus and perinæum, not to mention the vaginal septa, are liable to be torn, and the child often perishes from injury inflicted upon its head and lungs. If, in such a labor, delivery be attempted with the forceps before the parts are properly relaxed, or if attempts be made to dilate the parts forcibly with the fingers, it is easy to perceive that rupture, of a more or less serious nature, must inevitably happen.

Since the attention of accoucheurs was first directed to the frightful frequency of lacerations of the cervix in primiparæ by Simpson and Emmet, the subject has assumed a degree of importance previously undreamed of, and the question naturally arises here: How are these injuries to be avoided? How are we to abridge the duration of labor in primiparæ, and to place them on the same level with the multiparæ? There is but one way to accomplish the object, and that is by the employment of relaxing agents. It is a well-known fact that labor is more easy in hot than in cold climates, a circumstance that would naturally lead us to employ hot applications, as the hot bath, hot fomentations, and hot injections. I will not deny that such agents might occasionally do good, but what sense is there in parboiling a woman when we have at hand other agents far more speedy and more efficacious in their action. I do not allude here to chloral, ether, chloroform, and tartar emetic, the latter of which, from its tendency to produce vomiting, could hardly in any case be a safe remedy, while the former, with some advantages, would seldom prove reliable to bring about the desired result. The great remedy which I have in my mind's eye is vene-

¹ Lusk, *Science and Art of Midwifery*, p. 134. Second Edition. 1884.

section, carried to a reasonable but sufficient extent to relax the system and through the system the genital organs. I do not introduce this as a new remedy, for general bleeding to overcome rigidity of the uterus and perinæum was practiced long ago, and is still practiced by many of our older physicians under such circumstances; but I desire to recall attention to it as the most prompt, powerful and efficacious of all the agents that the accoucheur can press into his service for the attainment of this end. I am not abashed if I am told, at the very threshold of this announcement, that venesection is an obsolete art, that none but old fogies would think of employing it, and that the blood during pregnancy undergoes such great changes as to render the loss of it, except in puerperal convulsions, an improper expedient during labor with a view of expediting it.

There was a time when this agent was very generally, I had almost said, universally used, even in my early days, in great rigidity of the sexual organs; fortunately, that day has gone by. But if the lancet was used too much then, it is certain, at least to my mind, that it is not used enough now. We are too apt, as a profession, to be influenced by prejudice, especially when it is backed by great authority. When the wether jumps, the rest of the flock are sure to follow. I recollect when it was customary to bleed pregnant women for the relief of headache, dizziness, or vertigo, pulmonary congestion from aortic obstruction, and pelvic and sacro-lumbar pains. The "false pains," as they are termed, often so harassing and worrying as to be a source of real suffering, may generally be promptly relieved by the abstraction of eight, ten, or twelve ounces of blood; and who would not bleed, bleed freely, when a plethoric pregnant woman is threatened with convulsions? To withhold the lancet in such a condition would simply be criminal, and yet some obstetricians, even of world-wide renown, would content themselves with the exhibition, in such an event, of chloroform, of chloral hydrate, or of both articles combined.

If I be told that a pregnant woman should not be bled because, while in this condition, she experiences a marked decrease of the red corpuscles of the blood, I answer that this would be simply begging the question. If this were the only change which this fluid undergoes to meet the physiological necessities of the system during utero-gestation, there might be some reason for such a conclusion. But this is not the fact, for, while there is a marked diminution of red globules, there is also a marked increase of fibrin and albumen, assimilating the mass of this fluid to the condition in which it is found to be in inflammation. Instead, therefore, of using these changes as an argument against the use of the lancet, they afford the strongest possible evidence in favor of it whenever a powerful relaxant is required to facilitate parturition. May plethora not be caused by the presence in the blood of an undue proportion of its fibroid, albuminoid, and aqueous constituents? Blood is formed rapidly in pregnancy, to meet the demands of the system, and it is not at all necessary to perform experiments on bitches to prove what daily passes under our observation in the human subject. The great

strength, the exuberant health, the florid cheek, and the genial warmth diffused throughout the entire system, sufficiently attest the presence of an active circulation, with an abundance of red globules, although they may be relatively fewer than in the non-pregnant state. No rational accoucheur would bleed an anæmic woman, or a woman laboring under cardiac disease, aortic insufficiency, chronic malarial fever, or any wasting malady whatever. Such affections point out their own remedies—supporting, and not depleting measures.

There is an idea, almost universally prevalent, that the people of the present day do not bear loss of blood as well as they did forty, or even twenty, years ago, an opinion which has exerted such an influence upon medical men, as well as upon the public at large, that venesection has become an obsolete operation, or an operation which is, at most, limited to a few old fogies—as they are sarcastically styled—ignorant of the benign progress of the healing art, and of the tolerance of the system. Whether this opinion be true or erroneous, this is not the time or place to inquire; suffice it to say that my solemn conviction is that the neglect into which this operation has fallen, not only in midwifery, but in general practice, is the cause, annually, of the loss of thousands upon thousands of human lives that might otherwise be saved.

If I were asked under what circumstances a pregnant woman, in sound health, without any complications, ought to be bled, I should answer, first, when she is threatened with abortion, miscarriage, or convulsions; secondly, when there is a rigid os, obstinately refusing to yield after the labor has been in progress for six, ten, or twelve hours; thirdly, as a rule, in tardy labor in primiparæ, especially after the age of thirty; fourthly, where there is, so to speak, rigidity of the general system, including, of course, the sexual organs; fifthly, when there is a decidedly feverish condition of the system, associated with severe headache, great heat and dryness of the genital organs, a rigid os, or os and perinæum, and inefficient, teasing labor-pains; and, lastly, in torpor of the uterus from the effects of inflammation, gout, or rheumatism, interfering with or retarding delivery. In all, or, certainly, in most, of these conditions, I should follow up the effects of the bleeding with an anæsthetic, or a hypodermatic, injection of morphia. I solemnly believe that, if these rules were properly observed, the process of parturition would be greatly facilitated, the pains of labor materially abridged, and the risks of lacerations, which now stand as such a blot upon obstetric practice, would be reduced to the merest minimum, not to say anything about the much greater safety of the child, and the more rapid recovery of the mother.

As to the quantity of blood to be abstracted, every case must be met on its own merits. While in some instances the loss of a few ounces may suffice, in others, especially in strong, robust, plethoric women, sixteen, twenty, or even thirty may be required. Dr. Dewees, to whom is justly due whatever praise or blame attaches to this practice, occasionally bled to the extent of forty ounces before he succeeded in overcoming the rigidity of the os. Sometimes,

indeed, he carried the operation even to syncope; always placing the patient in the erect or semi-erect position, so as to expedite and increase the effect.

Dr. Dewees informs us that he was led to adopt the employment of general bleeding in midwifery, near the close of the last century, from having witnessed its beneficial effects in the practice of Dr. Physick, in relaxing the muscles in dislocations of the shoulder-joint.

Out of the injuries now considered, often unavoidable, but in the great majority of cases the effects of gross ignorance, timidity, indecision, or the maladroitness of the forceps and of other instruments, has grown gynecology, a twin sister of surgery, the scientific foundation of which was laid hardly thirty years ago by the immortal Sims, aided by Bozeman, Thomas, and Emmet, of America, by Baker Brown, of London, and by Gustav Simon, of Heidelberg, all pioneer laborers in this great field of the healing art, now trodden by many thousand feet, and illustrated by special treatises and contributions alike honorable to their respective authors and creditable to their respective countries.

DISCUSSION.

Dr. Battey, of Georgia.—Mr. Chairman: I would like just one moment to put myself upon the record in confirmation of one of the views by our late lamented associate of this Section, and it is this:

Although a very much younger man than Dr. Gross—very much younger—the summing-up of my obstetrical experience is (to put it in a word), in looking back over it, in not a single instance have I regretted the use of my lancet in obstetrical practice. In many, many instances, as I now recall them, I think that positive good would have grown out of the more frequent use of it. I bleed, sir, still.

Dr. H. F. Campbell, of Georgia.—Mr. Chairman: I am glad of the opportunity of being able to discuss a paper, the principles of which, perhaps, would meet with no commendation from many, no matter how much we venerate the illustrious man who honored this Section with his last contribution. I am glad that I entertain views so entirely consonant with his. I am glad that my friend from the same State as myself (Dr. Battey) agrees, to a great extent, in the few remarks that he made, with myself.

Blood-letting in labor, blood-letting especially in puerperal eclampsia, has, in my opinion, been most unjustly laid aside, most unjustly condemned. Let us look back and see what has been given us in the place of blood-letting—chloroform, chloral, bromide of potassium, and a variety of other ex-sanguinating remedies—while, at the same time, it is absurdly claimed that anæmia of the brain is the cause of convulsions. It is also claimed that uræmia is the cause of convulsions.

Now, let us look at the natural and logical results. Let us take the anæmia question. If anæmia of the blood causes puerperal convulsions, why give those very remedies that produce ex-sanguination of the brain? If convulsions are caused by anæmia of the brain, why give chloroform? Why give bromide of potassium? Why give chloral—all remedies that ex-sanguinate the brain?

On the other hand, let us look at the uræmia question. If urea, as it is said, collected in the blood, results from congested kidneys, if congested kidneys arrest the flow of urine and give rise to uræmic blood, we ought then to ex-sanguinate the kidneys, to bring the kidneys down to the point of proper and healthy elimination, that the blood may be freed from them.

Now, about this question of blood-letting producing convulsions. If a woman had convulsions, it was claimed, at one time, that there was irritation of the brain; now, it is claimed that it is anæmia of the brain. In order to prove this question, I took two birds. I cut the carotid arteries and all the tissues of one of these birds, that were in front of the cervical portion of the column. That bird bled, bled, fell, and died without a kick, showing that, if anæmia of the brain would produce convulsions, certainly my bird, which was an ordinary barn-yard fowl, would not have died without a kick. [Laughter.] In the other bird, I left all the arteries and other tissues in front of the column intact, and then severed the cord by a subcutaneous incision between the cervical vertebræ. The convulsions were exactly those witnessed in the fowl after decapitation, only they were more prolonged, as life was sustained by continued circulation. Indeed, the severing of the arteries arrested the convulsions. That bird might have been hopping until now, had I not severed the carotids and produced anæmia of its brain. [Loud and prolonged laughter.]

Dr. Harvey, of Indiana.—Mr. Chairman: While no one excels me in respect and honor to the lamented author of the paper which has been read, I take it that the subject-matter is to be treated of as freely as though he were here among us; and especially do I deem it right and proper that we should discuss this paper, when such doctrines and teachings have been given to us this afternoon. It is a matter of necessity, it seems to me, that the views which are taught here by the paper and by the gentlemen who have discussed the paper, should meet with an expression upon the other side of the proposition,—because I know that such a feeling exists. [Applause.]

We are certainly not going to turn back in this age of the world and begin over again and bleed our patients. While I admit the necessity of the use of the lancet occasionally, in certain well-selected cases, I want to say, that, although I am a young man, I entered the medical profession in the days of blood-letting. And while I have seen good results, important results, in labor, from the use of the lancet, I must say that I have seen better results from the use of chloroform and opium, both in convulsions and the relaxation and the prevention of lacerations and other accidents spoken of by the paper. [Applause.]

I think that we ought to feel grateful to our lamented friend for having considered the subject and for bringing it before us as has been done. But I am certain that, by the remedies that are now in use, these accidents will be prevented much better than by blood-letting, which, although it acts occasionally beneficially, certainly does harm to the patient in the long run. [Applause.]

Dr. Kinloch, of South Carolina.—Mr. Chairman;

My friend who has just preceded me has anticipated some of the remarks I propose to make. My whole impression from the reading of this paper is that it is a paper representing simply the force of early impressions, and it shows how tenacious those impressions are, and we must not forget that opinions of great men have their power for evil as well as for good. [Applause.]

I disagree, sir, entirely with the sentiments as expressed in that opinion as to the surgical use of blood-letting. I have practiced medicine, sir, for thirty-five years, as a general practitioner, and have had my fair share of obstetrical practice, and have never yet bled a woman in labor, and I may say, without boasting, that I have only lost two women from consequences connected with the parturitional state. I would ask my friend, if he were here, if he would apply the same rules to surgical as to obstetrical practice. And if the rules are not applicable to surgery, they are not applicable to obstetrics.

In reference to his remarks—I do not remember his exact language—that God should have created a skilful gynaecologist at the same time he created woman; to meet the difficulty of parturition, I would say that, according to his view, every woman ought to be born with a lancet around her neck to meet the difficulty. [Laughter and applause.]

Dr. Seymour, of Troy, New York.—Mr. Chairman: It seems to me, sir, from the experience of the different members who have spoken, that there must be some difference in the diseases of the localities in which they practice. Certainly it is the experience of the older men in the section in which I have used the lancet, that the diseases of the present time cannot sustain it, and I will ask the Section if it can be justified, in their experience, to employ bleeding in puerperal or other diseases in a condition of diphtheria and other poisons.

Dr. Smith, of Washington, D. C.—Mr. Chairman: An old friend of mine who has just left the room, remarked to me that the paper of Dr. Gross, which has just been read, takes rank with Washington's Farewell Address. [Applause.] I make this statement merely to say that the old doctors still believe in bleeding, the young do not believe in it quite so much. [Applause.]

Dr. Claiborne, of Virginia.—Mr. Chairman: I suspect that in this case, sir, the truth lies, as it ordinarily lies, in the middle,—that there are some cases which should be bled, and some which should not. And whilst I stood here yesterday, the advocate of chloroform and, as I believe, the use of chloroform is in a great many instances superior to venesection, yet I should be very sorry myself to throw the lancet utterly away. I am neither an old man nor a young man; I am in the middle, and therefore I claim to be nearer the truth. I have practiced medicine about thirty-two years, the most of that time engaged in obstetrical practice in a city where I had, of course, an opportunity of seeing a great many cases of obstetrics; and it is especially fitting that I should state to-day one word in memory of the venerable gentleman who has left with us his last contribution. At the last time on which I had occasion to appear be-

fore this convention, some one, in discussing the subject of blood-letting, made the suggestion that he doubted whether a single lancet could be found in the whole assembly. I pulled one out of my pocket and said that I had used it for twenty years,—which “brought down the house,” and Dr. Gross arose and complimented me. I think, sir, in view of that occasion, that I should say this one thing—that the truth lies with him as it does with us. [Applause.]

Dr. Reamy (having temporarily vacated the chair).—As the time has nearly expired, and I find no one else on the floor, I take this opportunity to express two or three thoughts that have occurred to me. I think with my friend on the left (Dr. Harvey), that since this is a contribution to this department as the teachings of this great man, while we have the greatest veneration for his kindness of heart and greatness of mind, his wonderful industry, and his almost marvelous life work,—while we mourn together his death, even in the ripeness of his years, yet when we receive this paper, it stands upon the same ground that it would stand if he were living, because it is to be published. Therefore I, with my friend on the left, cannot let sentiments uttered in this paper from so distinguished a source, go upon the record unchallenged.

Perhaps enough has been said with reference to the fallacy taught as to bleeding, but still there is a little point in the matter which has not been brought out. Summing up in this paper, the distinguished author says that he would bleed in threatened abortion. There is no distinction drawn here as to what kind of a threat, as to the causes leading to the threatened abortion,—simply that if a woman were threatened with abortion he would bleed her. I need not qualify my remarks when I say that the inconsistency of such a recommendation is apparent. Granting that the blood-letting could do no possible harm ultimately, which we do not grant, and granting everything for it that is claimed, the proposition to bleed in every case of threatened abortion need not be condemned—it condemns itself!

He would also bleed in a case of fever! If a pregnant woman has fever, he does not make the distinction that, if the obstetrician or general practitioner in charge of that woman recognizes this fever as septic fever, the threatening of the storm that is probably to take her off, he would bleed her because she had received poison into her system, and fever had been produced by it! Why would he bleed such a woman as this, lessen her vital power, take from her the blood which is “the life thereof?” that she should therefore be the better prepared to fight the germs in her system? and bleed her that the next day she may enter upon the throes of labor minus that amount of life the lancet has taken from her? [Loud applause.] Rather husband every particle of strength, knowing that it will be required to resist the influences that are against her!

He would bleed her in a case of rigidity! He would bleed in a case of nagging pains! Now, I will not dwell upon this. An obstetrician in these times who has not been taught that the lancet is the grand remedy for all the ills that a parturient woman can enter upon, would, in cases of this kind, give her a dose of

morphia, chloral or chloroform, let her sleep for four or five hours, and come back and deliver her. Or, if her circulation required, would give her a sedative. He would bleed her in puerperal convulsions, perhaps. With my friend, Dr. Lusk, who has written so well, and whom the author of the paper has quoted, I would, and you would say, that the lancet has properly come in vogue again in those cases, and that in a certain proportion of those cases bleeding is the best remedy. There is no doubt about it, and at the same time that it includes but few of the cases. Those who have tried the hypodermic injection of morphia, and seen the woman sleep quietly and sweetly, who, a few moments ago, was in peril from most violent convulsions, would not, I fancy, be willing to bleed in every case—only in properly selected ones. [Applause.]

Now, just one word in regard to the forceps. This distinguished author ought to have sent to this Section a cut of the forceps to which he referred. He must have remembered that the instrument used by those who used it so infrequently at the time of which he speaks, was an instrument but a little improvement on the instrument used by Chamberlen himself. Those are not the forceps spoken of yesterday by my friend upon the left (Dr. Taylor, of New York). Instruments are not now what they were.

But he asserts that teachers of obstetrics have a fearful responsibility upon them for sending out obstetricians to use the forceps—to use it indiscriminately, and do with it so much damage. Now, without doubt, forceps are too frequently used by some practitioners. This instrument is used for the sole purpose of saving time, and, of course, it is wrong—to save time to the physician, I mean, for the purpose of getting to a good supper. It is wrong. But even my friend, Dr. Lusk, on my right, will grant that this charge in general is not sustained by the facts. The students who now go forth and are taught in this department, are more competent after two years' practice, very much more competent; and I do not refer to one college or to any single student. I say that the students who go out of the average medical college to-day, know how to use the forceps, are better instructed in their use, understand the principles better, know when and how to use it, than the average practitioner of 40 years' experience in those days. There is no question about it. The books that have been written upon this subject within the last few years, from those of the time of Hodge until now, make this subject much plainer. It is a very different thing from what it was. Therefore, I think this view is entirely out of place. The forceps is not the weapon of ruin described. It is not used indiscriminately and by bungling men to injure the uterus, vagina and bladder as has been described. I therefore wish to enter my protest against that particular part of the paper. I do not think that the forceps are used by the average practitioner as often as is asserted. The gentlemen who have been quoted may have used the forceps once in seven cases, but the average practitioner throughout the country does not use the forceps so frequently. I speak from observation and from information obtained from communications within the

last year. They do not use it upon the average more than once in fifteen or twenty-five cases. The distinguished author of the paper is, therefore, laboring under a mistake—an error that ought to be corrected.

Dr. Taylor, of New York.—Mr. Chairman: I rise simply to make an apology for the remarks of the author of this paper. The views that he has stated are the same that I was taught, and I think the Section will pass a vote that this is an antiquated view that was taught some 50 years ago. I do not see any difference in the views stated by Dr. Gross and those which I was taught long ago. At the same time, I do not take the view now that I did at that time.

Dr. Wathen, of Kentucky.—Mr. Chairman: Granting that the administration of chloroform and chloral to the pregnant, parturient, or puerperal woman causes anæmia of the brain, as remarked by Dr. Campbell, would not this be far less injurious than blood-letting in such cases, for that depletes the brain more than either of these remedies, causing general anæmia, so that the woman is less able to pass safely through the trying ordeal of the puerperal state. I have never seen a woman with threatened abortion, or with continued or malarial fever before labor, in which I could possibly conceive that blood-letting would be of any benefit. Blood-letting, in a robust person with an increased volume of blood, in the beginning of an attack of puerperal eclampsia, may be indicated for the purpose of preventing fatal injury to the brain until other means will control the convulsions. I cannot concur in the opinion of Dr. Gross, that the abstraction of large quantities of blood from the pregnant woman leaves her system in a better condition to pass safely through the puerperal state. That this woman, who, after parturition, needs everything that will sustain her, and enable her to recover from the puerperal condition, who cannot take large quantities of good nourishing diet that makes rich blood, whose generative organs have to go through the process of involution, and who has to provide milk to nourish her child; is in a better condition after having been profusely bled, as he advises, than one who has not been bled, is a statement to me so absurd that I believe the profession of the country will not adopt it; so pernicious is it in its influence, that I trust before adopting it the profession will consider well the consequences. [Applause].

JEWISH HYGIENE AND DIET, THE TALMUD AND VARIOUS OTHER JEWISH WRITINGS HERETOFORE UNTRANSLATED.

BY C. H. VON KLEIN, A.M., M.D., DAYTON, O.

[Read in Section of State Medicine and Hygiene of the American Medical Association, May 1884.]

We are now in the age of pride and the Niobe of nations. But when we look back even to the dark age of the Egyptians, we find that our sanitary measures are far behind any other advancements of modern civilization.

Hygeia, commonly called the goddess of health, and from which the term hygiene has its etymology, was a pretender, as well as her father Esculapius, who styled himself the god of medicine.

But when we look back beyond the days of those pretenders, we find that nations lived hundreds of years before them, whose literature was ever preserved by a nation which has preserved itself and survived nations of ordinary power.

When the Egyptians strove amongst themselves, their literature was destroyed, and the loss of the library of Alexandria is felt at the present age.

But of those people of whom I am now about to speak, though driven from country to country, and from nation to nation, at all ages and in all centuries, and are still persecuted, nevertheless their literature is preserved and shines forth with them in full maturity.

Hippocrates, who is supposed to have lived about 400 years before Christ, whose writings on medical art have been preserved, and who endeavored to explain the causes of disease in the human frame, and their symptoms, and pointed out their preventatives, and laid down sanitary regulations and exercises for the preservation of health, appears to have been acquainted with those large volumes of scientific writing, as he well describes their contents.

I am surprised at Galen, the great master, one of the most illustrious men in the annals of medical science, that he does not mention something about them. But I am not surprised at Paracelsus, the father of quacks, who styled himself Theophrastus Bombastus, Philosophus, and other great names to which he was not entitled.

Ever since the days of Hallè, and to the present day, men have lived in both hemispheres who became illustrious for their researches in sanitary science, still, on those great works which embrace the teaching and learning of human hygiene, they are mute.

I mean the illustrious works of the Jewish Talmud, the greater part of its contents, hygiene, a perfect treatise for preserving health. One might not think it possible that the researches of the learned could overlook such a valuable scientific writing. It is strange but nevertheless true, and can be partly explained. They are writings and teachings of a creed whose name was, before the crucifixion of Christ, and ever since has been hated, persecuted, and rebelled against.

Secondly, they are written in languages that modern scientists are unacquainted with, from the fact that the Talmudic language is a conglomeration of the Hebrew, Chaldaic, Aramaic, Syriac, Arabic, Greek and Latin. It was preserved by oral delivery for many generations before Christ, and until about the second century after Christ when the Mishna was compiled. About the middle of the sixth century the entire work was finished.

The *Talmud* (teaching) comprises the *Mishna* and the *Gamara*. Its contents are of a diversified character, relating not merely to religion, but to philosophy, medicine, history, jurisprudence and the various branches of practical duty.

The *Mishnah* (*repetition*), or in abbreviated

form *shas*, (six), and the *gamara*, (*completion or supplement*), comprising the Talmud Babylon and Talmud Jerusalem is composed of six *sedarim* or orders, containing 63 *massecoth*, or tracts, and 524 *perakim*, or chapters; of which 231 are devoted to sanitary regulations or exercises.

The first *seder* called *זרעים seder zeraim*, the order of seeds, treats of sowing the productions of the earth, trees, uses of fruits, etc. It comprises the following treatises:

1. *מסכת ברכות massecoth berachoth*, the treatise of blessings.
2. *מסכת פאה massecoth pehah*, treatise of the corner.
3. *מסכת דמאי massecoth demai*, treatise of the doubtful.
4. *מסכת כלאים massecoth ciliam*, treatise of the heterogeneous.
5. *מסכת שביעית massecoth shebieth*, of the seventh year.
6. *מסכת טרומה massecoth terumah*, of the oblation.
7. *מעשר ראשון maasher rishon*, of the first tenth, or tithe.
8. *מעשר שני maasher sheni*, of the second tenth.
9. *חלה challah*, of the cake.
10. *ערלה orlah*, of the prepuce.
11. *בכורים bicurim*, of the first fruits.

The second *seder* called *זמן מועד seder moed*, the order of festivals, when they should begin and terminate, the different ceremonies to be observed on such occasions, etc., comprises the following treatises:

1. *מסכת שבת massecoth shabbath*, of the laws of the Sabbath.
2. *ערובין erubim*, of mixtures, showing how, on the evening of the Sabbath, the food collected by various neighbors should be united as if they belonged to one household, so that persons living at a distance should not break the Sabbath by too long journeys. [This treatise has some hygienic bearing].
3. *פסחים pesachim*, the passover.
4. *שקלים shekalim*, shekels, treatise on contributions.

5. *יומא yoma*, the day of atonement, treats of the solemnities peculiar to it.

6. *סוכה succah*, tabernacles, how they are to be built and used. This contains, also, some hygienic rules on ventilation.

7. *ביצה betzah*, egg, whether an egg laid on a festival day should be eaten that day or not.

8. *ראש השנה rosh hashannah*, New Year's, how the day should be kept.

9. *תענית taanith*, fasts, treats of the various fasts throughout the year.

10. *מגילה megillah*, the roll, treats of the feast of Purim.

11. *מועד קטן moed katon*, minor feasts.

12. *חגיגה chagigah*, sacrifices on festivals, treats of the three great festivals when all the males were obliged to appear before the Lord, and the sacrifices they were to bring.

The third *seder* called *נשים seder nashim*, the order of women, this section discusses the distinctive rights of men and women, marriage, divorce, the customs, inclinations and sickness of women. It is divided into the following treatises:

1. **יבמות** *yebamoth*, brother's widow, treats of the law obliging a brother to marry the relict of his deceased brother.

2. **כתובות** *cethuboth*, marriage settlements, relates to marriage contracts, dowries, etc.

3. **נדרים** *nedarim*, vows, what vows are binding or not, who can make vows and who not.

4. **נזירות** *neziruth*, Nazarites, the laws relating to them.

5. **גיטין** *gittin*, divorce. This treatise has many valuable points on medical jurisprudence on that subject.

6. **סוטה** *sotah*, jealousy, trial of, treats of women suspected of conjugal infidelity.

7. **קידושין** *kiddushin*, betrothing, treats of the laws of espousal. It states that all ass-drivers are wicked, camel-drivers are honest, sailors are pious, physicians are destined for hell, and butchers are company for Amalek.

The fourth *seder* is called **סדר נזיקין** *seder nezekin*, the order of damages, and is composed of the following treatises:

1. **בבא קמא** *baba kama*, the first gate. It assesses damages done by a beast according to the benefit it receives. If it eats a peck of dates its owner would be fined a peck of barley, as dates are not more nourishing to a beast than barley.

2. **בבא מציעא** *baba metziah*, the middle gate, treats of the laws of usury, landlord and tenant, etc.

3. **בבא בתרא** *baba bathra*, the last gate, relates to commercial transactions, buying and selling, inheritances, etc.

4. **סנהדרין** *sanhedrin*, treats of the great national senate.

5. **מכות** *maccoth*, stripes, relating to the forty stripes which were to be inflicted on certain offenders.

6. **שבועות** *shevuoth*, oaths, who are qualified to take them. A vast amount of medical jurisprudence is found in these chapters, as it treats of persons who are disqualified—women, slaves, idiots, deaf persons, the blind, the wicked, despised relations, and those interested in their evidence.

7. **עדיות** *edaioth*, evidences, respecting witnesses and witness-bearing.

8. **אבות** *aboth*, fathers, contains a history of those who handed down the oral law.

9. **הוריות** *horaioth*, punishment, how persons were to judge in cases of trial, and how transgressors were to be punished.

10. **אבדה זרה** *abodah zarah*, idolatry, or the worship of stars and meteors, and how to avoid idolatry.

The fifth *seder* is called **סדר קדשים** *seder kodashim*, the order of holy things, treating of sacrifices, oblations, their different species, etc. It is composed of the following:

1. **זבחים** *zebachim*, sacrifices, the nature and quality of the offerings.

2. **מנחות** *menachoth*, meat offerings.

3. **חולין** *chol'in*, unconsecrated things. This treatise is a notable endeavor towards the protection of animals, as well as to the hygiene of mankind. It treats of what is clean and unclean, of not eating the

sinew that shrank, and not killing the dam and her young in one day.

4. **בכורות** *beccoroth*, first-born, respecting the first-born of beasts.

5. **ערכין** *eracin*, estimations, relates to the valuing and taxing of things dedicated to God.

6. **תמורה** *temurah*, exchanges, the manner in which exchanges are to be made in sacred things.

7. **כריתות** *cerithuth*, cutting off, treats of offenders cut off from God.

8. **מעילה** *meilah*, trespass, treats of things partaking of the nature of sacrilege.

9. **תמיד** *tamid*, daily sacrifices.

10. **מדות** *middoth*, measurements, relates to the measure of the temple.

11. **קנים** *kinnim*, birds' nests.

The sixth and last *seder* is called **סדר טהרות** *seder taharoth*, the order of purifications, relative to the purity and impurity of vessels, to household furniture, and other things and the way they should be purified. It is composed of twelve treatises almost entirely devoted to hygiene, as follows:

1. **כלים** *celim*, vessels, treats of vessels and household goods which convey uncleanness.

2. **אהלות** *aholoth*, tents, treats of tents, cottages and houses retaining uncleanness, how persons who enter them become unclean, and how they are to be cleansed and disinfected.

3. **נגעים** *negaim*, plague of leprosy, treats of leprosy of men, garments, or dwellings, how their pollution is conveyed and how they are purified.

4. **פרה** *parah*, the red heifer, directs how she is to be burned and her ashes used in purifying.

5. **טהרות** *taharoth*, purifications, how purification is to be effected when a person who has touched an object has been made unclean.

6. **מקואות** *mikva'oth*, pools of water, concerning the reservoirs of water in which the Jews bathed, or washed themselves.

7. **נדה** *niddah*, separation, the uncleanness of women during the menstrual period, etc.

8. **כשירין** *meeshirin*, liquors, treats of fluids and their purification.

9. **זבים** *zabim*, issues, treats of nocturnal pollution, seminal emissions, masturbation, etc.

10. **טבול יום** *tebul yom*, the day of baptism, treats of certain days when the Jews have to wash their bodies, or immerse themselves in order to become clean.

11. **ידים** *yadain*, hands, respecting the washing of hands before eating any meal.

12. **עוקצין** *oketzin*, stalks of fruits, relative to the stalks of fruits and how they become unclean by touching other fruits.

It can be seen from the above treatise that it is full of hygiene. It is true that it contains many fabulous, trifling, absurd, childish and irreverent things, and we coincide with Milman when he says:¹ "the Talmud, that wonderful monument of human industry, human wisdom and human folly."

The only people at present, with very few exceptions, who seem to be acquainted with the Talmud

¹ Milman, History of the Jews. Book xx.

are the Jews, and they appear to be silent or skeptical in regard to it. I cannot conceive why those Jewish physicians living in the most enlightened parts of civilization, in America and Europe, in a city like Vienna, for instance, where in fact the greater part of the medical faculty of the University of that city is composed of Jewish writers and teachers, who are second to none, why they should be silent on the writings and teaching of this great work which has been suppressed for so many generations.

It rests with me in my humble judgment to think they are guilty of two unpardonable mistakes,—one the fear of prejudice to their reputation by revealing their treasures,—the other, their false impression that it is theological and of no value to science. It is said¹ Galileo read medicine with a Jewish physician who taught him the Talmud, and from which he formed his ideas of astronomy, and that should remind them of him who to the last moment said “it moves for all that.” They forget that the² Codex Romana is taken from the Talmud, on which is based all the moral and civil law of all civilized governments. They forget that among the commentators were physicians of no simple ability, men like Maimonides, רמבם Rambam, commonly called Moses Egypticus, who was a physician to the Sultan; Nachmandides called רמבן Ramban, who wrote valuable works on medicine; Rabbi Solomon ben Isaac, commonly called רש"י Rashi, and many other illustrious men of the middle ages, like Ibn Gabrial, Ibn Ezra, Abarbanel, and Alfosi, some of them were even counsellors to crowned heads,—the illustrious Abarbanel³ was privy counsellor to Alphonse the V, King of Portugal. If men of this rank could take advice from those men, I think we surely could be benefited by it. We could translate with great pride Egyptian, Grecian, Roman and Hindoo, names not worthy of mention, but of those men whose names would decorate the index of medical authors, the annals of medical science is obliterated.

Those names just mentioned are but a few of the great commentators, whose discourses taken separately would no doubt be approved by the present most advanced minds of sanitary science.

Those works would have long been in the hands of progressive physicians, if not for the short life of Chiarini, an Italian, who proposed to publish a French translation of the whole Jerusalem and Babylon Talmud. In his *Theorie du Judaïsme* and in his *Talmud Babylon*, Leipsic, 1831, he explained his views and intentions. His death, however, while attending the sick, of cholera, in 1832, unhappily cut short his labors.

There were numerous others who have attempted to translate separate treatises and chapters. The best of all is the one lately published by Doctor Rabinowitz, of Paris, though not complete but worthy of note. I trust it will soon be translated in many other modern languages.

Happening to be one day in the Union Hebrew College of Cincinnati, I listened to a boy of four-

teen, who so clearly recited to his instructor and translated it into English the Talmud חולין *cholin* giving all the anatomical names of the animals, and describing the pathological views of the organs, their healthy and unhealthy appearance, that with pain I thought if here is but a boy, probably without a finished education, who can translate so readily, how easily could a physician of his race, with all the accomplishments of modern education perform the task. It left one to charge them with gross negligence and rational hypothesis for their assumption.

There are besides the Talmud many other valuable works among the Jews which are almost entirely devoted to hygiene, viz. : אדם חיי *Chi Adam, life of man*; שולחן ערוך *Sulchan Oruch*, a set table; יורה דעה *Aarach Chaim*, path of life; יורה דעה *yorah deah*, teaching of knowledge, etc.

I would enter into detail of the תריג מצות *Tarjag Mitzvoth*, six hundred and thirteen commands of the law, more than one-half of which pertain to hygiene, and show that the whole period of Jewish life, from Alpha to Omega, is based upon sanitary measures and morality, which is the basis of health. But my time being limited, I will attempt to prove this as briefly as possible, and comment upon it, basing my views upon the researches of many scientific investigators and naturalists.

To do this we must commence with the first origin of the race. Our earliest acquaintance of Jewish history discloses the fact that it has commenced with a sanitary act. ¹Abraham was the first Jew who became such by circumcision. In his days there lived a people all around, in the foremost rank.

The Canaanites and Egyptians were distinguished for their sensual propensities, especially for their low passions in lust and harlotry, so that scarcely one female from the age of three years and upwards could be found without having been defiled; not one woman was safe from being ravished; a husband had to guard against jeopardy on her account. For the truth of this statement we must refer to Biblical history. When ²Abraham was to start for Egypt he took the precaution to deny his wife Sarah, claiming her to be his sister, he feared the Egyptians might slay him and take possession of her, whereupon the ancient Rabbi's comment “because the Egyptians were then well known for being an unchaste, lascivious and lewd character.” ³It relates further that Abraham sent his servant Eliezer to select a wife for his son Isaac from amongst the maidens of his own kinsmen and there was but one maiden, Rebecca, the daughter of Bethuel, and she was a pure virgin, never having been defiled by any man. It implies, says the great commentator Rabbi Solomon ben Isaac (Rashi), “that all the girls of other parentage were either naturally ruptured or misused in an unnatural way.

By such a state of prostituted humanity Abraham deemed necessary some prophylactic, so as to protect his descendants against raging diseases which might occur from such a state of immorality.

¹Genesis xvii.

²Genesis xx.

³Genesis xxiv.

⁴Rashi's Commentary on the Bible. Genesis xxiv.

Abraham was a patriarch and philanthropist, a lover of humanity; his father, an idol maker, made him acquainted with human weakness of faith. He knew well he could make his people follow him by impressing upon them a power above mankind, so he declared circumcision an ecclesiastical act, and like other true men, upon his own person, at his old age, ventured the operation.

By this he has accomplished something that every physician of the present day approves. Humanity might be proud if every man in the world was circumcised. It is true they do not claim it as a sanitary measure, but I do not care, be it to serve God or the devil, I for one would feel proud of its operation. The horrible suffering from phymosis and paraphymosis is but too well known and can not occur within the tribes of Israel.

It appears that the Jews were educated to morals from their beginning, contrary to the "History of Prostitution" by Dr. Sanger, wherein he claims that prostitution commenced with Jewish women, and was a common thing among them even without shame. He endeavors to prove this by relating the criminal intercourse of Tamar and Judah. This is one of the curious errors into which learned men occasionally fall, strangely and unaccountably. 'Tamar was not a Jewess.

He further aims to prove by Judah sending his friend, a man of high standing, to redeem his pledges. It can be proved just the contrary by a careful perusal; that when he sent the Adullamite to replevy his cloak, bracelet and staff, and when he returned saying he could not find her, Judah said: "Let her take it to her, lest we will be shamed." And after he found out Tamar his daughter-in-law played the harlot, and that she was pregnant, he would not recognize her.

If prostitution was so common among the Jews they would surely have some infection, or at least some disease, but we must admit that there is no disease mentioned within the whole book of Genesis except that Leah had sore eyes.

It is true that the Egyptians were so wicked in their practice, that it may seem incredible to us, but it admits of the fullest proof that ³prostitution was a part of their worship, and in some of their temples large numbers of females were kept, and the price of their shame went to the support of their priests. Sons cohabited with their mothers, brothers with their sisters and with their nearest kinsmen; man with man, and man with beast.

Such was the state of affairs among the Egyptians at the time of Moses the great legislator. He, with his philanthropic heart and active mind, saw that his people were in danger of becoming educated to the same mode of life as the Egyptians. Moses, like Abraham, saw that he could be believed only by frightening them by commands through a heavenly king. He at once proceeded to Mount Sinai to receive such commands. When he returned he appeared with mystical performances, with fire all around him, heavy

clouds were produced by the smoke, thunder and lightning followed as a matter of course. These had great effects upon the people and his commands were kept holy; not only the ten commandments, but all other commands that Moses claimed to be the gift of a God. Here again he instructs them: "'After the doings of the land of Egypt wherein ye dwell shall ye not do: and after the doings of the land of Canaan, whither I bring you, shall ye not do * * * none of you shall approach to any that is near of kin to him, to uncover their nakedness. The nakedness of thy father or the nakedness of thy mother shalt thou not uncover; thou shalt not uncover the nakedness of thy father's wife; * * * of thy sister; * * * of thy son's daughter; * * * of thy father's wife's daughter; * * of thy father's sister; * * * of thy mother's sister," etc., "also thou shalt not approach unto a woman to uncover her nakedness so long as she is put apart for her uncleanness; * * * thou shalt not lie with mankind as with womankind. Neither shalt thou lie with any beast to defile thyself therewith; neither shall any woman stand before a beast to lie down thereto, * * * for in all these the nations are defiled which I cast out before you."

Indeed, it can be seen by the Egyptian doctrine of metempsychosis or transmigration that it tended directly to induce this crime. It is not, however, a matter of inference, but of historical truth that this crime was practiced in Egypt both by males and females, but the code of Moses intercepted the Jews from following the footsteps of their neighbors; and right here it is proper for us to remark that its influence continued unto all generations. There were intervals when the Jews became perfidious. There were many who became ²uncircumcised in order to devow their nationality. Under such circumstances it became a necessity to establish laws more rigid than those given by Moses. Here arose the great Rabbis and compilers of the Talmud and formed a סנהדרין Sanhedrin who established a court of law which had the power to enact religious ordinances and to decide legal cases, with pains and penalties according to their crime, having jurisdiction over life and death. This tribunal consisted of seventy-one men,³ the most learned among the Jews, who were the highest power of the nation.

Besides this great body at Jerusalem there existed many minor Sanhedrins consisting of twenty-three members, in every large country, while at smaller places the judiciary consisted of three persons, composing their minor courts. The former mentioned Sanhedrins are the ones who ordained the great laws of hygiene. The last mentioned minor courts are still in existence and operation in almost every congregation throughout Europe. They are termed בית דין *baith din*, house of judgment. Their main acts are decisions upon what is כשר *cashir*, clean, or טריפה *traipha*, unclean, so that if anything occurs within a Jewish household that raises the question of

³Some claim seventy-two, including the High Priest.

cleanness it is referred to this body, and their decision is generally abided by. These questions arise very frequently, especially among the Orthodox Jews, as their cleanliness is amazingly great.

In washing the hands, נטילת ידים *natilat yadaim*, they are not only instructed to do this, but they are told in what manner: for instance, they are not to wash their hands by dipping them in a vessel, but the water must be poured upon them; they must pour with the right hand upon the left, and with the left on the right, etc., three times; after this they wash the face and rinse the mouth, drying the hands and face with a towel. This must be done as soon as they arise from the bed,—even in the daytime. They must not touch any portion of the body before this is done; also before and after each meal, after each evacuation or urination, or the touching of dead bodies or anything unclean. In districts of Orthodox Jews they have public baths which are used every morning before breakfast by each individual; these are termed בית טבילה *Bait Tbilah*, a house of baptism. This certainly is a very notable endeavor to prevent disease.

It lays down sanitary regulations for what they must eat and drink. The diet is so regulated that one article of food will not interfere with another in digestion; for instance, after eating meat they are to wait three hours before milk or its substances dare be used, as the milk is liable to coagulate and irritate the stomach; even vessels in which meats are prepared are prohibited to be used for milky substances, or *vice versa*. This is done for the purpose of strengthening the commands so that they will not allow themselves to consume meat and milk at the same time. They are also prohibited from eating חיות רעות *chait roet*, wild beasts that do not chew the cud, or have the hoof parted, of the species of a bear, lion, tiger, etc., as such live almost exclusively upon animal food. This is reasonable, as they are liable to be infected by morbid poisons from the consumption of dead animals that might have died from hydrophobia or other raging diseases, such as are sometimes found among dogs, cats, rabbits, foxes, wolves, etc., for whatever disease originates spontaneously in those animals is subject to be transmitted from one to the others; they are therefore dangerous as diet. Even עופות רעות *aphet roet*, wild fowls of the species of the crow, eagle, ostrich, owl, stork, bat, etc., are prohibited, as they consume dead animals.

The meat the Jews consume from the beast or the fowl must be killed in a certain way, and with a certain instrument, not according to the vulgar custom by striking on the head, by a rude knife, or in a coarse and violent way that would mangle or lacerate the body, which might produce instant inflammation and probably blood poison, thus making it unclean and unfit for anybody to consume.

The killing of the beast as well as the fowl must be by bleeding through the jugular vein. Prior to the killing the animal must be well rested, and its respiration normal. There must be no broken limbs; their lungs must be blown up to the trachea and if it does

not expand it is soaked in water twenty-four hours, when if it does not expand, the animal is unclean.

The veins and arteries must be dissected from the animal; this is done for no other purpose but to ascertain whether there are deep-seated abscesses or not, (such abscesses being generally found about the arteries and veins) that would make the animal unclean. The blood of all animals is prohibited as the consumption thereof is dangerous to human life, as all animals are subject more or less to scrofula or other blood diseases. According to 'Drs. Buchner, Kerner, Dunn, Horn, Shuman and others, poison has developed in sausages made of blood and to which they have given the name of Allantotoxicum.

Therefore the Jews do not eat meat, either of the beast or fowl, unless prior to eating it has been well soaked and salted. Their mode of preparing is first to soak it half an hour, then it is well rinsed off with clean water, and salted on both sides, placed upon a board slanting, there to remain from twenty to thirty minutes, then again it must be rinsed three times before its use is proper. The prohibition of the use of חזיר *chazir* swine for food among the Jews is unnecessary to dwell upon, as its effects are but too well known to the laymen as well as to the physician. Not only from the danger of trichinæ but of all other diseases that the hog is inherent to. The hazard from the use thereof and its importation have of late years become national issues in all civilized governments. It should not only be an issue where it is to come from, but its use should be entirely eradicated. Mountains would sink down from the dead caused by the use of this miserable brute. Fish without scales and fins דגים בלוי סנפיר וקשקשת *dagim balæ snapir wacash-cashet* are also prohibited among the Jews. This stands to reason, as frightful poisons are found in many kinds of fish, not to say that all fish without scales and fins are poisonous, but all poisonous fish are without scales and therefore they must be dreaded. Naturalists have declared that fish live upon their kind, that is to say fish without scales live only upon such as have no scales, etc., so they are liable to be poisoned from others.

All שרצים *sharatzim*, creeping things, or reptiles or food containing the same is strongly prohibited and the use thereof is considered a great crime by the Jews.

Water, vinegar, and other liquids suspected of foreign bodies must be strained through a cloth. All vegetables subject to vermin, such as parsley, caraway, lettuce, green onions, peas, mushrooms, berries, cherries, and all vegetables whatsoever must be picked and examined leaf by leaf, kernel by kernel, and grain by grain.

All fruits such as apples, pears, cherries, citron, apricots, peaches, oranges, lemons, nuts, etc., that are decayed or mouldy, the use of is prohibited; the seeds thereof are always considered as unfit for use. By this it can be seen the ancients have already feared the germ of disease.

All wines such as יין כסך *yayin mesech*, drugged

¹Christison on poisons.

wines are interdicted, as such wines might influence or propagate gout or cause other afflictions.

Even the manner in which food should be cooked and prepared is laid down, for example the Talmud asserts that an egg cooked in sand, as is done in hot climates, or laid beside a hot kettle, or wrapped in towels, is not proper food to be consumed, this may appear to us as senseless, but nevertheless it stands to reason that an egg cooked in the above described manner may become partly hatched. By this it can be seen that hatching eggs by artificial temperature is not entirely a modern invention.

One, and above all, of the hygienic laws of the Jews is the separation of women during their menstrual period *הלכות נדה halchot niddah the laws of menstruation*. It is the duty of every husband at least two or three days prior to the expectation of that period to separate from his wife not only from the bed, but even the chamber they occupy if possible, or if any spots be visible upon her clothes, or she should inform him of it, he should at once sever from her and they must remain apart during all the period of her sickness and until six days thereafter, and during that time they are not allowed to eat out of one vessel, and it is advisable not to dine at the same table, nor in any way play or joke with each other. This last to prevent the awakening of passion. In six days after the period has ceased, she must test herself with a clean white cloth, if no red spots appear she must then go *במיקוה mikvah*, pool or *טבילה tabilah*, bathing. Bath houses for that purpose are generally erected by Jewish congregations, but the wealthy people sometimes have them erected in their residences. The bathing must be done by immersing so that every hair on top of her head is covered with water; her legs and arms must be spread in order to allow the water to surround all parts of the body. Gentlemen, I can not describe in less than a volume the laws and regulations of separation.

The same laws as the above are applied to newly married women: After the first intercourse *השמיש tashmish*, they must make the separation and go through the same *modus operandi* as a menstruant. This to allow healing.

They are also instructed how to visit the sick *חולים בקור bakur cholim*, whom they shall visit, and in what diseases. Not only that, but even the clothes they wear are regulated, how they should be made and of what fabrics. The cloth must not be a mixture *שטנז shatnez*, of linen and wool; this may appear very frivolous to us, but I say there are sanitary measures even in this, as these two textures counteract each other, wool retains its temperature, is a non-conductor of heat and keeps the body warm, while linen is a conductor of heat and cools the body. The custom of burying their dead in linen, is done for no other purpose but to prevent infection, as wool is a retainer of contagious and infectious matter. Pasteur's experiments are but too fresh in our minds. I do not know whether he attributes the contagion of the sheep to the animal body itself or to the wool. I can not conceive that an animal interred for many years could still contain contagion, as the body would

be entirely decomposed. But I do believe the wool might retain its infection for hundreds of years, especially if buried in dry ground.

In accordance with the above proofs it can be seen, as heretofore stated, that the laws of morals and health were with the Jews from their earliest history. And those who are acquainted with the Talmud, which is based upon the fundamental principles of the Bible, know that there is not another religious sect or creed in the universe, with the exception of the Jews, and the Mohammedans, who have in their theology, hygiene and diet. It is an established fact that the Koran¹ is taken from the Talmud, or the Mohammedans would not have it.

One thing is certain; the Mosaic and Talmudic laws have accomplished more by their terrific fear of some unknown power that they inculcate than all the legislation of the civilized world with their rigid pains and penalties.

Some say the works of Shakespeare were written 200 years before their proper time. I have just as much reason to believe that the Talmud was written a thousand years ahead of its time. It appears to have every field of literature cultivated, and those pertaining to health to the utmost extent.

You may ask, what have the Jews to show for their sanitary or hygienic measures? Gentlemen, I will say they have a superior claim to the respect of society. Statistics speak for them and show that they produce a vast amount less of venereal diseases than any of the civilized or uncivilized nations on the face of the earth. Above all, I believe that the sanitary mode of Jewish life has great tendency to cultivate the brain and mind.

The Jewish race appears to produce a greater per cent. of great men (according to their numbers) in every branch of science and art than any other sect or creed on the earth. Who does not know the great composers and writers in music, Meyerbeer, Mendelssohn, Rubenstein and others? Not a word will I say about the stage, as the name of Rachel and others, is but too well-known. Not a whisper of the great thinkers and poets, Heine, Phillippsohn, Zunz and Auerbach, but we cannot afford to skip the names of Spinoza, Acosta and Moses Mendelssohn.

As commercial men their superior is not known. As financiers they rule the world. There are, however, very few who follow the profession of law, as they are generally debarred from practice in many of the European countries, but if permitted, they are not excelled in that profession. The American bar is proud of and honors the name of Judah P. Benjamin, of New Orleans, his attainments have made him a great man in the courts of England.

I was astounded after various inquiries and correspondence with all the medical colleges of the world, which was done by me at great labor, that 67 per cent. of Jewish physicians maintain professorships in medical colleges; 36 per cent. are medical authors. Medicine appears to be the favorite study, and as a rule, they always maintain a high standing. There have been many Jewish physicians in a professional

¹ Geiger, Was hat Mahommed aus dem Judenthum genommen

capacity at the courts of famous kings. The celebrated¹ Maimonides was physician to King Salah-ed-din, of Egypt, already mentioned in the fore part of this paper. Rabbi Meir to the King of Castile; Zedekiad, physician to Louis the Pious of France, and Montalto to Queen Marie of Medicis.

It was once decided by the fathers of the church that a Jew could not act as medical adviser to crowned heads, and yet Pope Boniface IX and Pope Julius III appointed Jews for their body physicians.² Of Francis I, it is related, while once seriously sick, he requested Charles V, Emperor of Germany, to send him a Jewish physician. The Emperor sent a convert, but Francis refused to accept his services, and said he had plenty of Christian physicians, he needed the services of a Jew.

By the foregoing it can be seen that what I have asserted, to wit: that the Jewish hygiene cultivates the mind, has already been recognized as a fact by the highest authorities of church and crowned heads.

In conclusion I will say it is high time for us to review the past history of that nation, and ascertain, while the nineteenth century still lingers, if it is not best for us to adopt some of their codes in life. Let us no longer berate a nation which was so brave and full of humility. Let us throw away the idle writings of priestcraft, through which we are deprived of writing our scientific attainments with those of the ancient Jews, and dividing the responsibility of health and life.

I may have accomplished little by these researches, but I have at least pointed out a subject in which science is deeply interested. As it has long been my desire to discourse with my honored colleagues, especially those with whom I feel connected by conjugality of sentiment on the subject of Jewish hygiene, I therefore trust that the Section of State Medicine of the American Medical Association will encourage at least some of these extraordinary measures of health, which will, I am confident, tend to final good in all science, all principles, all feelings, and all actions.

MEDICAL PROGRESS.

SURGERY.

SUTURE OF THE MEDIAN NERVE.—Prof. Tillaux has read a remarkable paper before the Academy of Science (*Union Médicale*, *Medical Times*) upon two cases of secondary suture of the median nerve, with rapid reestablishment of functional activity in the paralyzed parts. By secondary suture he means the suture which is only applied at a period more or less remote from the division of the nerve, when the two ends have become separately cicatrized. The first case was that of a woman who, while cleaning a window, cut her right wrist so deeply as to completely divide the median nerve. Primary suture of the

nerve was not practiced, and after the healing of the wound all the parts supplied by the median remained completely paralyzed. Incapable of working for her living, the girl was admitted to the hospital four months after the accident, and the wound, on examination, showed a rectilinear transverse cicatrix, painful on pressure, on the wrist. At this spot could be felt a tolerably distinct prominence, which was supposed to be formed by the central end of the divided nerve. The whole of the parts supplied by the median nerve were completely insensible to contact, to pain, or to temperature, the patient not feeling the slightest sensation on plunging the ends of the paralyzed fingers into boiling water or picking up burning coals. The muscles of the thenar eminence were atrophied, and the opposing power of the thumb was lost. The paralyzed parts were colder than those of the opposite side, and the skin had assumed a slightly violaceous color. The operation was as follows:

Chloroform being administered, the two ends of the nerve were exposed by a vertical incision, and were found separated from each other by about a centimetre, the central end being enlarged and that of the periphery tapered off. The extremities of both of these were excised by scissors, so as to get fresh surfaces of the same diameter; and instead of employing forceps, which might have contused the nerve, a very fine needle, armed with a *crin de Florence*, was passed from one end to the other. This was gently tightened until perfect juxtaposition of the two surfaces of the section was secured, carefully preventing the neurilemma becoming folded in towards the axis of the nerve, which might have impeded reunion. The thread was tied, cut close to the knot, and left in the wound. The external wound was drained, united by silver wires, and covered with a Lister dressing—the most minute precautions of the antiseptic method having been observed. The hand was maintained motionless in a state of flexion during a whole week, without the dressing having been touched. On the eighth day union was complete. By the third day the index and middle fingers felt the contact of a pin carried gently along their surface, and the sensibility continued to increase from day to day, so that six weeks after the operation the patient left the hospital, the sensibility and motion having returned to such a point that she could work at the needle or crochet, and was in a condition to resume her occupation.

(2) Exceptional cases are rarely solitary, and in the hospital was a woman suffering from an affection of the abdomen, who fourteen years previously had cut her wrist with a bottle, with the effect of producing the same paralytic symptoms with those related above. Witnessing the success of the operation in that case, she requested that it might be performed in her own, and the result of the operation was complete success.

In what way did innervation become reestablished? It would seem natural to suppose that it was through the immediate approach and rapid junction of the central end of the nerve with the peripheral end. But Professor Vulpian declares this to be impossible,

¹ Post-Biblical History, page 65. Sigmund Hecht.

² Post-Biblical History, page 66. Sigmund Hecht.

inasmuch as the peripheric end of the nerve, totally degenerated, had lost all property of transmission, as is invariably demonstrated by experiments on animals. Professor Ranvier, who consented to examine the portions of the nerve cut off for the purpose of vivification, declares also that this explanation is impossible, since the nervous tubules, the agents of transmission, have disappeared in the peripheric end, leaving nothing to be found but fibrous tissue.

THE TREATMENT OF SCIATICA BY CONGELATION.—

Dr. Debove (*Bulletins et Mémoires de la Société Médicale des Hôpitaux de Paris*) in considering the use of revulsives in sciatica and their beneficial action through the excitation of the extremities of the affected nerve, found that they were always restricted in the number of nerve filaments influenced, as it would not be proper to apply a vesicant or cauterization from the hip to the calcaneum. It was therefore suggested to him to obtain this revulsion by means of congelation, for the parts could be congealed and resume the integrity of their functions. There was at all events no objection to making the experiment, as the greatest evil would be the production of an eschar, which was an ordinary result in the classical treatment by cauterization.

Accordingly he used the chloride of methyl, which gives a temperature of 9.4 F., or, in hastening its evaporation by a current of air, 4.7 F., and which is readily applied. His first patient had been treated at various times by cauterization with the red hot iron and without benefit, and had been confined to the bed for a month. He applied the remedy over the painful surface from the hip to the external malleolus; a minute later the patient, who up to that period had been unable to put his foot to the ground, walked without limping and declared himself cured. He was astonished at the relief, Dr. Debove was none the less so himself, but he recalled the influence of the imagination in affecting marvelous therapeutic cures, particularly in sciatica, which has been cured even by cauterization of the lobule of the ear. But since this first case he has been able to repeat his experience sufficiently to warrant him in affirming that this method effects a speedy and constant cure. This case had been affected by the disease for three months and has had no return of it. His other cases were either relieved at once or had slight relapses which were entirely relieved by a second use of the chloride of methyl.

These patients were affected with simple neuralgic sciatica of the rheumatismal form, existing from fifteen days to three months, they all suffered so severely as not to be able to put foot to ground.

The apparatus used was the siphon of commerce, containing chloride of methyl, costing about \$1.20 a quart. To the extremity of the beak of the siphon, he adjusts a lead pipe provided with a small orifice, to allow of a proper direction of the jet, and to prevent waste. It is applied over every painful portion from the sacrum to the malleolus, and the skin is immediately seen to congeal, turn white and become hard as stone. The patient complains of a painful

burning sensation, but, so say the patients, it is nothing like as painful as cauterization.

The skin rapidly reacts from the congelation, which leaves a more or less marked erythema—the most that has been produced was a slight vesication—never an eschar. From that time on the patient is relieved and able to walk, a new application is made where the pain reappears at one or two points, the following days the relief continues, or perhaps there are one or two painful points, which are again congealed and entirely relieved.

ANATOMY AND PHYSIOLOGY.

DECUSSATION OF NERVES.—According to the *Lancet's* summary of the clinical observations of M. Pitres, a considerable modification will have to be made in the prevailing opinion that in all cases the pyramidal tracts decussate at their well-known site in such a manner that the bulk of the fibres of one side passes over to the lateral column of the spinal cord, whilst the small remainder continues downwards in the anterior column. From careful clinical observation, it seems not at all improbable that further complexity ought to be introduced into the anatomy of the nerve-paths in the brain. Secondary degenerations of cerebral origin are sometimes exclusively confined to the opposite lateral column of the cord; sometimes to the opposite lateral column and the internal part of the anterior column of the same side as the cerebral lesion. Pitres has also collected ten cases of unilateral cerebral lesion, in which the secondary degeneration occupied both lateral columns of the spinal cord. The cerebral disease varied in its nature, extent, and site; the secondary sclerosis traversed the peduncles, pons, and anterior pyramid, and then abruptly became bilateral below the decussation of the pyramids. The secondary changes were sometimes exactly symmetrical, sometimes more marked on the same side. The columns of Türck were generally spared, or presented but slight damage, whilst the other structures of the cord were normal. M. Pitres has sought to explain the coexistence of symmetrical medullary lesions with unilateral disease of the brain. His explanation is founded on the individual variations of the decussation of the pyramids as described by Türck and Fleming. There may be simply a crossed pyramidal tract, or there may be a direct as well as a crossed pyramidal tract, and each may bear almost any numerical relation one to the other. Further, the pyramidal tracts of the two sides of the brain may or may not proceed after the same plan; the decussation may be complete for one tract and incomplete for the other. In certain subjects it seems possible that the fibres of one pyramidal tract in the bulb may split into two portions, one of which may proceed down the opposite lateral column, while the other descends in the lateral column of the same side. The disturbance of balance and progression appears to be more persistent and more grave when the secondary sclerosis is bilateral than when it is unilateral. Partial paraplegia, exaggeration of the knee-jerk, and contracture of the lower limbs may exist, however, where the sclerosis is unilateral.

MOVEMENTS OF THE UTERUS, by Frommel (*Zeitsch. f. Geb. und Gyn.*)—Experiments made since the time of Harvey have proved that it is the muscular force of the uterus which expels the foetus. This fact has been verified in the woman, in cases of paralysis, and foeti have come into the world after the death of their mothers.

Kehrer concluded from his experiments, that it is the vascular pressure and not the quality of the contents of the vessels that determines the muscular movements, and that the centres for the rhythmic contractions are to be found in the brain and cord.

In 1864 Frankenhäuser announced that he had found the centres for contractions of the uterus in the cerebellum and cord, the force being transmitted by the great sympathetic; in his theory the sacral nerves were the moderators for uterine contractions. In 1867 he declared that there were ovarian nerves, independent of the uterine plexus, which had motor filaments going to the uterus.

Spiegelberg believed that the uterus had its own motor centre. Rein has confirmed that idea, at least so far as the cerebro-spinal system is concerned; for, having cut all connections between the uterus and that system, he has seen the organ contract, and comes to the following conclusions:

1. The uterus is capable of spontaneous rhythmical contractions.
2. They can be produced in all the stages of its development. They are more regular with females that have borne children than with the nulliparæ or with those who have not reached their complete development.
3. A considerable lowering of the temperature of the body lessens these contractions, without depriving them of their energy, if the temperature is elevated, the contractions are accelerated, and in high fever they are checked.
4. The regularity of the uterine function depends directly upon the condition of the temperature of the body. An elevated temperature has a particularly perturbing influence.
5. Disturbances of the circulation of the blood have a considerable influence upon the movements of the uterus; compression of the vena cava produces the same effect after a longer interval.
6. The uterine contractions do not depend upon any external centre.—(*Annales de Gynecologie*).

MATERIA MEDICA AND THERAPEUTICS.

DETECTION OF BRUCINE AND STRYCHNINE.—The following tests for these substances are proposed by Dr. O. Lindt (*Pharmaceutical Journal and Lancet*). For brucine a convenient test is selenic acid containing nitric acid (five drops of selenic acid, of sp. gr. 1.4, and one to two drops of nitric acid, of sp. gr. 1.2). If the fatty oil is first removed from sections of strychnos nux vomica and *S. ignatii* by petroleum ether and this reagent used, the laminated cell-walls quickly take on a bright red color, which gradually turns to orange and yellow, while the cell cavity and the granular substance contained in it remain uncolored, indicating the absence of brucine. Nitric acid alone

does not answer, the coloration of the alkaloid being marked by the formation of xanthoproteic acid. For the detection of strychnine, Lindt discards the potassium bichromate reaction, because the violet color is developed only in immediate contact with the crystal; and the solution of strychnine in sulphuric acid escapes so rapidly from the preparation that no conclusion can be drawn from a subsequent straining as to the original position of the alkaloid in the nux vomica seed. But it is readily shown by a solution of cerioxide sulphate in sulphuric acid, if the fatty oil, grape sugar and brucine have first been removed by maceration in petroleum ether and absolute alcohol. The reagent imparts a violet-blue color to all the thickening layers of the cell-walls. But the color quickly disappears, while the deposits of albumen assume a bluish opalescent tint, which finally turns to a reddish-violet. The interior of the cell becomes of an intense red color. The reagent retains its activity for a considerable time. The microscope is, of course, necessary to follow all the details of these microchemical tests.

MEDICINE.

NEPHRITIS CONSEQUENT ON PAROTITIS.—During last October mumps or idiopathic parotitis appeared in Berlin as an epidemic. It was more violent in the environs than in the city. Not many children escaped, and a good proportion of adults were attacked. Dr. Croner has communicated to the Berlin Medical Society the history of a patient suffering, during this epidemic, from parotitis followed by nephritis. The patient, a boy, aged six, had an attack of mumps, which followed its usual course. The child obstinately kept in bed, although his general condition was improved. On the fifth day fever appeared, and the right parotid gland was considerably swollen. The fever diminished after 24 hours, the child regained his appetite, and his illness bid fair to follow the usual course. He complained of feeling ill, and would not leave his bed. A fortnight after the child suffered from symptoms of parotitis, his eyelids were swollen. Dr. Croner, on examining the child, observed oedema of the dorsal surface of the hands and feet, also ascites to a slight degree. The urine was also scanty, containing blood, and was highly albuminous. These symptoms of nephritis became modified. The patient had suddenly a fresh attack fever six days after the first indications of nephritis were observed. The submaxillary glands were enlarged and painful. This condition slowly improved, but subsequently all the symptoms reappeared, and the right submaxillary glands were enlarged, and caused pain. About the middle of January of this year, albumen disappeared from the urine; the albuminuria had continued during five weeks. Convalescence followed, and the child was completely cured. Dr. Croner has found but one similar case on record, published by Henoch. He observes that the opposition met with from the infant patients, and especially from the parents, which prevents introducing a stylet into Steno's duct, in order to obtain some of the glandular secretion, prevents researches relating to the infectious element of parotitis.—(*British Medical Journal*.)

SATURDAY, SEPTEMBER 27, 1884.

KARL BRAUN'S LAST ONE HUNDRED LAPAROTOMIES.—Professor Karl Braun, of Vienna, has recently published an interesting and instructive account of his last one hundred laparotomies.¹ The operations, indicated by tumors in connection with the female genital apparatus, were performed in the Vienna Gynecological University Clinic, No. 1, of the General Hospital, usually in the presence of numerous physicians and students, during the last five years—1879–1883, inclusive. The results of the operations are as follows:

Of all laparotomies, 73, or 73 per cent., recovered, 27, or 27 per cent., died; of 90 laparotomies, with exclusion of ovarian carcinoma, 70, or 77 per cent., recovered, 20, or 22 per cent., died; of 74 ovariectomies and parovariotomies, in cases of cystomata, 60, or 81 per cent., recovered, 14, or 18 per cent., died; of 10 ovariectomies in cases of ovarian carcinoma or sarcoma, 3, or 30 per cent., recovered, 7, or 70 per cent., died; of 16 myomotomies, with or without hysterectomy, 10, or 62 per cent., recovered, 6, or 37 per cent., died; of 64 ovariectomies, without hysterectomy, 54, or 85 per cent., recovered, 10, or 15 per cent., died; of 10 ovariectomies with hysterectomy, 6, or 60 per cent., recovered, 4, or 40 per cent., died; of 56 ovariectomies in cases of pedunculated cystomata, 49, or 86 per cent., recovered, 7, or 12 per cent., died; of 18 parovariotomies, of the broad ligament, 11, or 61 per cent., recovered, 7, or 37 per cent., died; of 9 enucleations of parovarian cystomata, 7, or 77 per cent., re-

covered, 2, or 22 per cent., died; of 3 partial excisions of cystomata (*Abkappungen*) and drainage of the sac, 1, or 33 per cent., recovered, 2, or 66 per cent., died; of 7 cases of cystomata, in which the viscous contents were removed by the hand, 5, or 71 per cent., recovered, 2, or 28 per cent., died.

Of the 74 ovariectomies, the recoveries and deaths resulted as follows:

After removal of	5 dermoidcystomata, 5 recoveries, or 100 per cent.
	7 unilocular cysts, 7 recoveries, or 100 per cent.
	1 <i>fibroma ovarii</i> , 1 recovery, or 100 per cent.
	2 cystosarcomata ovarii, 2 recoveries or 100 per cent.
	1 gelatinous tumor, 1 recovery, or 100 per cent.
	58 myxoidcystomata, 44 recoveries, or 75 per cent., 14 deaths, or 24 per cent.

Of 10 ovariectomies, on account of *carcinoma ovariorum*, 3 survived the operation, but 2 died, one year afterwards, of a return (*Rezidive*) of the disease; the recoveries, therefore, are 1, or 10 per cent., deaths, 9, or 90 per cent.

Of 5 simple myomotomies, 4 recoveries, or 80 per cent., 1 death, or 20 per cent., were recorded. Of 11 myomotomies, with hysterectomy, 6 patients, or 54 per cent., recovered, 5 patients, or 45 per cent., died.

Of 9 myomohysterectomies with extraperitoneal treatment of the pedicle, 5, or 55 per cent., recovered, 4, or 44 per cent., died.

Of 2 myomohysterectomies with intraperitoneal treatment of the pedicle, 1, or 50 per cent., recovered; 1, or 50 per cent., died.

Of 3 simple myomotomies, with extraperitoneal treatment of the pedicle, 3, or 100 per cent., recovered.

Of 2 simple myomotomies, with intraperitoneal treatment of the pedicle, 1, or 50 per cent., recovered, 1, or 50 per cent., died.

Of 3 myomotomies, and 11 ovariectomies, the patients were pregnant. They made excellent recoveries.

From this analysis the following table of recovery percentage is constructed.

	Per cent.
Dermoidcystomata, unilocular cysts.....	100
<i>Fibroma ovarii</i> , simple myomotomies.....	100
Pregnancy in myomotomies.....	100
Pregnancy in ovariectomies.....	100
Ovariectomies in cases of pedunculated cystomata.....	86
Ovariectomies without hysterectomies.....	85
Ovariectomies in cases of cystomata, and cysts in general..	81
Myomotomies without hysterectomies.....	80
Laparotomies without <i>carcinoma ovariorum</i>	77
Enucleations in cases of parovarian cystomata.....	77
Ovariectomies in myxoid cystomata.....	75
100 laparotomies (with inclusion of carcinoma).....	73
After removal of viscous, sac contents, by the hand.....	71
Myomotomies and hysterectomies.....	62
Parovariotomies of the broad ligaments.....	61

¹Wiener Medizinische Wochenschrift, 1884. Nos. 22, 23, 27, 29, 30.

	Per cent.
Ovariectomies with hysterectomy	60
Myomohysterectomies and extraperitoneal treatment of pedicle	55
Myomotomies with hysterectomy	54
Myomohysterectomy and intraperitoneal treatment of pedicle	50
Myotomy and intraperitoneal treatment of pedicle	50
Parovariotomy, with partial excision and drainage of sac	33
Ovariectomies on account of carcinoma or sarcoma	30
Since death occurred in two cases, at the expiration of one year after the operation, the recovery percentage, after malignant ovarian tumors is only	10

PROFESSOR KARL BRAUN'S OPERATIVE METHODS IN LAPAROTOMY.—Professor Karl Braun, of Vienna, is justly considered one of the greatest obstetrical and gynecological surgeons of the day. Aside from highly original, intellectual endowment,—cultivated and developed by the vigorous, scholastic training of the *Gymnasium*,—local conditions have conspired to make him the great authority he is. From March, 1849, to Sept., 1853, Karl Braun acted as sole assistant in the Vienna Obstetrical Clinic; from 1853 to 1856, he acted as head-master of the Trieste Lying-in Hospital; in Dec., 1856, he returned to Vienna, and assumed control of the Obstetrical Clinic. In October, 1873, the Lying-in Department of the Vienna General Hospital was divided into three clinics. Karl Braun took charge of the First Clinic, while the Second and Third Clinics were placed respectively in care of Professors Josef Spaeth, and Gustav Braun. The colossal material which has come under Professor Karl Braun's observation, during his thirty-five years of uninterrupted professional activity, is difficult of adequate conception. During twenty-five years, 1849–1874, inclusive, he superintended 100,000 labors. Since 1877, he has performed Cæsarean section, with hysterectomy,—Porro's operation,—twelve times. In another editorial, we noticed at length his laparotomy statistics, as collected from 100 cases, occurring during the last five years, 1879–1883, inclusive. His operative methods have always attracted attention, and contributed much to the comparative perfection of the *technique* of laparotomy. A brief review of his operative *technique* appears in the *Wiener Medizinische Wochenschrift*, Nr. 30, 26. July, 1884.

As regards antisepsis, the rules of Thomas Keith are observed. The operating room is thoroughly cleansed the night before the operation, and thoroughly fumigated with burning sulphur. The room is then freely ventilated, and, in winter, moderately heated. One hour before the operation the room is filled with the vapor of an aqueous solution of car-

bolic acid by means of a steam atomizer. This preliminary, one hour's disinfection, constitutes the sole function of the spray apparatus. The patient receives a bath and is gently purged, the day before the operation. In the ante-room she is anæsthetized with the English chloroform mixture, the *mons* shaved, bladder emptied, vagina disinfected, skin surface of the abdomen thoroughly washed with a soft soap and 5 per cent. carbolic acid solution; the abdomen is covered by warm compresses, and a caoutchouc cloth, with a long central slit; the extremities, well enveloped in flannels, are fixed. The operator and assistants wear clean clothes. Their fore-arms and hands are thoroughly disinfected by means of soft soap, nail-brush, potassium hypermanganate and dilute hydrochloric acid, thymol and salicylic acid water, or one to two thousand solution of corrosive sublimate. The instruments are polished, passed through a flame, and disinfected with carbolic acid. Sponges and fine, disinfected, hemmed patches of shirting muslin lie for weeks in 5 per cent. carbolic acid solution. Immediately before use, they are washed in pure water, and then placed in a warm aqueous solution of thymol, 1 to 1,000.

In cases of cysts and cystomata with fluid contents, a large, flat protection sponge is placed beneath the lower angle of the abdominal incision, and the fluid removed by a thick trocar; before the removal of the trocar the inner wall of the cyst is washed out with lukewarm thymol water. The cyst, thus emptied, is withdrawn through the abdominal wound by suitable forceps. Adhesions to the parietal peritonæum, omentum or tubes, when slight, are peeled off from the cyst wall by the index finger. In cases of intraligamentous cystomata, when adhesions to the mesocolon and large intestine exist, it is better to cut into the *mesenterium*, to work with the finger-ends under that structure on the cyst wall and attempt enucleation. When adhesions to the colon of 3 centimetres extent exist, it is advisable to cut out a portion of the disinfected cyst wall, and allow it to remain on the mesocolon, in order to prevent rupture of the intestinal canal.

When the pedicle, in cases of ovarian cystomata, is long enough, it is securely compressed in a clamp, ligatured, below the clamp, in halves, by the figure of eight turn; subsequently the ligature is made to encircle the entire pedicle. The ligature selected for this purpose is of strong silk. Above the clamp the pedicle is canterized with the thermo-cautery, allowed to cool off, and, if perfectly bloodless, returned to the abdominal cavity. When the omentum, tubes, or thick adhesions are divided, the procedure is iden-

tical. After enucleations of intraligamentous cystomata, bleeding vessels are ligatured, the folds of the broad ligaments and mesocolon are brought into exact apposition by the running or interrupted suture. In applying these sutures, it is necessary to carry them deep down to the floor of the peritoneal sac—due care being observed to exclude the ureters—in order to secure the nicest approximation of wound surfaces. When intraligamentous cystomata cannot be removed from the uterus, they must be amputated and treated by the extraperitoneal method.

When intraligamentous cystomata can neither be removed from the uterus, nor amputated, it is best to ligature the diseased broad ligament close to the uterus, remove the outer portion of the diseased broad ligament, and return the uterus to the abdominal cavity. When adhesions between a cystoma and the colon cannot be divided, and the ureters are similarly attached, the cystoma may be partially excised, and the rest of the sac sewed into the abdominal incision, and the cavity of the sac drained.

In solid tumors of the uterus, operative procedure is identical with that of Porro's operation. In pedunculated, solid uterine tumors, it is well to attempt to preserve the ovaries and the uterine cavity in an intact condition. The pedicle is ligatured with a rubber cord, held in place by a perforated shot, compressed with a Leiter's wire ecraseur, and the stump thoroughly cauterized. After the removal of the tumor, the pedicle is pierced between the ligatures with one or two long needles placed transversely, and treated by the extraperitoneal method. When the solid tumor is attached to the uterus by a broad basis, two ligatures, the rubber cord and the wire ecraseur are placed around the base of the tumor, the circulation interrupted and local anæmia produced. The tumor is then rapidly divided by a circular incision through its greatest circumference; the lower half of the tumor is enucleated out of its tough capsule by the fingers, a pedicle formed, which can then be treated in the usual extraperitoneal manner. In this way the uterus and both ovaries can frequently be preserved.

In general, the pedicles of ovarian tumors are returned to the cavity of the abdomen, while the stumps, in cases of myotomy and myomohysterectomy, are treated by the extraperitoneal method.

Every bleeding vessel in peritoneal adhesions is surrounded with a silk ligature, and securely tied; parenchymatous hæmorrhage of the peritonæum is controlled by light touches of the thermo-cautery, heated to a gray glow.

Before closure of the abdominal incision, the *toilette* of the peritoneal cavity is completed with the

greatest care, and the air, which enters during operation, is pressed out.

In closing the abdominal incision, the upper and lower angles of the wound are surrounded by silk sutures, which include the peritonæum. Silver sutures, with lead plates, and perforated shot, separated by a distance of three ctm., are then passed transversely, so that the peritoneal surfaces, on either side, are brought into accurate apposition, to the extent of at least one ctm., and are compressed in this position. Deep and superficial sutures of silk complete the union of the incision.

Over the abdominal wound, after suitable cleansing, a powder of sodium benzoate is thickly dusted. Finally, a heavy Lister dressing of iodoform, and carbolic acid gauze, absorbent cotton and mackintosh is applied.

CHICAGO FLOATING HOSPITAL ASSOCIATION.—The object of this Association is to maintain one or more floating hospitals on the lake, near the city, with all the necessary accommodations for infants and young children with their mothers and nurses, including boat to take them to and from the same at stated hours each day during the hot months of summer, thereby giving the sickly children of the poor all the benefits of cool and pure air a part of each day. There is probably no other public charity in the city that accomplishes as much good in promoting health and saving life, with the expenditure of the same amount of money. The following official report will show the work and expenditures of the season just closed:

CHICAGO, ILL., Sept. 16, 1884.

The Floating Hospital Association, in making their annual report, desire to thank those who have so generously provided the means for their summer work.

The first boat was sent out to the pier on Monday, July 7, and the season was continued to and included Friday, September 12, a period of ten weeks—the longest in our history; 21,489 persons were cared for during this time.

\$1,761.71 has been received,
\$1,428.00 has been expended,
\$ 333.71 we have now on hand,

which it is proposed to use in the purchase of new hammocks, and other necessities, made imperative by the very decided increase in the attendance from year to year. It was feared at one time during the summer that we might not be able to go on, but the very liberal support given us by members of the Board of Trade and other constant friends, placed the matter beyond doubt. No accident of any kind occurred, and nothing has marred the success of the work. For

ice and milk we were indebted, as we have always been, to the kindness of the respective dealers.

JOS. STOCKTON, Pres.
C. L. RUTTER, Sec.

List of donations other than cash, season of 1884 :

Coal. Robert Law.
Ice. Washington Ice Co., A. S. Piper & Co., E. A. Shedd & Co., H. P. Smith & Co.
Crackers, for the whole season. H. H. Kohlsaas.

Sundries. Edwin Heywood.

NEW WORKS ON PRACTICE OF MEDICINE.—Quite opportune, so far as relates to students who may be about to select text-books, two new works on Practical Medicine have just made their appearance—one from the publishing house of William Wood & Co., New York, by Alfred L. Loomis, M.D., LL.D., Professor of Pathology and Practical Medicine in the Medical Department of the University of the City of New York, Visiting Physician to Bellevue Hospital, etc.; and the other from the publishing house of Jansen, McClurg & Co., Chicago, by Nathan S. Davis, A.M., M.D., LL.D., Professor of the Principles and Practice of Medicine in the Medical Department of the Northwestern University, known as the Chicago Medical College, Visiting Physician to the Mercy Hospital, Chicago, etc.

Both these works will be noticed more at length in the proper department of the JOURNAL at an early day.

CHOLERA IN EUROPE.—The epidemic has continued with unabated severity in Italy during the last week. During the 24 hours ending September 17, there were 463 fresh cases of cholera in Naples, and 265 deaths. On the 18th there were 507 new cases and 283 deaths. On the 19th the number of cases reported in Naples was 437, and in the Italian provinces exclusive of Naples there were 149 cases, making a total for the 24 hours of 586 cases, of which 343 were fatal. On the 21st in Naples, 373 cases and 146 deaths; other places, 89 cases and 47 deaths. On the 22d in Naples, 362 cases and 192 deaths. Elsewhere in Italy, 67 cases and 34 deaths. For the last date the bulletin from Spain was as follows: Alcantara, 5 deaths; Elche, 5 cases, with 4 deaths; Novelda, 2 new cases, with 6 deaths; Monforte, 5 cases and 3 deaths; at Tarragona, 6 cases and 3 deaths; elsewhere, 2 cases and 1 death.

YELLOW FEVER.—The death of Captain Simpson, a yellow fever patient, is reported at the Quarantine

Hospital, Boston, Mass., under date of September 18. On the 21st, a severe case of yellow fever was discovered in the upper story of the Hotel Espanol, at No. 116 West Fourteenth street, New York City. The patient was Domingo Morales, who arrived on the steamer Newport from Havana on the previous Tuesday. The vessel with its cargo had been detained at the quarantine, but the passengers, 36 in number, after inspection by the health officer of the port, and appearing free from disease, were allowed to proceed to the city and became dispersed.

MEDICAL COLLEGES.—During the week just closing, all the regular medical colleges in this city have opened their annual courses of instruction; and the same is true of nearly all the medical schools in this country.

SOCIETY PROCEEDINGS.

MASSACHUSETTS MEDICAL SOCIETY.—SUFFOLK DISTRICT.

SECTION FOR CLINICAL MEDICINE.

Dr. G. L. Walton read a paper upon Hysteria as Affected by Removal of the Ovaries.¹

Dr. John Homans spoke as follows: I think this operation cannot yet be definitely judged or accurately valued. I consider it to be still on trial. Many successful cases are reported and others which are not favorable. Alienists and psychologists are divided upon this subject, some recommending the operation in selected cases, while others are not friendly to it under any circumstances. The removal of the ovaries should be thought of in relation to painful menstruation, and consequently in those conditions which depend upon or are induced by painful menstruation. In skilful hands the operation of ovariectomy and the other more common operations of abdominal surgery are no longer so dreaded as they were a few years ago, and the results of ovariectomy to-day are equally as favorable as those of capital operations of the extremities. Abdominal surgery is different from other surgical procedures, and cannot be taught; it must be learned by observation and experience.

Thus far I have operated upon three cases of the kind to which attention is directed in the paper of Dr. Walton. The first patient was a lady twenty-two years old, very bright and intelligent, highly educated, and thoroughly refined. Menstruation had always been irregular and painful. As the disease proceeded the patient first became hysterical, then gradually grew to be destructive, and finally became insane. It was thought that removal of the ovaries might have a beneficial effect, and the case was first brought to my notice by her friends, who sought my opinion in regard to this means of relief. There was

¹See page 331 of this JOURNAL.

at that time great tenderness in the left iliac region with rigidity on touching the part. She had already spent one whole year in bed at her home, and had passed a year at the Adams Nervine Asylum. She had been the frequent subject of gynæcologists and of specialists of various kinds. Finally she was placed in an insane asylum and was kept quiet by means of morphia. The pain was still present in the left side and much worse at the menstrual epoch. At such times the application of leeches to the *os* generally afforded some relief, but the case was gradually becoming worse and it was feared that her insanity would eventually become chronic.

In March, 1883, I removed both ovaries, with the Fallopian tubes. The patient did perfectly well, and made a good recovery from the operation. Soon she began to experience relief from the old distress, and the iliac pains entirely left her. Then the headache diminished, and she became again a bright, intelligent, and perfectly sane person. She began to write, and furnished considerable manuscript for one of the daily papers. Finally her correspondence was intercepted by the family, and it was found that she had resumed the use of morphia, using the money earned from the newspapers to surreptitiously purchase the drug. On being reasoned with, she promised to give up the morphia, which she did by gradually diminishing the dose, until for months she has taken none at all. On examination, the uterus was found to be in an infantile condition, about half the size of the thumb. From this time no unfavorable symptoms have shown themselves, and the patient and her friends consider the result as very successful.

My second case was a young lady who has had a somewhat celebrated history, from the fact that the disordered mental condition had been of some years' duration, and was of a very striking character. This patient was the subject of a scientific essay by Dr. W. B. Goldsmith, under the title of "A Case of Moral Insanity," in the *American Journal of Insanity* for October, 1883, and a few extracts from her history, as given by Dr. Goldsmith, will clearly set forth her condition. He says:

"The patient is a girl 18 years old, rather short and small, but of well-knit, muscular figure, and very active and strong. Her head is fairly well formed, though slightly inclined to the bullet pattern; her expression amiable and bright, and her general appearance calm. In her seventh year she had a severe attack of scarlet fever, followed by a marked change in her mental condition. She became easily excited; seemed unable to apply her mind, and though apparently not malicious, could not be made to obey. Her father committed suicide at about this time, and this appears to have been the first occasion when she seems to have completely lost self-control. Soon after this she was sent to school, where she caused much trouble in various ways, and the teacher declared she spoiled the discipline of the entire school. After this she became subject to violent paroxysms of temper, in which she would scream and throw herself about, and break furniture and tear clothing. When between 8 and 9 years old, she was found naked bathing with some boys, and at this time admitted that she had

frequently indulged in sexual dalliance with boys older than herself. She was now placed in various "Homes," from each of which she was dismissed on account of her violent and destructive paroxysms, and because she could not be made to observe any rules or regulations. She finally was placed in the Hospital for the Insane, at Taunton, Mass., when 9 years old, and there remained four years. No intellectual impairment was there detected in her, but she was thought to be in a condition of moral insanity. Dr. W. H. Gage wrote of her, 'She was an extremely difficult patient to manage.'

"From the Insane Hospital at Taunton she was removed to a similar institution at Worcester, where she remained about twenty months, whence she was removed by her friends contrary to the advice of the hospital authorities. She remained quite well for four months, when on some trivial occasion she became much excited and leaped from the roof of a veranda, and was found screaming and maniacal on the walk below. The mania lasted two days, when she was placed in the Lunatic Hospital at Danvers. At this time her attacks of violence were generally induced by some slight disappointment or irritation, and would commence by attempting to destroy windows, pictures, or anything fragile. She was very violent toward her attendants, striking them and tearing their clothing and hair in a most vicious way. She has shown violence to every attendant with whom she has been for any length of time. Since her admission to the asylum at Danvers she has taken a variety of drugs, and exhausted the list of punishments and rewards practicable in a hospital for the insane. She has been kept thoroughly under the influence of bromides for weeks together; and the same is true for a less time of chloral hydrate; she has taken iodide of potassium, and has been overpowered by hyoscyamine; she has battled with various forms of mechanical restraint, and has demolished many; has tried every grade of ward, from the most violent, to a parole ward where she came and went at will, and all without any perceptible injury or advantage."

I operated upon this patient last July, and removed both ovaries together with the Fallopian tubes. The wound healed by first intention, and she returned home in four weeks, and has been at home ever since. She has appeared to be perfectly well since the operation. Not a drop of menstruation has appeared since the ovaries were removed. Dr. Rowe has expressed the fear that a relapse of the mental disease might recur in these cases even after one or two years. In this case any hæmorrhage seemed to be a sufficient cause for a paroxysm, and the menstrual exacerbation was thought to be aggravated by the fact that it was of hæmorrhagic character, and the removal of the ovaries seemed to be beneficial in the way of preventing this recurrent loss of blood.

The third case was not a suitable one for this operation. The mental disease was of ovarian origin, coming on suddenly soon after marriage, and might, perhaps, have been benefited by an operation at an earlier date. There was undoubtedly commencing dementia before the ovaries were removed, and the

patient's condition has become steadily worse from that time. The wound healed by first intention, and not a drop of menstruation has appeared since that time. The patient has become very violent and destructive, and has made dangerous attacks upon her attendants and upon other patients. She destroys her clothing, and has become filthy, passing her dejections in bed or in her garments. In this case removal of the ovaries has not benefited the patient, and the case has probably progressed exactly as it would have done if nothing had been attempted in the form of an operation.

It is of no use to remove the ovaries by the vagina, but if the operation is to be done at all, it should be by the abdominal incision, and the tubes should also be removed, when a much more favorable result may be expected.

Of these three cases the first may be classed as one of hystero-mania, the second as one of pure hysteria, and the third at present as advancing dementia.

Dr. Cushing inquired who it is that gives consent to a capital operation when this becomes necessary in an insane patient?

Dr. Homans replied that the consent of the guardians or next friends must in all cases be obtained, and also the consent of the patient. Few patients to whom this operation might be expected to prove of benefit are so insane as not to be able to understand and consent to its performance.

Dr. Rowe stated that he had seen many cases of each of the diseased conditions mentioned by Dr. Homans which have exhausted all the resources of asylums, but he had never thought of ovariectomy as a means of treatment. This should be henceforth taken into more careful consideration. In all capital operations the consent of the natural or constituted guardians of the patient as well as his own should first be obtained.

Dr. Putnam remarked that he had had no experience in this method of treatment of insanity. The operation would seem to commend itself even in cases in which the ovaries are not diseased. In many cases in which nervous symptoms are prominent, the cure may be aided by judicious control of these functions. In ovarian troubles it may be useful to remove the periodical stimulation of these organs. In many instances of trephining, the nervous symptoms have been benefited or entirely relieved, when no fracture was found, no depression of bone existed, or any other evident mechanical interference with the functions of the cerebral structures could be anywhere observed. In like manner the supra-orbital nerve is cut in cases of spasm of the eyelid, followed by relief to this condition. It is thought to act by removing one source of irritation to the motor centres.

Dr. Homans added that removal of the ovaries with cystic degeneration of their structure is sometimes followed by insanity. This operation is still young in its relation to mental disease, and is liable to abuse. It should be especially guarded in its application to these unhappy cases, and should be done only as a last resort. In one case in which the ovaries were removed per vaginam the condition of the patient was much worse than before the operation.

If the tubes had been taken too, the result might have been different. Such a person ought not to be allowed to breed, and if anything is attempted, both ovaries and both Fallopian tubes should be removed, and thus the utmost possible good be accomplished for the patient. In one case of double ovariectomy the patient has flowed regularly and irregularly ever since that time. Removal of the ovaries does *not* cure dysmenorrhœa. This important fact should not be forgotten in advising any operation short of complete extirpation of both ovaries and Fallopian tubes.

Dr. J. J. Putnam said he had had no experience in the use of Battey's operation, but was quite prepared to believe that its effects might be beneficial both where the ovaries are diseased and even in some cases where they are not. The favorable action of the treatment in the latter group would probably be due to a restriction of the activity of the nervous system within narrower bounds.

Dr. Farlow exhibited an antiseptic pad which had been devised for the benefit of ladies while traveling or while menstruating and after parturition. It is made of coarse cheese cloth, and is filled with borated absorbent cotton, and can be easily prepared by any one. This pad is for sale by druggists at one dollar a dozen.

Dr. Fitz showed a series of specimens from a case of senile gangrene operated on by Dr. Warren, and reported upon by him at a meeting of the Society for Medical Improvement March 24, 1884.¹ No untoward symptoms occurred till within twenty-four hours of death, and the appearance of the wound was favorable till that time. At the autopsy the edges of the wound were firmly adherent throughout the greater part of its circumference, and there was no discoloration or swelling. Both popliteal and interior tibial arteries were found calcified just below the popliteal space, and both contained thrombi. Venous thrombosis extended upwards from the amputated stump into the femoral vein, terminating just below Poupart's ligament. The thrombus was pale-red, friable, and softened centrally.

Several branches of the pulmonary artery of both lungs, at least a line in diameter, containing reddish-gray thrombi, and at the base of the right lung there was a peripheral nodule of hæmorrhagic infarction of the size of a walnut. Both lungs were œdematous, and the right pleural cavity contained four ounces of opaque pink fluid, the pleural surfaces being besmeared with a thin yellow membrane. There was no necrosis of the pleura.

The spleen was more than twice the usual size, intimately adherent to the abdominal wall and to the omentum. It was dense and heavy, the surface irregularly depressed and nodulated from the presence within the organ of numerous nodules of anæmic necrosis, varying in size from that of a plum to that of a hazelnut. These patches were often porous on section from the presence of numerous cavities containing a relatively clear fluid. Between the necrotic patches the spleen was indurated and reddish-gray

¹See *Boston Medical and Surgical Journal*, 1884, xv, 340.

in color, while scarcely a trace of splenic structure was to be found normal in color and consistency. A circumscribed patch of thickened intima of the aorta was present, which included the origin of the coeliac axis and the superior mesenteric artery. The former was entirely occluded by fibrous tissue, and the calibre of the latter was diminished one-half for a short distance from the aorta, and then was considerably dilated.

The hepatic branch of the cardiac axis was dilated, the splenic artery was narrowed, its walls thickened, and its cavity completely obliterated throughout its entire course by means of an adherent, dark-red, firm thrombus. The splenic vein was also obliterated by a reddish-gray, centrally-softened thrombus, which was continued into the portal vein. The trunk of the latter was filled with the thrombus which extended into the hepatic branches of this vessel.

Peripheral portions of the liver showed a nutmeg appearance, and a nodule of anæmic necrosis the size of a plum was found.

There was a varicocele of the right side, the spermatic vein entering the right renal vein. A moist, dark-red, distending thrombus was continued from the immediate vicinity of the testicle into the right renal vein, whence it extended toward the inferior vena cava as a thrombus the size of the tip of the little finger.

The chief interest of these specimens lay in the evidence of long-standing serious disease without striking symptoms at the time of the operation; also in the comparatively slight alterations of the liver, despite the obliteration of the coeliac axis and the obstruction of the portal vein. Embolism of the pulmonary artery was to be regarded as the immediate cause of death, while the thrombosis of the renal vein was presumably of marantic origin, and might not have been of above 24 hours' duration.

Three varieties of thrombi were present, each independent in origin from the others, and neither having given rise to recognizable symptoms till the day before death, when the occurrence of pulmonary embolism was suggested. The stomach gave evidence of extensive softening of the mucous membrane, with putrefactive emphysema, although neither condition was associated with the usual favoring circumstances.

Dr. W. F. Whitney showed a specimen of Actinomycosis, the first ever exhibited in New England. It occurs in horses, cattle, sheep, etc., and has been frequently observed in Europe. This specimen was from a bull, and was sent to Professor Lyman, of the Harvard Veterinary School, and by him referred to Dr. Whitney. The disease was located on the lower jaw-bone, and was as large as the two fists. The character of the growth is fibrous, and shows large numbers of patches of a yellow color, which contain lime salts, and also masses of the parasitic growth.

Dr. Fritz stated that this disease has been observed in isolated cases in the western part of the United States, but that this is the first case reported in this vicinity. The disease can be communicated to man from the domestic animals. Usually the jaw is the part first attacked, and from this point the disease

may extend to the thorax, spine, and elsewhere. The origin of the disease fungus is not yet definitely known. It has been thought by some to enter the organism by means of defective teeth.

Adjourned at 10:15 o'clock.

FOREIGN CORRESPONDENCE.

LONDON LETTER.

LONDON, Sept. 1884.

The fixtures for the opening of the winter session at the medical schools of the metropolis have, with one exception, been made. The session 1884-85 of the London Hospital will commence on Wednesday, Oct. 18, when the prizes for the past session, and the nursing probationers prizes will be distributed at 8 p. m. by the Lord Mayor. The medical department of King's College will meet on the 1st of October at 4 p. m., when the prizes will be distributed, and an address given by the Rev. H. Wace, principal of King's College. The session both at St. Bartholomew's and Guy's hospitals will commence on the first of October, but for neither has an opening address been announced. At St. Thomas' Hospital Medical School the session will be opened on Wednesday, Oct. 1, when an introductory address will be delivered by Sir Risdon Bennett at 3 p. m. The session of the faculty of medicine at University College will commence with an introductory lecture given by Dr. W. R. Gowers. On the same date the Middlesex Hospital will open with an introductory lecture by Dr. David W. Finlay. After the lecture the prizes awarded during the past summer and winter sessions will be distributed. At St. Mary's Hospital School the session will be opened with an introductory address by Dr. Lees on the 1st of October, and next day at 8:30 p. m., a conversazione will be held in the new school building. In connection with this hospital a new wing, containing seventy additional beds, was opened by her Royal Highness Princess Louise, on the 2nd of last month. The session at Charing Cross will this year open without an introductory address. The West London Hospital Preparatory School of Medicine will have its first session opened some time in October.

Dreading the danger of conveying patients stricken with small-pox and other contagious fevers to their special hospitals, and that public fever ambulances may possibly, during their passage through crowded city streets, tend to distribute infection, Dr. Gayton, the senior medical officer of the Metropolitan Asylum Board, has so perfected the ambulance van that it can no longer even be suspected as a possible centre to circulate infection. Instead of the open glass and wooden louvre shutters as hitherto, the apertures in Dr. Gayton's safety ambulance consist of a double layer of perforated metal enclosing a sufficient layer of suitable absorbent material saturated with an acknowledged germicide. Fresh air is admitted through modified and improved "Tobin" ventilators, of a horn shape with the larger end opening externally,

whilst inside the van the smaller extremity of this air tube is provided with a disinfecting chamber constructed like those of the other apertures or windows of the van. In these improved safety fever ambulances the Metropolitan Asylum Board now judiciously carry their small-pox convalescents from their Hamstead hospital to their river wharf, whence the patients are transported to the hospital ships lying off Purfleet.

Statistics have often been collected to determine the respective popularity of suicide among men and women, among inhabitants of different countries, and of the different means employed. These, however, have only had reference to actual suicides; and a contribution to the literature of the other side of the question, where intending suicides have failed in their purpose, is supplied by the annual report of the Reformatories and Refuge Union, just issued. From this it appears that of all those cases of attempted self-murder dealt with by the Union during 1883, not a single case of the non-effective use of a revolver occurred, which can only signify that firearms are either more fatal or less popular with the wretched class of beings that would leave the world by crime. In the choice of means other than firearms, a curious discrepancy between the behavior of the sexes appears. In the first place, nearly twice as many men as women attempted and failed to take their own lives; of the women, all had been rescued from drowning. Not a single instance is recorded of an abortive attempt at female suicide by poison or the knife. Only three of the men, on the other hand, attempted to drown themselves, while more than half had taken poison. One would have expected, perhaps, that poison would have been at least as popular with women as with men, and that the rougher sex would have taken more violent means. It is a little surprising, too, that men should fail more often than women in their determination to do away with themselves.

Philip Chelham, the oldest Free-Mason of England, and it is supposed in the world, has just died at Southport. He was in his 97th year, and was initiated a Free-Mason in 1811. He had been Past Master of Lodge 322 since 1841. In 1802 he volunteered as Assistant-Surgeon on board His Majesty's ship "Phoebe, and was at Trafalgar, though not in action.

In reference to the resignation of the medical staff of the Northwest London Hospital, which has excited some comment, at the request of the Committee of Management, Sir T. Spencer Wells, Mr. John Marshall, President of the College of Surgeons, and Mr. Ernest Hart, the editor of the *British Medical Journal*, have consented to act as a Committee of Reference, to whom the rules and regulations of the hospital will be submitted with a view of remodeling them, in conference with a deputation from the Committee of Management, on a basis which may be considered satisfactory and likely to meet the views of the profession, as well as those of the Governors.

At a conference held at the Health Exhibition, Mr. Wm. Earsie read a paper on Cremation. He said the general consensus of opinion was in favor of the introduction of the practice. With regard to the only

tangible objection made to cremation, that it might serve as a screen for poisoners, he thought the conditions enforced by the Cremation Society before allowing the use of their crematorium at Woking, would fully meet the case. Dr. Cameron, M.P., after referring to the immense number of persons who are buried without certificates, said that if cremation was legal, Government had no right to interfere in the matter. As to the objection that it would shield crime, he thought that was disposed of by the fact that numbers went to their graves without any certificate of death. Sir Spencer Wells was of opinion that the present style of burying the dead perpetuated disease, and that cremation would be a great boon. Dr. Farquharson, M.P., observed that the growth of opinion upon the subject was very rapid, and as it had been held that cremation was legal, no doubt when the subject again came before Parliament it would meet with more success.

Dr. James Collis Browne died on August 30 at his residence, Mount Albion, St. Lawrence-on-Sea. Dr. Browne was the inventor of chlorodyne. The deceased was about 66 years of age, and was known in the yachting world for his experiments on the construction of yachts on the principle of his well-known Kalafish.

DOMESTIC CORRESPONDENCE.

SOLAR SYSTEM.

Matter, besides possessing its qualities and properties, exists in the solid, liquid, gaseous and fourth or *single atom* states. The sun emits a compound ray of carbon and hydrogen in this state not in direct rays but in the form of a slightly-spiral shaped figure eight, whose outward and downward rays pass between the orbits of Saturn and Uranus onwards and upwards, lapping over and around the planets of Neptune and Uranus, causing the retrograde motion of both planets and satellites when they again dip downwards and homewards toward the sun, thus forming one vast globe of light and heat, the matter of which is not cast into space, but returns, carrying with it the cosmic matter of other worlds as food for the *strata* of *chlorine gas* enveloping the sun, by which it is burned, causing *light*. The hydrogen is the reflecting ray and *reflects* the sun's light in daytime as it does that of the moon, planets and stars at night, as well as the cosmic matter revealed by the spectroscope. The carbon ray is the dynamic, for I hold that *all force*, from the *vis-nervosa* of the most insignificant insect to the most powerful steam engine, is *carbon*, and that this carbon may be either positive or negative potential and when *Kinitic* is *heat*. Thus the sun's rays are not the *direct* luminous particles of Newton or the stagnant ethereal fluid of more recent philosophers. Tides are not the result of the sun or moon's *attraction*, but the rays absorbed by the moon relieve the pressure on the earth's surface the width of its track, when, pressure on all other sides being equal, the liquid matter is elevated as seen in new and full moons, the direct and returning rays in decussating

each other leave a triangular space on both the eastern and western horizon, over which the pressure is not equal to the surrounding, and causes the daily tides. It will be seen on a study of these spiral-shaped figure eight rays that at the equinox the direct and returning rays are equal in pressure over an equal area of the planets' surface, and by their spiral curvature give the inclination to the planets' axis, their diurnal revolution and gradual rotation of the four seasons during which the direct are not equal to the return rays, and in this preponderance of force the planets are gradually pushed toward the sun as on the 21st of December, where the rays again battle for the supremacy, when during the preponderance of the direct rays the planets are again repulsed to the other extreme, as on the 21st of June, all of which I hold to be the result of the force of the direct and returning rays and *not* the mythical law of gravitation.

BOOK REVIEWS.

THE FORMATION OF POISONS BY MICRO-ORGANISMS.

A biological study of the germ theory of disease. By G. V. BLACK, M.D., D.D.S. Published by P. Blackiston, Son & Co., Philadelphia.

This little book of 170 pages requires in this journal only mention of the topics discussed by it, as the article by Dr. Black published in number eleven of vol. iii, has already given the gist of the most original portion, and in regard to it the readers can judge for themselves.

The first half of the book gives a historical review of the germ theory of disease. It describes each important discovery and the methods of research adopted by each investigator. The last portion has been presented to our readers in abstract in the paper read by Dr. Black before the section on Practical Medicine and Materia Medica of the American Medical Association.

In the book before us four chapters or lectures are devoted to the consideration of the formation of poisons by micro-organisms. The first two treat of digestion and molecular changes incident to vitality; the third of the waste products thus developed and of their nature; the fourth of the poisonous nature of the waste products of bacterial growth. A short appendix is devoted to dental caries.

FIFTH ANNUAL REPORT OF THE STATE BOARD OF HEALTH OF ILLINOIS. 1883. Cloth, 633 pages.

This report contains: Abstract of proceedings at the meetings during the year 1882; medical laws and institutions of the United States and Canada; small-pox epidemic, 1880-82; vaccination in Illinois; Proceedings of the Sanitary Council of the Mississippi Valley; mortality statistics, and many other matters collateral to these general topics.

Several minor points are worthy of note. In this report the value of the immigrant inspection service of the National Board of Health is clearly demonstrated. The questions used for the examination of

candidates for licenses by the State Board, clearly show the impropriety of such examinations being conducted by other than practical teachers in medical science. In justification of this criticism we quote the following:

What chemical elements are contained in pure grape sugar not found in cane sugar? A catch question and not justifiable in an examination. Give the therapeutic uses and applications of aqua *fluvialis* or *fontana*? These terms are not in general medical use. We will suggest answers to the following questions: What is meant by "a qualified prognosis?" Ans. A confession of ignorance. How would you recognize the cancerous cachexia? Ans. By the diagnosis of cancer in an anæmic patient. When are mammary abscesses salutary? Ans. Never. What are the chief causes of an excessive mortality and their remedies? Ans. War, pestilence and famine. The remedies are chiefly prophylactic—Statesmanship, properly enforced sanitary regulations, and good crops. What precautions—other than for the safety of the subject—would you observe in the exhibition of an anæsthetic, and why? I should place my property in my wife's name to avoid the possibility of a suit for malpractice.

w.

MINUTES OF THE SIXTEENTH ANNUAL SESSION OF THE NEBRASKA STATE MEDICAL SOCIETY, held at Omaha, Nebraska, May 13 and 14, 1884. Cloth, 357 pages.

Judging from the official report of the proceedings this must have been a spirited and interesting meeting.

It is to be regretted by the profession at large that Dr. James Carter's vigorous paper, the report of progress in practical medicine, pathology and special therapeutics, was cut by striking out his remarks on the ethics of the doctors of Omaha, for the free discussion of all questions of ethics is the best mode of maintaining the purity of the profession.

The numerous cases reported and the free expression of opinion on the part of practitioners gives the proceedings their chief value as medical literature.

TRANSACTIONS OF THE MEDICAL ASSOCIATION OF THE STATE OF MISSOURI at its Twenty-sixth Annual Session, held at Jefferson City, Mo., May 15, 16 and 17, 1883. Paper, 262 pages.

Among the minutes we observe a resolution setting forth the benefits of a National Board of Health to the States in the valley of the Mississippi, and requesting the representatives in Congress from that State to secure the continuance of said Board.

The essays and discussions occupy over 200 pages of the volume. There are scattered through the whole many interesting papers and medical and surgical facts. We may be pardoned for calling special attention to the following:

The Elastic Ligature, Jequirity Ophthalmia, Glaucoma, Report on a case of Rhinoplasty, Electricity in Skin Diseases, Therapeutics of Ergot, etc., in the Reduction of Spleen and Fibroids, Vaginismus, Volvulus, Injuries of the Head, with Report of Cases.

TRANSACTIONS OF THE MEDICAL SOCIETY OF THE STATE OF TENNESSEE AT ITS FIFTY-FIRST ANNUAL MEETING. Paper, 139 pages.

It is greatly to be hoped that the society will be successful in its attempts to protect the public in that State from the outrages of quacks by appropriate legislation.

MISCELLANEOUS.

NEW INVENTIONS.—A NEW HYPODERMIC CASE.

Dr. J. H. Parkinson thus describes in the *Pacific Medical and Surgical Journal*, what he calls the "Bijou Hypodermic Case," as manufactured to his order by Messrs. Geo. Tiemann & Co., of New York.

The case is of nickel, the metal being of a sufficient thickness to stand a very considerable amount of violence. In shape it follows the rectangular figure, the corners being rounded to prevent its injuring the pocket, or other contents which it may come in contact with. The dimensions are, length, $2\frac{3}{4}$ inches; breadth, $1\frac{3}{8}$ inches; thickness, $\frac{5}{8}$ inch. On opening the box, which is fastened by a strong spring catch, nearest the front is a glass silver-mounted syringe of 20 minims capacity, graded on the piston-rod, the button at the end of which is slightly concave for the thumb. A small silver cap slides on the nozzle of the instrument, and limits the evaporation from the piston. Forty-eight hours' disuse will (in California) in the unprotected syringe as a rule, render the most effective piston unfit for service, without a troublesome preliminary soaking. On each side of the syringe held in small brass clips, are the needles, two in number, one inch in length, very finely made, and of steel. These, like the air cap, slide on the nozzle, and being ground to an accurate fit dispense with the troublesome and complicated screw and leather washer arrangement. At the back of the case is the addition for which he claims credit. In place of the small 2 dr. vial, which usually accompanies this pattern, is a small silver box, two inches in length, $\frac{1}{8}$ inch in breadth, $\frac{7}{32}$ inch deep anteriorly, and $\frac{6}{32}$ inch posteriorly, so as to accommodate itself to the rounded edges of its containing case, the lids of each opening in the same direction. The space internally is divided by small transverse partitions into nine compartments of uniform size. In these compartments are the pellets, the number varying with their bulk, and ranging from five to twelve. The names and strength are printed on a small slip of paper attached to the outside of the lid, and correspond to the space immediately beneath. When the compartments have been filled with the discs, so as to leave a clear space $\frac{1}{8}$ inch between them and the lid, the vacancy is packed with absorbent cotton to prevent friction and consequent disintegration. In the bottom of the case, immediately in front of the pellet box, rests a small silver tube containing wires for the needles, and above it fits a Fisher's iris forceps, which enables the smallest discs to be readily

and easily extracted from their compartments, whilst the round extremity is of service in crushing them to promote their readier solution.

The list of pellets as carried by Dr. Parkinson, comprises $\frac{1}{8}$ gr. morph.; $\frac{1}{6}$ gr. morph., with $\frac{1}{180}$ atropia; $\frac{1}{4}$ gr. morphia, with $\frac{1}{150}$ atropia; $\frac{1}{3}$ gr. morph., with $\frac{1}{120}$ atropia; $\frac{1}{2}$ gr. morphia, with $\frac{1}{60}$ gr. atropia and $\frac{1}{60}$ gr. strychnia; $\frac{1}{8}$ gr. pilocarpine; $\frac{1}{20}$ gr. apomorphia.

OFFICIAL NOTICE.

ANNUAL DUES from members of the Association—*Five Dollars* per annum—are payable directly to the Treasurer. Such payment entitles them to receive the JOURNAL of the Association for one year.

SUBSCRIPTIONS TO THE JOURNAL from those who are not members should be forwarded to the office of publication, Chicago.

BACK VOLUMES OF THE TRANSACTIONS may be procured, at reduced rates, by addressing the Treasurer.

THE INDEX to the 33 Volumes of Transactions will be forwarded, postpaid, on receipt of *One Dollar* by the Treasurer.

According to a resolution passed May 9, 1884, at the Washington meeting, continuous payment of Annual Dues is required, to retain permanent membership.

RICHARD J. DUNGLISON, M.D.,
Treasurer.

Lock Box 1274, Philadelphia, Pa.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM SEPTEMBER 13, 1884, TO SEPTEMBER 19, 1884.

Caldwell, D. G., Major and Surgeon, granted leave of absence for 1 month and 20 days, to commence about Oct. 15, 1884. (S. O. 95, Hdqrs' Div. of the Mo., Aug. 16, 1884.)

Cronkhite, Henry M., Captain and Assistant-Surgeon, from Dept. of the Platte to Dept. of the Missouri.

Taylor, Arthur W., First Lieutenant and Assistant-Surgeon, from Dept. of the Missouri to Dept. of the Platte. (Par. 1, S. O. 215, A. G. O., Sept. 13, 1884.)

Macauley, C. N. B., First Lieutenant and Assistant-Surgeon, assigned to duty at Ft. Sisseton, D. T. (S. O. 99, Dept. of Dakota, Sept. 6, 1884.)

OFFICIAL LIST OF CHANGES IN MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING SEPTEMBER 20, 1884.

P. A. Surgeon G. E. H. Harmon, Sept. 16, from Navy Yard, Norfolk, to Naval Academy.

P. A. Surgeon W. A. McClurg, Sept. 16, from Naval Academy to Naval Hospital, Philadelphia, Pa.

P. A. Surgeon Philip Leach, Sept. 16, from Hospital, Chelsea, Massachusetts, to the Palos.

Surgeon J. W. Coles, Sept. 16, as member and recorder of Nav. Exam. Board, and to Hospital, Philadelphia.

P. A. Surgeon E. Z. Derr, Sept. 16, to Navy Yard, New York.

Surgeon B. S. Mackie, Sept. 16, from Training ship Jamestown, to member and recorder Nav. Exam. Board.

Med. Inspector D. Knidleberger, Sept. 18, from Hartford, sick.

P. A. Surgeon S. H. Dickson, Sept. 19, permission to leave United States.

Journal of the American Medical Association.

ORIGINAL ARTICLES.

A CONTRIBUTION TO THE RELATIONS OF OVULATION AND MENSTRUATION.

BY A. REEVES JACKSON, A.M., M.D., PROFESSOR OF GYNÆCOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS OF CHICAGO, ETC.

Read in the Section on Obstetrics and Diseases of Women, May, 1884.

MR. CHAIRMAN AND GENTLEMEN.—The aim of all investigation should be the attainment of truth. And, in order that the discussion of any scientific question should be profitable, it is essential that the arguments advanced be based upon known facts. Any process of reasoning without such foundation is presumptuous, if not impertinent. In deference to this plain and just principle I shall abstain from making any assertion, or educating any inference not fairly warranted by the observations of trustworthy investigators.

In the year 1673, De Graaf, a Dutch anatomist, described, in connection with the anatomy of the ovaries the bodies which have since borne his name. They were thought to be the ova of mammalia, and this belief obtained for many years. Sir Edward Home noticed the ruptured follicle during menstruation, but attached no importance to the coincidence.

In 1821 Dr. Power clearly enunciated the doctrine of the periodical ripening and rupture of the follicle at the menstrual period; and the discovery by Baer, in 1827, that the follicle was only the enveloping structure of the ovule and not the ovule itself made the rupture an intelligible and significant fact; and this may therefore be regarded as the birth of what is known as the ovulation theory of menstruation.

Négriér, in 1831, and, following him, Gendrin, Paterson, Barry, Raciborski, Bichoff, Pouchet, and others, furnished additional proofs, based upon anatomical observations, tending to show that menstruation was not only simultaneous with, but dependent upon and in consequence of ovulation. The doctrine seemed so consistent and reasonable, and was apparently so well sustained by the evidence adduced that its general acceptance by physiologists is easily understood. Nevertheless, there have always been some who doubted its correctness, and who con-

sidered the evidences alluded to as insufficient and inconclusive.

These alleged proofs consist (*a*) of observations made post-mortem upon the bodies of women in whom the date of the last menstrual period was known, and (*b*) of the effects following the artificial removal of the ovaries during life; and it is asserted that these observations justify the following propositions, namely:

1. In the human female, at regular periods of about twenty-eight days, a Graafian follicle is ripened and usually bursts, discharging a matured ovule which passes into the Fallopian tube and is transmitted to the uterus.

2. Coincident with, and dependent upon the maturation and extrusion of the ovule, certain changes occur in the mucous membrane of the uterus which result in a sanguineous discharge from that organ.

3. The removal of the ovaries is necessarily followed by a cessation of menstruation.

Certainly, if the facts which have been observed really warranted these conclusions there could be no ground for discussion. But facts are phenomena, and in order that they may lead to true results they must be accurately observed and fairly interpreted. Further, *all* the facts which bear upon a given subject must be taken into account, otherwise the conclusions obtained will almost certainly be fallacious.

I will endeavor to show that these conditions have not been complied with in the discussion of the subject under consideration, and that, if they were, very different results would be obtained. Indeed, it is easily proven that either ovulation or menstruation may occur independently of the other, and that, hence, there is no necessary connection between the two functions.

(*a*) *Ovulation may occur without accompanying menstruation.*—Ovulation is a function of the ovary, and includes the ripening of a Graafian follicle and the discharge of an ovule. The evidences of the process consist in (1) the presence of an enlarged or ruptured follicle; (2) the presence, in the latter, of a blood-clot or corpus luteum; (3) cicatrices marking the seat of former rupture; (4) the occurrence of conception.

Malpighi and Vallisneri long ago observed that developed Graafian follicles are occasionally found in the fully-grown fetus. Ritchie¹ also has demonstrated that in the ovaries of new-born infants and children as early as the sixth year may be found highly vascular Graafian follicles; and that, at the age of fourteen and prior to menstruation, they are found as large as

¹Ovarian Physiology and Pathology. London 1865.

small raisins, filled with their usual transparent granular fluid. These observations have been confirmed by the more recent researches of Grohe, Slavjansky,¹ Sinéty,² Haussmann,³ and others.

Haussmann, whose observations were made upon 84 subjects, asserts that such early development of the follicles as was noticed by Ritchie, takes place in about ten per cent. of all cases.

Of course, ovulation is the necessary condition of impregnation; and it is admitted by all obstetric writers that conception may occur in the absence of menstruation. Our literature contains many instances of girls who have become pregnant prior to the first appearance of the flow; of women who have conceived subsequently to the menopause; and of others in whom pregnancy has occurred during lactation before the reappearance of menstruation.

Rondelet⁴ cites an instance of a woman who was delivered twelve times, and Joubert mentions another who bore eighteen children, neither of the women having ever menstruated. Leishman relates the case of a woman who married at 27, and who menstruated the first time after her eighth labor. St. Germain⁵ tells of one who married at 20, became pregnant in the early months of her married life a few days after menstruation. She subsequently had eleven children, the last in her forty-fifth year, having never menstruated during the entire period of twenty-five years. At the age of 78 she was in good health. Dr. S. T. Gregory⁶ relates the case of a woman whose general health was always good, the mother of seven children, and who had never menstruated, and who had never experienced the usual symptoms preceding or attending menstruation. In a paper read before the New York Journal Association, Dr. Fordyce Barker⁷ related several cases of women who had given birth to large families of children, and yet had never menstruated. In one case which occurred in his own practice, a woman who had menstruated irregularly and scantily previous to marriage, ceased entirely afterwards, and yet gave birth to ten children.

Very many other instances of similar character are on record. Indeed, they are so numerous as to scarcely attract attention.

I am aware that the argument based upon this class of facts is not satisfactory, for it may be justly urged that in many of the cases menstruation might have taken place had it not been prevented by conception. But this objection will hardly stand against another class of cases in which follicles have matured and corpora lutea have formed during pregnancy.

Scanzoni admits that the Graafian follicle enlarges and matures during pregnancy, but he has never found one which had burst. Mayrhofer,⁸ however, has found during pregnancy the freshly formed corpus luteum, and thinks it may be formed monthly during that condition. Slavjansky⁹ has described the state of

the ovaries in a case of extra-uterine gestation. The patient was 24 years old, and had had one child previously. She died from rupture of the left Fallopian tube at three and a half months. Menstruation was suppressed during the pregnancy. The right ovary contained a recent true corpus luteum with all the characteristics strongly marked. Near it was a maturing Graafian follicle. In the left ovary was a cavity, the walls of which corresponded to those of a ripe Graafian follicle. A small prominence was noticed near the thinnest portion of the wall. It was removed on the point of a needle, and found to consist of a mass of epithelial cells, in the midst of which was an ovule. Hence, it was clearly not a cystic degeneration, but a ripe Graafian follicle ready to burst.

Sinéty, too, has made two observations which can only be explained on the theory that ovulation and menstruation are independent processes.

The first of these was reported to the Biological Society of Paris, April 25, 1874.¹ The subject was a woman who had died of phthisis, and who had not menstruated for five months. One ovary contained a ruptured Graafian follicle. The second case was reported to the same society in 1877. The observer described the anatomical characters of the uterus and ovaries of a woman who had never menstruated. She died at the age of 38. With the exception of the absence of the flow, she had presented all the features of puberty from the tenth year. The uterus was externally of normal size, but the cavity was formed almost entirely by that of the neck; the cavity of the body was infantile, as was likewise the mucous membrane. Ovulation, however, had been very active, the ovaries presenting many false corpora lutea.

(b) *Menstruation may occur without accompanying ovulation.*—Inasmuch as the menstrual periods occupy from one-sixth to one-fourth of a woman's lifetime for thirty years; and, further, as Graafian follicles are maturing and rupturing, and corpora lutea are forming and disappearing continually, we should expect that a broken follicle or a corpus luteum in some of its stages would frequently be found coincident with menstruation. Indeed, it could not be otherwise. So that persons who are satisfied of the correctness of the ovulation theory because they find such coincidences, have usually no lack of evidence to sustain their belief. Yet, abundant as such evidence unquestionably is, it sometimes fails; for menstruation frequently occurs without any such simultaneous change in the ovary. From many instances of this character which have been recorded, I select a few for your consideration.

Dr. W. W. Gerhard² presented to the College of Physicians of Philadelphia the uterus and appendages of a multipara, 25 years old, who died of apoplexy during a menstrual period. Although the woman had been the subject of menorrhagia, an examination of the ovaries failed to show any recent ripening or rupture of a follicle. Dr. Stedman³ has reported the case of a married woman, 45 years of age, who died of some pulmonary affection, having

had no symptoms of uterine disease. Her last confinement occurred at thirty-nine, when she had twins. Menstruation was regular almost to the time of death. On examination not a trace of the left ovary was found, but in its place was a thin and simple serous cyst, nearly two and a half inches in diameter. On the other side there was a collection of cysts forming a mass twice the size of an English walnut, upon the surface of which were spread out the flattened, dense, atrophied remains of the ovary.

On December 2, 1876, M. De Sinéty read before the *Société de Biologie* an account of the autopsy of one of Charcot's cases of hysterical hemianæsthesia, and pain in the situation of the ovary of the same side. The patient had begun to menstruate at 13 years, and had menstruated almost regularly since that time. Histological examination showed that there was not a single Graafian follicle arrived at maturity, nor were there any corpora lutea or cicatrices in either ovary. It was evident that no ovules had been expelled from the ovaries for a considerable time. It was, in fact, a case of menstruation without ovulation.

Some of the reported cases of hernia of the ovaries throw valuable light upon this subject. For example, Dr. Alfred Meadows¹ relates the case of a single woman, 23 years of age, who began to menstruate at 15, and continued to do so at regular intervals, with some pain, down to the age of 20, when, after stooping, a swelling suddenly appeared in the right inguinal region, caused, as was learned subsequently, by the herniated ovary. At the menstrual period following this she suffered violent pain of a character different from any she had previously felt; it preceded the discharge; at the same time the tumor was much increased in size. From that time onward, for three years she suffered in a similar manner, the pain being so acute that at every monthly period she was obliged to lie in bed for a week or more. Sometimes the tumor would swell to the size of "two fists," and be exquisitely tender to the touch. She had no suffering during the inter-menstrual period. The tumor was removed. The upper portion, or pedicle, which went through the abdominal ring, was found distended with fluid. This was punctured, and about an ounce of the contents let out. The pedicle was then tied, and the tumor removed. It measured about two inches in diameter, and proved to be the right ovary. It was found, on section, to have undergone remarkable structural change. "Instead of presenting the usual dense, compact appearance, it contained throughout numerous irregularly-shaped spaces, varying in size from a pin's head to half an inch in diameter, and all were filled with the same kind of fluid as flowed from the pedicle. These cells or cysts appeared to communicate with one another, and the whole organ to be infiltrated, as it were, with the fluid in question. There were no proper Graafian vesicles to be seen." No Graafian follicles, no ovules, no ovulation, to account for the great increase in the size of the ovary preceding and during the catamenial period! What is the fair inference? Is it not

that the swelling of the ovary was caused by the pelvic congestion attendant upon the menstrual period?

Dr. Robert Barnes¹ relates a case of a single woman, aged forty-one, who had always enjoyed good health, and in whom the catamenia had occurred punctually, but scantily, and attended by some pain. "She sustained a rupture in the left groin at twenty-four, and has since worn a truss. About three years ago she first observed a second swelling a little below the old rupture. This mass, she asserts, becomes almost twice its usual size at the menstrual periods, and tender and even painful. It continues in this state for a week at least after the disappearance of the catamenia, and then gradually lessens and can be handled without causing pain." April 24, a menstrual period commenced and lasted five days. Another period commenced May 20, and ceased on the 25th. On the 7th of June the tumor was removed by Mr. Pollock. An examination showed that it was an ovary filled with small cysts of varying size, but not a single matured follicle.

In this case, also, we find regularly recurring menstruation with simultaneous swelling and tenderness of the ovary, but without any preceding or accompanying follicular rupture.

I have had three opportunities of examining the ovaries of women who died at or near the menstrual period.

One of these was in the case of a healthy unmarried woman, twenty-eight years of age, who died from an overdose of morphia, taken accidentally. She had menstruated regularly, and a period had ceased four days before death. Both ovaries were normal in structure and size, the right being somewhat larger than the left. It contained several Graafian vesicles scattered throughout the stroma. Two of these were larger than the others, one being about an eighth of an inch in diameter, and the other as large as a small currant. The latter was near the surface and caused a slight projection. The left ovary contained fewer vesicles, but had the indistinct remains of a corpus luteum not less, certainly, than four or five weeks old. A second case was that of a young girl fifteen years old, who died from the effects of a burn. She had commenced menstruating eighteen months before, but the function had been performed regularly only about ten months. A period had ceased twelve days prior to death. Neither ovary contained corpora lutea, nor bore the marks of recent rupture. The largest vesicle, which was about a quarter of an inch in diameter, was found in the left ovary about a sixteenth of an inch from the surface. The third case was also in the person of an unmarried woman, who died of peritonitis three days after an operation for the removal of a cystic kidney. A menstrual period had ceased five days before death. Springing from the right ovary was a thin-walled cyst containing about four ounces of a clear, yellowish, serous fluid. In the left was a ruptured follicle which contained a partially adherent blood-clot as large as a pea, and which seemed five or six days old.

Prof. G. Leopold² has recently made a most valu-

¹ *Amer. Jour. Obstetrics*, etc., vol. vi, p. 231.

² *Amer. Jour. Obstetrics*, Jan., 1882.

² *Archiv f. Gynäkologie*, Bd. XXI, Heft 3, 1883.

able contribution to this subject, based upon an examination of 32 pairs of ovaries which were removed from patients of whom the date of the last menstruation was known. The post-menstrual period varied from one to thirty-five days. Leopold does not consider that his researches, or any others that have yet been made, are sufficient to settle the points in dispute; but they certainly show that the Graafian follicle may rupture at any time without reference to the menstrual period, and that, consequently, there is no necessary temporal connection between the two processes.

The 32 lithographic figures which accompany the paper, and which I here present for your inspection, seem conclusive upon this point,—at least, so far as their number may warrant any conclusion. To illustrate, in figures 1, 4, 5, 11, 14, 15, 18, 21 and 23, are representations of burst follicles, none of them having been broken for more than one to three days, but their relation to the last known menstruation varied from one day to three weeks, being respectively 1, 5, 12, 15, 16, 20 and 21 days. Likewise, there may be seen delineations of large projecting follicles, just ready to burst through their enveloping structures in figures 1, 2, 6, 9, 12, 14, 17, 18, 20, 21, 24, 26, 28 and 30; and these were removed at periods after menstruation all the way from one to 26 days. Figures 22, 23 and 24 show the conditions of the ovaries 21 days after menstruation. If they be compared with each other it will be seen that they have scarcely any feature in common. In one (fig. 22), there is a large typical corpus luteum; in another (fig. 23), there is a recently-burst follicle; and in the third (fig. 24), there are numerous mature superficial follicles. The ovaries depicted in figures 20 and 21 were removed on the 20th day. In the first there is a mature follicle which is ready to burst; in the second there is a burst follicle precisely like the one seen in fig. 1, removed on the first day, and also a large ripe follicle on the point of bursting. The ovaries represented in figures 31 and 32 were removed 35 days after menstruation. In one (c, fig. 31) there is a typical corpus luteum five weeks old, and a recently-ruptured follicle; while in the other (c, fig. 32) there is a corpus luteum ten days old. The ovaries shown in figures 16, 17 and 18 were removed 16 days after a period. In one of them (c, fig. 16), there is a typical corpus luteum, probably 12 days old, and two follicles ready to burst; in fig. 17 there are several mature follicles; and in fig. 18 there is a freshly-broken follicle, and another just ready to burst. In short, there is no single condition of the ovary which corresponds even approximately with the menstrual period; and it would be the merest guessing to select any one of the specimens and assign to it the date to which it belonged.

Lawson Tait, in a paper read before the Midland Medical Society, and published in the *Medical Times* for March, 1884, gives the record of 49 cases of operations for removal of both ovaries, and he rests satisfied that the evidence so far has completely destroyed the ovular theory of menstruation. These cases are as follows:

1. Cases, nine in number, where it was evident that menstruation and ovulation were concurrent.

2. Cases of negative proof against the ovulation theory of menstruation, fifteen in number.

3. Cases, twenty-five in number, affording positive evidence against the theory.

(c) *The removal of the ovaries does not necessarily determine the cessation of menstruation.*—Many persons, who, recognizing the inevitable logic of facts, are willing to admit that menstruation may occur without coincident ovulation, deny its possibility in the absence of the ovaries. This, which was formerly almost the universal belief, is still the prevalent one. It is based upon the fact that, in most cases in which the ovaries have been removed, women who before menstruated regularly have ceased at once, or very soon, and forever.

After ovariectomy became a frequent operation it was noticed that in many instances the ablated organs were so greatly diseased as to make it incredible that they had continued to perform their normal functions; but, inasmuch as one ovary was frequently left, it was not difficult to suppose that it had been doing, and might continue to do the work of both. By and by, however, as double ovariectomy became more common, it was observed that in very many cases there appeared a subsequent bloody flow from the genital organs, recurring with more or less regularity, and persisting for varying periods from a few months to many years. In some of these the discharge was perfectly regular in point of time, was accompanied by the usual symptoms of the menstrual period, and continued to appear until the approach of the ordinary time of the menopause. At first, instances of this character scarcely attracted attention; then, as their number increased, they aroused curiosity; next, they excited wonder; and, finally, inquiry. At first the discharge was regarded as a mere accidental hæmorrhage, dependent, possibly, upon some uterine disease, and its rhythmical character was either not noticed, or thought to be only a causeless coincidence. But the frequency of the cases demanded more earnest consideration, and at length investigation began concerning their significance.

In a paper which I had the honor to publish in the *American Journal of Obstetrics*, in October, 1876, I mentioned a large number of instances in which menstruation continued after removal of both ovaries. Many others of the same kind have been published since. They are no longer uncommon. I present here a few of the more recent that have come to my knowledge. And I beg to have it observed that I do not include any of those cases, so frequently noticed, in which within a short time after ovariectomy a bloody discharge occurs from the genitals, lasting from a few hours to a few days; or those even in which the flow, regular or irregular, is seen for only two or three months; but only such as from their rhythmical character and persistent recurrence seem to possess greater significance.

In the Transactions of the State Medical Society of Michigan for the year 1870, is published an instance of this kind by Prof. E. W. Jenks. The patient was an unmarried woman, aged 30 years. Both

ovaries were removed, for cystic disease, September 15, 1869, ten days after a menstrual period. Eighteen days subsequent to the operation menstrual morbid symptoms manifested themselves, and continued two or three days, although no discharge of blood or mucus appeared. Twenty-eight days later the symptoms indicative of the onset of menstruation returned, this time accompanied by a slight discharge of mucus from the vagina. In four weeks more the *molimen* appeared distinctly, and there was a discharge of mucus tinged with blood. After this there was a regular monthly discharge of blood, lasting the average time of the monthly flow; and this had continued down to the date of the report—June 4, 1870,—nine months after the operation.

MM. Verneuil and Terrier¹ record the case of a woman, 36 years of age, who underwent ovariectomy for multilocular cysts. Both ovaries were removed July 6, 1875. On December 25, following, menstruation appeared, was profuse for four days, and lasted six. It appeared again February 20, was very abundant, and lasted ten days. It then recurred every alternate month until the summer of 1876, then it became regular, once a month, lasting from six to eight days.

At a meeting of the *Société de Biologie*, held December 2, 1876, M. de Sinéty reported the case of a patient who had undergone double ovariectomy, and in whom, a few months afterwards, menstruation had recommenced and recurred at regular intervals.

On October 18, 1881, Billroth² operated on a woman aged 29, who was married at 18, and had five children without any trouble. The sixth pregnancy ended with the expulsion of a decomposing six months' fœtus. Both ovaries were removed, together with portions of the bladder and ileum. Menstruation returned three months after the operation, and continued to be regular, lasting from three to four days.³

Dr. T. A. Emmet reported to the American Gynecological Society⁴ the case of a woman from whom he removed the Fallopian tubes and ovaries at the Woman's Hospital, in New York, eighteen months previously, and who, after a lapse of three months succeeding the operation, had menstruated regularly thirteen times.⁵

In addition to a case reported in the paper referred to, a second one has occurred in my own experience.

Through the courtesy of Dr. Charles H. Venn, of Chicago, I visited Mary S., in January, 1882. She was 21 years of age, unmarried, and had commenced menstruating at 13. On March 12, 1883, I assisted Dr. Venn in performing Battey's operation for intractable dysmenorrhœa. The ovaries seemed in every respect normal. The operation was done twelve days after the cessation of a menstrual period. The next period came duly, but the discharge was scanty and without pain. A second and third period had each a similar history. The fourth, however, was

marked by a great increase in the amount of discharge, and a return of the former pain. Since then menstruation has been entirely regular, very profuse, and attended by great pain, which is only alleviated by hypodermic injections of morphia and chloroform inhalations.

The persistence of a periodical hæmorrhagic discharge after removal of the ovaries is no longer denied, although many are unwilling to consider it as menstruation. Its occurrence has been explained on several more or less reasonable hypotheses.

Thus, it has been urged as a possible explanation that some portion of the ovarian tissue may have been left behind, and that this remaining portion has been sufficient to continue the work of maturing and expelling ovules. Surely, the mind which could rest content with such an explanation would be easily satisfied. In refutation of its force it is only necessary to call attention to the obvious anatomical and physiological difficulties involved in the supposition, and to the fact that no such condition has been shown to exist in any of the cases under consideration.

Again, it has been suggested that supernumerary ovaries might be present, and one or more left behind. Since the occasional existence of accessory ovaries has been demonstrated, I am quite willing to admit that the argument has some weight. But this anomalous condition is extremely rare, and like the former, has not been found present in any one of the reported cases of supposed non-ovarian menstruation.

Biegel¹ states that in 350 post-mortem examinations he found accessory ovaries in eight,—two being in new-born infants. They were situated on the boundary line separating the peritonæum from the serous covering of the ovary, and varied in size from a hemp-seed to a cherry. They consisted of normal ovarian tissue, and some of them were sessile and contained Graafian follicles, although most of them were attached by a slender pedicle, and were in every way rudimentary.²

But the favorite theory in regard to these cases, is that the organism in the course of years becomes so accustomed to the discharge of blood that this still continues although the ovaries be removed; that, in short, the apparent anomaly is explainable on the doctrine of the influence of habit.

I have elsewhere³ taken occasion to expose the fallacy of this argument, and need here only call attention to the fact that in many, if not most of the cases in which menstruation has persisted after removal of the ovaries the so-called habit was actually broken up; it was not a continuance, but a recommencement of the function. This was the fact in five out of the six cases to which reference has been made in this paper. In one, menstruation was suspended for six months, in another "a few months," and in three others three months each—intervals sufficiently long to efface the effect of mere habit, and to show that we must seek for some other more potent impelling force to account for the subsequent resumption of functional regularity. What this motive power is we do not yet know.

¹Annales de Gynécologie, August, 1877.

²Wiener Med. Woch., Nos. 2 and 3.

³The report of this case was made fifteen months after the operation.

⁴Annual meeting, September, 1883.

⁵In a recent letter Dr. Emmet informs the writer that this patient has menstruated regularly eighteen times.

¹Wien. Med. Woch., May 26, 1877.

²Dr. T. G. Thomas observed one case in which he found a third ovary, having removed two, and allowed it to remain.

³Loc. cit., p. 27.

In regard to it I do not desire to offer either opinion or theory. My object has been only to present facts. To my mind, these facts justify at least the following conclusions:

1. Ovulation and menstruation may each occur independently of the other.
2. Ovulation is an irregular but constant function of the ovaries; while menstruation is a rhythmical function of the uterus.
3. Graafian follicles mature and rupture at any time, without any necessary connection with menstruation.
4. Menstruation may persist regularly without interruption, or may temporarily suspend and resume its regularity after the removal of both ovaries.

DISCUSSION.

Dr. Campbell, of Georgia.—Mr. Chairman: You are aware, sir, that the reading of that paper must be very agreeable to myself. You are aware of the subject of my concluding remarks at the meeting of the Gynæcological Society, some months ago, and I am very glad indeed to have such confirmation of the views I presented at that time. I believe, with the distinguished author of that paper, that menstruation and ovulation, although having a relation to each other, so far as cause and effect are concerned, are independent processes inaugurated to act together, but by no means the one dependent on the other. Ordinarily, when we wish to study experimental physiology, we take some lower animal. We have only the analogous results. But in this case, of the human female, we have the experiment performed upon the subject herself; and oöphorectomy has been over and over again performed, and the facts are being rapidly developed that it does not arrest menstruation, that it does not put an end to the uterine processes. In case after case that has come under my observation in which oöphorectomy has been performed, I find that menstruation has fully continued after the removal of the ovary, sometimes more or less disturbed. You will remember in a case mentioned by Dr. Emmett last September, in our discussion, in which both ovaries and Fallopian tubes were removed, the woman had continued to menstruate for thirteen months while under his personal care, and he was informed five months later, when removed, that she was still menstruating.

In a private letter from Dr. Englemann, of Missouri, I received an account of the only case in which he performed double oöphorectomy.

In that case the woman continued to menstruate for three years, without any disturbance of the function whatever. And I do not know why she should not. The egg-making apparatus is there, and has its own supply of blood; the nest-making apparatus is there, and has its own supply of blood; and I see no reason why taking away the egg-making apparatus should interfere with the nest-making apparatus, and menstruation is an accompaniment of nest-making. And I think that the result of experimental physiology, as performed on the subject itself—the woman—by cutting out her ovaries, is establishing the fact that ovulation is not the controlling power; or, in other

words, that menstruation is by no means the expression of ovulation.

In another case that has come under my observation both ovaries were removed, and for over eight months since the operation the menstrual flow has returned, with all the neurotic symptoms that attended it before the operation; and not only that, but an excessive hæmorrhage, in which ergot and every hæmostatic means possible have to be used, or she has an alarming hæmorrhage.

According to my view of menstruation, we have studied it too much in regard to the apparatus. We give too much credit to histology. We do not look to what is the philosophy of menstruation. My view of it is, that a woman at the age of puberty has certain endowments, presents certain developments, general developments occur. The internal and external organs of generation are developed, and with the maturity comes an endowment of blood. For what? To support her and make her grow fast and better? Oh, no; some of this blood is used in developing a vesicle into an ovule, and in conception an ovule into an ovum, the ovum into a fetus, and the fetus into an infant, which, after being nourished by it for nine months is expelled. I know I have now from twelve to eighteen months of absent menstrual blood to account for. During this time it is utilized in lactation to sustain and nourish the separated, but still dependent pensioner until it can masticate its food—when this waste will begin again in a monthly flow, or, more happily the blood becomes utilized in another fecundation, which of course is the most economical way, if she does not use it this way she must waste it in natural or vicarious menstruation, or suffer ill-health or discomfort.

What is menstruation, then, as we have it? A waste of the blood that is given to woman for procreation.

This is the object of the endowment of blood; and the only woman I knew who made perfect use of her blood was one with whose case I am familiar.

This ideal woman told me, "I was married at 17, and never had menstruation afterwards, although I had twelve children." She used her blood and continued to utilize it, until the close of her menstrual life, and in the end she had not one drop of her sinking fund to set down to profit and loss. [Laughter and applause.] She had none of the disturbances attendant upon the change of life; and she had, at last, a dozen healthy men and women to show as the result of her procreative business transactions. [Laughter.]

This, Mr. Chairman, is my theory and philosophy of menstruation, and also my method of studying the process and its phenomena. [Renewed and prolonged applause.]

Dr. Englemann, of Missouri: Mr. Chairman.—As we have been frequently going too far in one direction, (menstruation and ovulation being considered inseparable and dependent upon each other), I think we are going a little too far in the other direction now. The facts are not quite all in, but this is something which will unquestionably be established by facts. There is no theorizing about it upon isolated cases here and there. There are exceptions to every-

thing. These conditions must be established by facts, as far as the facts go to show.

I have examined a large number of menstruating uteri. The ovule bursts upon the first, second or third day of the menstrual flow,—that is, under normal conditions. We have a monthly congestion in the female sexual organs, and ovulation and menstruation are the evidences of that congestion,—coexistent evidences, not one dependent upon the other. There is a flow of blood to those organs. The ovaries show that congestion in one way,—they ripen the ovule. The uterus shows a congestion, if impregnation does not take place, by a discharge of blood. Both functions are performed—side by side—related—on a par—not one dependent upon the other. The congestion of those organs has its purpose in each.

We have isolated cases. Here and there, indeed, we see something peculiar,—one appearing to show that ovulation is not dependent upon menstruation or menstruation upon ovulation. But, as a rule, if one of these functions is disturbed, the other is likely to be. Sometimes one function is disturbed and the other goes on.

But we do not always know the full facts—the case of double oöphorectomy, to which Dr. Campbell has referred, is still more peculiar than I thought it to be. I removed an ovarian tumor, on one side, as large as an ordinary hat, with a large pedicle. The pedicle was cut short. On the other side was another ovarian tumor which I removed, as large as a child's head, and I have that specimen in alcohol. That patient was restored to the best of health; menstruated for three years regularly, and will be confined in a month! [Laughter.] She has both ovaries removed, sir; the one was completely removed, and the other was as large as a child's head. I have it in alcohol, as I have said, and you can see what is left. A bit of the pedicle was left, of course, but nothing in the shape of healthy ovarian tissue at all. I think it is most important that that exists, in order that it should be examined. Here you have both ovaries removed as well as they can be removed in oöphorectomy; and menstruation ensued. When she first wrote me of her condition I was afraid she was doomed. She had borne children before, she knew what it was, but did not suppose such a thing could happen. But the physician who is attending her tells me that it is a normal pregnancy, and that she has but about a month more before confinement.

The Chairman: Do you think that she might have a third ovary.

Dr. Englemann: I have never seen any such a thing; and in the operation, which was a very difficult one (for I removed about thirteen small cysts, at the same time), I went up the abdominal cavity as far as the liver and found nothing unusual. So that I think this is a most striking example, which tells us that when we think that we have certain oöphorectomy, we are not always sure as in the cases of destroyed ovaries, which have been referred to here.

Dr. Robertson, of South Carolina.—Mr. Chairman: I think this is indeed a remarkable case! A woman conceiving without ovaries! [Laughter.] I think this is the most remarkable case recorded in medical

history—that a woman without ovaries has conceived and is about to bring forth! I hope the case will be recorded and reported, and that we shall hereafter hear the final result of a woman without ovaries conceiving and bringing forth! [Renewed laughter.]

Dr. Battey, of Georgia, (being greeted with loud applause)—Mr. Chairman: This question, sir, as is well known, is one that has greatly interested me. I think, sir, the question is one of facts. It is not one that is ever to be settled by theory. It has happened to me, sir, to see more than one hot and furious discussion brought to a very speedy close by a mutual understanding of what the disputants meant by certain terms. When gentlemen misunderstand each other as to the significance of terms, they dispute interminably, and never arrive at a conclusion. Now, I think we have one of those cases here. Insufficient attention has been given to the meaning of the term menstruation. What is the meaning of the term "menstruation?" No definite and satisfactory answer has been made as yet, to my knowledge, to that question. There is, I think, sir, "menstruation" and "pseudo-menstruation," if you will allow those terms. In other words, there is a menstruation which occurs to a married woman of 25, who is putting every second or third year a babe into our world, and then there is a menstruation that occurs to her babe, but four months old. But that is a different menstruation. It has a different purpose. Its results are different. There is a menstruation which occurs to a lady 92 years of age, who changed life at 45 or 48, gone through a long series of quietude and exemption from menstruation, and under the magical touch of electricity from above has again begun to menstruate and menstruated for two years. Is that "menstruation" or "pseudo-menstruation?" Gentlemen, we must understand each other on these points. If the menstruation in the babe at four months old is like the menstruation of the lady of 25 years old, then I will hold the ground with you, that it is a function of little or no significance, and having a cause or no cause as you choose to claim.

Now, what do the facts prove? I cannot give the authorities, but I lay down dogmatically what are the facts! The facts are that the ovaries are not necessary to pseudo-menstruation. The facts are that the Fallopian tubes are not necessary to pseudo-menstruation. The facts are that the uterus is not necessary to pseudo-menstruation. The facts are that the vagina is not necessary to pseudo-menstruation. And the facts are that the vulva is not necessary to pseudo-menstruation. Those are the facts!

Now, then, if I understand my friend, Dr. Campbell, correctly, he laid down the proposition, as he understands it, that cessation of menstruation does not follow upon the extirpation of the ovaries. I go further than my friend, Dr. Campbell. I lay down the fact that sterility does not follow the extirpation of the ovaries.

I had the honor, sir, three years ago, of bringing before the International Medical Congress, at London, a case from my practice, of the extirpation of both ovaries, followed in little less than two years by the birth of a healthy child. That was the first case. I

think, of that kind that has been presented. I thought it was unique, until I came here to-day and find the case that Dr. Englemann has brought before us. I feel comforted, sir, by that case.

But I have a third case, not so strong, perhaps, as these two, but still remarkable. I extirpated an ovarian tumor and dermoid cyst with the left ovary. There was an enlargement at the time of the right ovary, but I did not think it proper to interfere with it. In 12 months' time my patient called my attention to the fact that the right ovary was considerably enlarged. I examined it and found that it was as large as a walnut. I examined her during the succeeding year. It increased in size, and developed beyond the size of a walnut. She begged me to remove it. I said: "No, possibly—who can tell?—possibly that ovary may give you a child yet." It did give her a child, Mr. Chairman. Of course it is true that there was probably some ovarian stroma that was left there.

But, gentlemen, I might take all day up on this subject. I will not consume your valuable time. [Applause.]

Brief remarks were also made by Dr. Healy, of Maryland.

Dr. Jackson, in reply.—Mr. Chairman: The paper really comprehended rather more than was read as you observed. It took up, however, simply the question as regards the temporal relations between ovulation and menstruation. I promised to draw no conclusions that were not clearly justified by facts. These facts are embodied in what some of you have had the opportunity of seeing—in these plates taken from ovaries removed from every woman in whom the date of the last menstrual period was known. There is shown in these plates that there is absolutely no temporal connection at all between the ripening, the bursting of a follicle, with the menstrual flood. These are facts, and they are facts that can be addressed to the eye of any one who will look at them. There are others which, as I say, have been recorded, of which these are simply confirmatory. They have more force, because we are taught more by what we see than by what we hear, and very properly, I think.

Now, with regard to the question of the definition of true and false menstruation. No such distinction has been made by me. I stated in the paper what ovulation was, that it consisted in the ripening and bursting of an ovule. Menstruation I regard as a sanguineous flow, dependent upon the mucous membrane of the uterus, and that may occur absolutely without this ovarian process. Unquestionably that is true; it cannot longer be denied, so that we cannot include in our definition of menstruation, a process dependent upon ovulation, and we cannot declare it a false menstruation because it occurs without the ovaries. To say that it is a false menstruation because a woman is young or old, is simply begging the question.

Dr. Battey.—I would like to ask the gentleman one question. Can this menstruation occur in the absence of the uterus as well as the ovaries?

Dr. Jackson.—I have never known it to do so, but I have seen recorded cases in which there was for a

time a sanguineous flow following the operation of removal of both ovaries and of the uterus above the cervix. Of such cases I think there are a number on record.

Now, if we grant that the definition of menstruation is a regularly-occurring flood, discharged from the mucous membrane of the uterus, then it is true menstruation, in that sense, whether the ovaries be present or not. [Applause]

ON RAILROAD INJURIES OF THE EXTREMITIES OF THE HUMAN BODY, WITH OBSERVATIONS ON THE SITE OF AMPUTATION, AND SUBSEQUENT TREATMENT OF THE STUMP.

BY THEODORE R. VARICK, M.D., MEDICAL DIRECTOR OF,
AND SURGEON TO, ST. FRANCIS' HOSPITAL, AND
SURGEON TO JERSEY CITY CHARITY HOSPITAL,
JERSEY CITY, N. J.

The consideration of severe injuries of the extremities of the human body, the result of railroad accidents, and, indeed, of all crushing blows inflicted by great momentum, is the topic which I have selected for discussion on this occasion.

I shall consider their proximate trauma, also their effects on the heart and great vessels.

For their effects on the nervous system I refer you to the antagonistic works of Erichsen and Page.

Lastly, I shall offer a few observations on the subject of amputations and the after treatment of the stump, also the reports of a few cases bearing on the subject under discussion.

In the good old days of stage-coaching, when the travel, as a rule, was limited to nine inside and three outside including the driver; when the speed of 12 miles an hour was a marvel, an occasional upset seldom resulted in more than a simple fracture, or when compound, scarcely ever comminuted, the offices of the surgeon were rarely called in for any other purpose than to apply splints, to reduce a dislocation, or to administer to sundry contusions.

In this progressive age, the increase of speed and multiplication of travellers are accompanied by increased frequency of accidents, and greater gravity of the traumatisms resulting from derailment, collisions, the coupling of cars, and the running down of unfortunate pedestrians who may not be able to get out of the way.

Owing to the great weight and high rate of speed, injuries inflicted by trains in transit are of the most destructive character, producing comminution of bone and laceration and pulpification of soft parts.

The traumatism is not confined to the immediate part struck, but extends far beyond.

The appearance of the integument is not always a criterion of the condition of the subjacent parts, as there may not be the slightest abrasion or mark of

contusion thereon, yet the underlying muscular and vascular systems may be hopelessly destroyed.

It is a common observation that, concealed under the tegumentary condition above stated, we find rupture of the muscles, the bellies of which are full of ecchymotic patches, and at points so pulpified as to be easily broken down by the fingers.

The inquiry naturally arises as to the "*modus operandi*" by which such results are produced.

It is difficult to imagine a force sufficiently powerful, by direct impact, to produce such a disintegration of the subcutaneous parts, without leaving its impress on the surface, and we are compelled to look elsewhere for the cause.

It is a well recognized fact that a muscle may be ruptured by its own contractile force, especially when taken by surprise, or unprepared for the call made upon it, or when in an unnatural or awkward position when struck.

A case in point has recently come under my observation. I. L. C., aged 54, a strong, heavy, muscular man, while wheeling a bale of hay on a truck, on making a sudden effort for the purpose of ascending an incline, felt, as he supposed, a smart blow on the calf of the left leg, followed by lameness. I saw the case six hours after the occurrence, and found a subcutaneous depression about two inches in extent in its transverse diameter, in the external belly of the gastrocnemius, into which, on pressure, the finger readily sank.

There followed in a few hours extreme ecchymosis of the part.

At the present time (two months after the injury) the lameness has not entirely subsided, and the depression is well marked.

So also the "lawn tennis" leg serves as an illustration of the pathological condition under consideration.

The effect of blows in producing muscular contraction is well illustrated by the tendon patellar reflex contraction of the quadriceps extensor femoris.

A very firm amount of pressure on the ligamentum patellæ, or the tendon immediately above, gradually applied, produces scarcely any action on the part of the extensors of the thigh; but let the same amount of force be applied in a sudden manner, and "up goes your foot."

The condition of ankle clonus is thus described: "If the foot is firmly flexed by pressure on the sole, and the tendo-achillis is tapped briskly, the foot at once undergoes flexion and extension in rapid succession for a considerable number of times. Gowers found the average number of contractions to be a little more than six in a second." "By the aid of the myograph Gowers has ascertained that the commencement of the ankle clonus occurs too soon after the blow upon the tendo-achillis for the impression to travel up to the spinal cord and back to the muscles of the leg. It is therefore concluded that, unlike the knee phenomenon, the foot clonus is produced by the direct stimulation of the muscles both on the front and back of the leg, through suddenly increased tension." Reynolds' System of Medicine, vol. i, p. 987.

In these instances, although the mechanism is different, the effect on the muscular fibres is the same.

A blow upon a muscle held in extreme tension causes violent and repeated contraction, and as in the case where great momentum inflicts the blow, it is fair to assume that rupture of the contracting muscle or its tendon to a greater or less extent may ensue.

In the tendon-reflex and ankle clonus, the joints are left free (except in the latter case when motion is only restricted by manual pressure) to move as the muscles contract; but in the case of railroad injuries, one end of the limb is often held immovable between the rail and car wheel, while the other is fixed by the weight of the body, so that the force of muscular contraction is expended on the muscle itself.

This involuntary contraction in conjunction with the efforts of the victim to free himself, would produce some of the lesions which come under our observation.

Again, the liquids of the human body are confined within strong tegumentary and fascial coverings. Blows of many tons' momentum rupture these envelopes in many places, pulpify and comminute the tissues beneath, and eject the liquids they contain with great force and to great distances. These ejected liquids are sometimes thrown into other tissues, and the blood and lymph are driven back through the larger vessels with the same momentum as that of the blow struck.

The whole vascular system being a series of tubes having a common centre at the heart, this organ on its right side at the time of the blow receives the impulse of venous blood, and should there exist any organic cardiac imperfection a fatal paralysis, commonly known as shock may result. Paralysis from over-distension.

It is fair to assume that the rupture of the vessels of the part when struck a heavy blow, is in reality a fortunate circumstance, so far as the life of the individual is concerned, as in this way a certain portion of the force is expended, for should the whole momentum of the projected current be thrown on the heart, instant death might result.

On the arterial side, the blood flowing toward the part struck is suddenly and forcibly arrested.

This sudden arrest of the circulation is felt by the heart at its systole, producing heart strain, synchronous with the augmented propulsion thither on the venous side.

These forces together produce the results above described.

These results are in proportion to the size of the vessels involved in the injury, or in other words to the proximity to the heart.

After death from direct or primary shock, the heart is found gorged with blood, distended to its utmost capacity, together with general engorgement of the whole venous system.

In view of the tremendous power of the *impinging* force, is not this a reasonable or at least a plausible explanation of the conditions described?

This injected and pulpified condition of the muscular tissue may exist in any part as high up as the point of origin of the muscle.

Even though the soft parts may not present the typical appearance described and seem healthy, yet their vitality may be so far injured at the time as to render their reparation impossible; or the gradual supervention of sub-fascial hæmorrhage higher up in the limb, may by gradually increasing pressure destroy the already weakened circulation of the part.

Sloughing not unfrequently follows when least expected.

The subject of treatment of those cases requiring amputation, has to a certain extent been foreshadowed in the preceding remarks.

In statistics of amputation performed at St. Francis' Hospital, Jersey City, published in *The American Journal of the Medical Sciences*, April, 1881, I use the following language, referring to the damaged condition of the parts above the seat of injury: "a recognition of these facts has led to the practice of giving the seat of injury a 'wide berth,' especially as relates to the lower extremity." "In those cases where the injury extends above the lower third of the leg, the rule is to amputate above the knee, or in other words, put a joint between the seat of injury and the point of amputation, as under these circumstances alone can we be assured of sound tissues at the point of operation."

It has occurred in several cases which have come under my observation where this rule has not been followed, that the operation, although most skilfully performed, has resulted in sloughing of the stump, involving the necessity of reamputation, resection of the bone or death of the patient.

The sloughing involves oftentimes not only the integuments, but also the connective and muscular tissues.

In some cases it has been observed that the muscles slough to a much greater extent than the skin, giving the stump a cupped appearance, with the bone projecting from the centre; the whole resembling an old-fashioned candlestick.

Since the introduction of anæsthetics, shock from operation has been reduced to a minimum, and therefore the removal of a few more inches of the limb is of very little consequence so far as the safety of the individual is concerned; and the perfection reached in the adaptation of artificial limbs amply compensates for the increased shortening.

All these considerations should outweigh the risks of an amputation in the immediate proximity of the injury.

It matters very little as to the method of amputating; each giving practically equally good results.

The subsequent treatment of the patient and manner of dressing the stump is often the determining cause of the favorable or fatal termination of the case.

It has been my practice for many years, after the vessels have been tied, to sponge the surface of the stump with water a little below the boiling point, not only for the purpose of dislodging any coagula that may have formed in the interstices of the tissues, but to stop further oozing.

The flaps should not be brought together until every particle of oozing has ceased, as it is a recognized fact that any extravasation in the cavity of the

stump allowed to remain is one of the most potent factors of *sepsis*, which frequently occurs when this precaution is not observed.

A drainage-tube of sufficient size having been placed in position, the flaps are to be brought together and retained by sutures alone.

A stream of some antiseptic fluid (I have as a rule used Volkmann's solution of thymol) is run through the tube until every trace of color is lost, and the liquid is absolutely clear.

Over all is applied a wad of oakum, which is confined with a roller of sufficient tightness to counteract any spasmodic action of the muscles and give the limb firm support.

The stump is washed out through the drainage-tube twice or thrice a day.

The tube is allowed to remain until all colored discharge has disappeared.

The ends of the tube are left free, in order that the syringing may be done without disturbing the dressing.

The fenestræ in the drainage-tube should be large enough to prevent clogging by the discharges, and the tube itself should be occasionally rotated so as to bring the fenestræ in coaptation with different parts of the wound.

Reliance should not be wholly placed on the tube, as there may be interspaces in the stump which may serve as receptacles for the accumulation of the discharges.

In order to obviate any possibility of such a contingency, it is my practice after washing out the tube, to insert the nozzle of the syringe into the wound alongside of the tube and thoroughly wash out the wound externally to the tube.

One great source of ill success, is using too small a tube. It is better to have one too large than one too small.

In cases where the injury is received above the knee, and the part requires immediate amputation; the stump should invariably be left open, and treated after the method recommended by the late Prof. Jas. R. Wood, of New York.

In open stumps there sometimes exists, especially in muscular subjects, a strong tendency to retraction of the flaps.

This is to be counteracted by the application of extension after Buck's method in cases of fracture of the thigh. The straps are to be applied on the anterior and posterior aspects of the limb, and they are further utilized as granulation progresses, by pinning the two together, thereby approximating the flaps. By this method the dressing may be renewed, and the wound thoroughly cleansed without any inconvenience to the patient.

Injuries of the hand and arm occur most frequently from coupling cars.

These injuries vary in degree from the crushing of a few phalanges, to that of whole upper extremity.

Owing to the greater reparative powers possessed by this part of the economy, we are justified in operating nearer the seat of injury than in the lower extremities. In injuries to the hand, especially, should conservative surgery be carried to its extreme limit.

Injuries to the dorsum of the hand and fingers are less serious than those involving the palm, or palmar aspect of the fingers.

It is my rule, provided the palmar arches are intact, and even one digital artery remains to a finger, to avoid amputation; allowing those hopelessly damaged to slough, and the line of demarcation to form before removing the part affected.

After removing portions manifestly destroyed, such as lifeless parts of fingers attached solely by tendinous and tegumentary connections (and the same remark applies to the toes and foot), the part is immersed in water as hot as can be borne with comfort, and allowed to remain in the bath about half an hour. It is then wrapped in oakum wrung out of warm water, or a hot flaxseed poultice, and the whole enveloped in oil silk.

These baths are repeated at intervals of three hours, until all sloughing ceases and the line of demarcation has formed.

The part is then dressed with bals. fir, and any portion of bone remaining uncovered by soft parts is removed, and the whole allowed to heal by granulation.

By following this plan of treatment, it has been my good fortune to save many a hand and foot which had been condemned as irreparable.

In conclusion, I beg leave to offer the reports of a few cases illustrative of the preceding remarks:

CASE I. B. received a c. c. c. fracture of the leg at the junction of the lower and middle thirds, the result of having been run over by a locomotive and train of cars.

Above the immediate seat of injury there was not the slightest mark to indicate that there was any damage to the subcutaneous soft parts.

Notwithstanding the opposition of two other surgeons, I amputated at the lower third of the thigh.

On dissecting the amputated part, the gastrocnemii were found lacerated and pulped at several points, at which were found extensive extravasations of blood.

Underlying the whole was found a string of coagula extending from the seat of injury to the popliteal space.

The patient made a rapid recovery.

CASE II. Pat. Gilligan, aged 27 years, was admitted to St. Francis' Hospital, Jersey City, Sept. 5, 1875, on account of a c. c. c. fracture of the right leg, at the lower portion of the lower third, having been run over by a train of cars. Amputation was performed at the junction of the lower and middle thirds. The soft parts at this point were apparently sound.

In a few days sloughing of the stump set in to a greater extent in the subcutaneous tissues than in the skin.

The stump ultimately assumed the cup-shaped appearance heretofore described.

The patient finally recovered, and was discharged from the hospital May 27, 1876.

CASE III. Reported by Dr. F. D. Gray, interne to "The Jersey City Charity Hospital."

"On the morning of August 2, 1883, Mark Selor, æt. 35, laborer, was admitted to Charity Hospital,

Jersey City, suffering from the effects of a railroad accident, which occurred several hours previous.

Examination showed that he had sustained a c. c. fracture of the right tibia and fibula about the middle third, also a crushing injury of the right foot. The patient was, however, suffering severely from shock, and the operation (amputation) was postponed till the next day, hoping that his condition would improve. Under the influence of stimulants and nourishment the patient rallied sufficiently to make the operation expedient.

"The point selected for the operation was about two inches below the knee joint. The external wound being quite extensive, and reaching pretty well up toward the knee, it was barely possible to secure sufficient sound tissue to make the flaps (antero-posterior.) In fact, the inner border of the anterior flap was made up in part of the edge of the wound. A drainage-tube was introduced, flaps united throughout with sutures and wrapped in towels wrung out of hot water, then again surrounded by a layer of cotton. The dressing was repeated often enough to keep up the warmth of the stump. Stump washed out three times daily with a 2 per cent. solution of carbolic acid. The patient rallied quite satisfactorily from the immediate effects of the operation, and for eight or ten hours did as well as could be expected. After this he began to grow restless and slightly delirious. On the morning of August 4 (day following the operation) the stump presented a swollen and discolored appearance. Its temperature was lowered, and on pressure it gave the crackling of emphysematous tissue. In short, it had all the appearance of beginning decomposition.

"Stimulants and nourishment together with anodynes were freely administered, but with no effect, as the patient grew rapidly worse, delirium and restlessness increasing, while at the same time he became exceedingly weak. Death occurred about 2 o'clock on the morning of August 5, about 36 hours after the operation.

"Before death the cellular tissue of the stump had become emphysematous from generation of gases, up to the middle of the thigh."

I am indebted to Dr. John D. McGill, surgeon to St. Francis' Hospital, for the reports of the three following cases.

CASE I. Patrick Nicholson, æt. 19, brakeman by occupation, was admitted to St. Francis' Hospital, Nov. 9, 1881, having sustained a c. c. fracture of the bones of the foot. The soft parts above the seat of injury and extending as far as the malleoli were more or less contused and lacerated. Above the malleoli the tissues appeared to have escaped serious injury and were apparently healthy.

Amputation was performed at the lower third of the leg, with long anterior and short posterior flaps. The open method in treatment was adopted. The patient rallied well from the operation.

Forty-eight hours after the operation the anterior flap presented a bluish-yellow tinge at its lower border, and some ecchymosis was observed on the leg above the stump. Twenty-four hours later the stump presented a swollen, unhealthy appearance. A well-

defined slough extended about an inch and a half from the lower border of the anterior flap. A solution of permanganate of potash was applied locally.

Quinine and opium internally. Quinine gr. v every three hours.

Poultices were subsequently applied to the stump and within eight days about one-half of the anterior flap sloughed. Two abscesses were opened in the leg above the stump, and several troublesome sinuses slit up.

After this the patient did well, and was discharged cured January 28, 1882.

In this case, although the tissues at the site of operation were apparently healthy at the time of amputation, subsequent events proved that the limit of injury to the soft parts was considerably higher up in the leg.

CASE 2. William Sire, æt. 27 years, railroad employe, July 26, 1882, sustained a compound fracture below the knee joint.

From the seat of injury to the knee joint the integument was intact, but the underlying tissues crept upon digital pressure. Amputation being decided upon, in view of the doubtful condition of the tissues below the knee, it was determined to operate at the lower third of the thigh.

An examination of the amputated leg disclosed the following:

Seat of injury about the middle of the leg, c. c. fracture caused by the wheel of a railroad car. Skin above the injury intact, but somewhat contused in places.

Muscles were of a bluish-red color. Small dots of blood were entangled in the meshes of the muscular fibres which had a torn, frayed look. That the nerves, arteries and veins had shared injury with the muscles was plainly evident. This condition of the soft tissues extended from the point of direct injury (some six inches below the knee joint) almost to the knee.

In this case it was apparent that had the operation been performed below the knee, owing to the fact that the soft tissues were injured beyond reparation, a disastrous result would have been certain.

As it was, the patient made a somewhat tedious but satisfactory recovery, and was discharged cured Sept. 8, 1882.

CASE 3. Timothy Daly, æt. 20 years, was admitted to St. Francis' Hospital Nov. 3, 1882, having sustained a c. c. fracture of the leg two or three inches above the ankle. The patient was employed as a brakeman on a coal car, had missed his footing and fallen between the cars. Before he could be extricated two or three cars had passed over his leg completely severing the foot. When admitted Daly was suffering severely from shock, skin pale, cold, and clammy, pulse feeble and rapid, lips bluish in color. Owing to the mangled and lacerated condition of the blood-vessels at the site of injury, there was but a small loss of blood. The condition of the patient was such that all operative interference was negatived until reaction should take place. Under the use of stimulants, with artificial heat applied to the extremities, the patient slowly reacted so as to be in condi-

tion to permit amputation about twelve hours after the injury was received.

In this case, as in case 2, owing to the nature of the accident and the evident irreparable injury to the subcutaneous tissues and blood-vessels, it was deemed expedient to operate above the knee. An examination of the amputated leg revealed about the same condition of the muscles and blood-vessels that was noticed in case No. 2, the degree of injuries to the tissues being perhaps a little greater.

Without the occurrence of other incidents worthy of note Daly made a satisfactory recovery, and was discharged cured Jan. 11, 1883.

Many more cases might be quoted did time and space permit.

That the method of treatment advocated has not been barren of results, I report that since August 12, 1879, during my various periods of service at St. Francis' Hospital, I have performed 21 major amputations without a death. All with the exception of two were for c. c. fractures, the result of railroad accidents.

Of these 15 were primary and 6 secondary, which are classified as follows:

Thighs, primary	6,	Secondary 4,	Total.....	10
Leg, primary	3,		Total.....	3
Hip joint,		Secondary 1,	Total.....	1
Shoulder joint, primary	1,		Total.....	1
Arm, primary	2,	Secondary 1,	Total.....	3
Forearm, primary	3,		Total.....	3
				21

In the Jersey City Charity Hospital during the same period I performed 5 major amputations with one death.

All these cases were for c. c. fractures, the result of railroad injuries, viz.:

Thighs, primary	4.
Leg, primary	1.
	—
	5.

The fatal result in one case was due to secondary hæmorrhage, occurring on the fourth day after the operation.

The patient was a broken down tramp, and the hæmorrhage due to sloughing of the stump, opening the femoral artery above the ligature.

Thigh, secondary	1.
Leg, secondary,	1.
Arm, primary	1.
	—
	3.

This gives a total of 29 cases with one death.

Finally the treatment may be epitomized in one sentence, viz.:

Amputate through sound tissues, and keep the stump clean.

The temperature and pulse at this date, May 4, are as follows:

	Temperature.		Pulse.	
	A. M.	P. M.	A. M.	P. M.
Thigh	98 $\frac{3}{4}$	99	76	84
Forearm	98 $\frac{1}{2}$	98 $\frac{1}{2}$	72	80

In both cases union by first intention exists to nearly the entire extent of the wounds.

NOTE.—Since this paper was written I have at the Jersey City Charity Hospital, as the result of railroad accidents, performed two primary amputations, viz: one of the thigh, and one of the forearm. The former on the 27th, and the latter on the 23th ult. Both cases are progressing favorably.

REPORT OF TWO OVARIOTOMIES.

BY W. D. HAMILTON, M.D., COLUMBUS, OHIO.

[Read before the Central Ohio Medical Society, September, 1884.]

CASE I. About the 20th of last February I first saw Mrs. Huldah Hammill, of this city. She gave the following history: Her age was 57. Four years previously she noticed a lump, about as large as a goose-egg, low down in her right side. As it increased in size the uterus sank lower in the pelvis, until finally it lay entirely without her body.

I found the lower extremities and abdominal walls dropsical. The features, which were pinched and anxious, presented the typical "facies ovariana." She suffered mainly from the mechanical inconvenience of carrying a large tumor. The mass, ovoid and symmetrical in shape, gave unequivocal fluctuation. Change of position affected neither its shape nor the line of dullness. Rectal examination revealed a hard mass low down in the pelvis, which was supposed to be made up of small subcysts with thick contents. An operation was advised, and the patient consented.

She was taken to the "Home for the Friendless," where for several days she received a thorough course of baths, catharsis and liquid nourishment. On the morning of March 12 the operation was done, with the assistance of Drs. Lee and Blake. An incision was made five inches in length. A large trocar drew off about twenty-five pounds of colloid fluid. Some of this escaped into the peritoneal cavity, through a ruptured posterior subcyst. Adhesions were found to the omentum and small intestine. The omental adhesions were torn loose and the bleeding points ligated. The intestine was attached to the tumor by a tough band a quarter of an inch long and half an inch thick. One end of this band was strongly incorporated into the wall of the gut; the other was similarly united to the cyst. When torn loose, it carried a small portion of the cyst with it. The adhesive band, still attached to the intestine, was then ligated to check the hæmorrhage. The pedicle, which was long and slender, was tied with the Staffordshire knot, as suggested by Lawson Tait, and divided in the usual manner. The uterus was readily returned to its place in the pelvis. A glass drainage-tube was put into Douglas' cul-de-sac, the cavity washed, and the wound closed with silk. Over this a compress and bandage were applied. The patient rallied from the shock completely, and was very comfortable during the rest of the day. A large amount of serum was discharged through and around the tube over night. The next morning, the 13th, the pulse was 126, the temperature normal; at 6 in the evening, pulse 130, temperature $101\frac{1}{8}$; at 10 o'clock, pulse 121, temperature $100\frac{1}{4}$. At that time she felt so well that she asked permission to get up and walk. She had taken nourishment regularly with relish. On the morning of the next day (the 14th) she complained of pain. There was considerable tympanites. Her suffering increased until the morning of the 15th, when she died, sixty hours after the operation. The

tympanitic distension was enormous. A rectal tube had no effect in relieving this obstinate symptom. Four hourly doses of epsom salts proved inert. The bowel seemed to be paralyzed. Dr. Blake, who made the post-mortem, says that there were indications of some peritonitis; that the pedicle was all right; that where the intestinal adhesion occurred the gut was thickened and sausage-like for two and a half inches.

I suppose that peristalsis had been arrested by the ligature of the intestinal adhesion. There was probably the condition of things described as "hernia littrica," in which a portion of the wall of an intestine becoming constricted, symptoms of obstruction appear. If instead of *ligating*, the part of the gut attached to the tumor had been excised, and its edges sewed together with catgut, her chances of recovery would have been better. It was the hernia that caused the tympanites; the tympanites in turn produced death by exhaustion. The temperature never exceeded $101\frac{1}{2}$. The facts of interest were:—the extreme uterine prolapsus, which completely obliterated the vagina; the hernia, and the great tympanitic distension which it occasioned. The tumor weighed thirty-two pounds. The patient was confirmed in the opium habit.

CASE II. Miss Mary N—, of Newark, Ohio, unmarried, age 32, was well until November, 1883, when from exposure, the menses were interrupted. She was confined to bed a few days with pain. There was some flatulent distension of the bowels. Later, a small, movable lump, as large as a hen's egg, was noticed in the region of the right ovary.

Menstruation was regular, lasting two days instead of a week as before, and with a diminution of discharge while it continued. She came to the city last May to learn whether she had a tumor. She was told that she had, and an operation was advised. Early in July, just after the menses, she entered the "Home." The usual preparatory treatment was enforced for two days. On the tenth of July the operation was done in a cottage built for the purpose, Dr. J. W. Hamilton, Dr. Blake and Mr. C. S. Hamilton acting as assistants.

A cut, $2\frac{3}{4}$ inches long, having been made, a multilocular cyst was exposed, which was found to be free from adhesions. The pedicle was slender and of good length, so that it was easily treated. The cavity was carefully cleansed by sponging, and the wound closed by Hunter's method. A single silver wire suture was passed through all the tissues in the middle of the wound.

Catgut continuous stitches closed the peritonæum and muscular layers, while the superficial structures were supported by silk. Thus the cavity was practically sealed. Antiseptic dressings were applied and remained unchanged for a week. These were such as are now used at the Woman's Hospital in New York.

Iodoform was dusted over the wound, then iodoform gauze, bichloride gauze, absorbent cotton, strips of adhesive plaster, rubber tissue and an abdominal bandage were neatly applied. When upon the eighth day, the dressings were removed, it was found that primary union had occurred. There was a slight trace of pus about the points of insertion of the silk. There was no odor whatever from the wound.

With the exception of a few days' nausea, resulting from the use of morphine, convalescence was uniformly satisfactory. The temperature at no time rose above $100\frac{1}{4}$, nor did the pulse exceed 102. The tumor weighed $7\frac{1}{2}$ pounds. The patient returned to her home about the fortieth day, and continues in perfect health. Success in this case was due largely to the wholesome surroundings and good discipline; she occupied a new cottage, destitute of superfluous furniture, and built upon land that had been drained for years. The air circulated freely beneath it and through it. Absolute quiet was enjoined, and all visitors excluded. Again, the method of closing the wound, which was rendered thoroughly aseptic by appropriate dressings, undoubtedly contributed to the recovery of the patient.

MEDICAL PROGRESS.

MATERIA MEDICA AND THERAPEUTICS.

A TEST FOR THE PURITY OF IODOFORM.—Dr. Bouma, of Leyden, is of the opinion that the symptoms of iodoform poisoning are due to the presence of impurities in the drug used, and in the *Centralbl. f. Chir.* (Glasgow *Med. Jour.*) brings forward striking facts from the practice of several surgeons in proof of this. He holds that no iodoform should be used which has not been tested for impurities, and states that he has not yet seen unfavorable symptoms arise in a case where this rule has been adhered to. The most reliable test is a modification by H. Azema, apothecary to the Leyden Hospital, of one given by most authorities, and consists in shaking up the iodoform with distilled water, filtering, adding to the filtrate an alcoholic solution of nitrate of silver, and allowing this to stand for twenty-four hours. At the end of this time a slight gray deposit will usually be found at the bottom of the test tube; but anything approaching to a black precipitate (reduced silver) indicates that the iodoform is not pure enough to be used.

Dr. Bouma believes, however, that iodoform which has been kept for some time exposed to light and air may cause evil effects, even though this test fails to detect impurities.

MEDICINE.

PLETISMOGRAPHIC EXPERIMENTS ON FEVER AND ON KAIRINE.—Dr. J. B. Queirolo (*Archives Italiennes de Biologie*) in giving the results of his experiments, refers to the existing views as to the essence of the febrile process. We have, among others, the idea that an increase in the production of heat is due to an increase in organic combustion, that it is due to a diminution in the dispersion of the caloric which proceeds from the body; that it is due to extraordinary biochemical processes; and that there is a great difference in the febrile processes according to their nature.

It is generally recognized that the change in the

faculty of dispersing caloric, which the skin has, is of the greatest importance in the production of fever: this has acquired a greater importance to-day since the demonstration of the fact that the retention of heat may of itself cause an increase of temperature, and that in many cases of fever the quantity of heat retained represents the whole of the increase of temperature.

The dispersion of caloric takes place, as is known, through the intervention of the cutaneous circulation; it is then submitted to the influence of the oscillations of this circulation, which are themselves influenced by the functional condition of the vessels. An exact knowledge of the modifications of the peripheral vessels in fever is therefore of great importance. In order to obtain with exactness the oscillations of the cutaneous blood-vessels in fever, Dr. Queirolo has made a series of pletismographic observations in febrile cases. At the same time he studied the modifications produced in the calibre of the cutaneous vessels by kairine, administered in febrile cases. His observations were extended to individuals in a state of health and to those suffering from fever from a variety of causes, such as miasmatic fever, croupal pneumonia, typhoid fever, etc.

The pletismograph was applied to the forearm simultaneously with the thermometer in the axilla and without interruption for a variable length of time, according to the nature of the case, from 4 to 8 hours. All causes which might interfere with the results of the experiment were carefully removed, and the following conclusions were deduced:

As to fever, 1. With the elevation of the febrile temperature there is a constriction of the peripheral vessels.

2. This constriction precedes in time the initial elevation, and the succeeding elevations are themselves preceded by a constriction of the vessels.

3. This constriction is the greater, as the thermic elevation is greater and more rapid.

4. With the decline of the fever there is a dilatation of the peripheral vessels.

5. The dilatation precedes for an appreciable time the decline of the fever.

6. When the decline of the fever is checked the dilatation of the vessels is checked also.

7. These facts are demonstrable in the fever produced by different processes.

As to kairine, 1. Kairine produces a remarkable dilatation of the peripheral vessels in individuals free from fever.

2. In febrile cases kairine lowers the temperature and dilates the vessels.

3. The dilatation of the vessels precedes for some time the lowering of the temperature.

4. When the action of kairine is finished, the fever, in becoming again elevated, is accompanied by a constriction of the vessels.

5. This constriction precedes for some time the thermic elevation.

It is probable that the mechanism by which kairine produces the decline of fever and apyrexia, is, at least in part, the same with that which produces the spontaneous decline of fever and apyrexia.

The mode by which kairine acts upon the cutaneous vessels of individuals in a state of health and in a febrile condition has without doubt a great importance in the genesis of fever.

TREATMENT OF INTESTINAL OBSTRUCTION BY ELECTRICITY.—Bloch, in *Vratch (Jour. de Med. de Paris)*, gives the case of a patient, 24 years of age, who had not had an operation from the bowels for eight days, and presented an enormous enlargement of the abdomen, with vomiting and hiccough. Purgatives and injections were used to no purpose, when electricity was tried by introducing one pole high up in the rectum, and applying the other pole alternately to different parts of the abdomen. Each application was kept up for from ten to twenty minutes; they were repeated ten times, four times at intervals of about three hours during the first day of treatment, and twice during the second day. The hiccough disappeared after the first application; the patient had a stool after the fourth application. Professor V. A. Manassein has frequently used this method with success for a number of years, in cases of habitual constipation resulting from atony of the abdominal walls and muscular coats of the intestine.

APPLICATION OF ELECTRICITY TO AFFECTIONS OF THE STOMACH.—Dr. Apostoli communicated to the Congress at Copenhagen (*Revue Medicale*) his experience with the continued and constant current, applied to the pneumogastric, upon the stomach, to relieve and cure certain nervous affections manifestly allied to hysteria, such as epigastralgia, gastralgia and vomiting. For some time past he has extended his observations to the gastric troubles of pregnancy and of phthisis. All the dyspepsias and all the reflex or purely nervous vomitings seem to him to be controlled by electricity. He believes, moreover, that this remedy is sufficient to render great benefit in other gastric disorders associated with simple (non-cancerous) affections of the stomach. To make its application the most useful, he lays down the following conditions:

1. He advises a simultaneous action on the two pneumogastrics by a double or bi-polar application, which method consists in placing two electrodes of equal size and of small surface at the interior angle of the clavicle, at a point as near as possible to the trunk of the vagus nerve. Each of the poles should stimulate a pneumogastric (the one positively and the other negatively), so that the action of both shall be restricted to a localized surface and prevent a diffusion of the current.

2. The current must be as constant as possible, and all interruptions avoided during its application.

3. The electric intensity must be proportioned to the receptivity of the subject and to the resistance of the affection to be overcome, the medium dose varying from 5 to 10 and if necessary 15 milliamperes, with a facility for increasing or diminishing progressively, according to the indications furnished by the patient.

4. The duration of the application should be, like

the intensity, proportioned to the disease attacked, and the application should not cease until some effect is produced; it should be prolonged until the patient declares that he is better, and not be suspended until a calmative effect is established.

5. Galvanization having rather more of a curative than a preventative action, it will be preferable to make the application during digestion, to combat either dyspepsia or vomiting; therefore the patient is made to eat or drink previous to the application, and the current possesses the property of causing digestion or of arresting impending vomiting.

6. The applications in the beginning should be as frequent as possible, and all digestion should be aided and completed by the galvanization; later, the intervals can be increased in accordance with the amelioration.

7. Every application, if properly made, should be well tolerated and without any consecutive eschar; in order to prevent too much pain and all danger of cauterization, the tampons should be carefully covered with very soft chamois skin, under which should be placed one or two supplementary layers of moist agaric, to concentrate to it a part of the galvanocaustic action. Any battery will answer, provided that it is furnished with a collector that will admit of a grouping two by two, or better one by one. A galvanometer of intensity divided into milliamperes must of necessity be inserted into the circuit.

8. A comparative chemical study of the two processes of galvanization (mono-polar or bi-polar) of the pneumogastric, gives the preference to the latter. The unanimous opinion of all the patients who have been called upon to judge between their relative values, has been that the simultaneous galvanization of the two vagi nerves in the neck (bi-polar) is the most rapidly active and efficacious.

9. In conclusion, the continuous galvanic current, well regulated, and localized, is the medicine for dyspepsia, gastralgia or vomiting. If these symptoms be purely nervous or reflex it exercises an immediate and sovereign action upon them; in all other cases, without supplanting classic therapeutics, it is destined to serve as an active auxiliary.

ON THE DILATATION OF THE STOMACH IN INFANTS.—Dr. J. Comby (*Archives Générales de Médecine*) calls attention to this affection in the following manner:

The dilatation of the stomach, so well studied in the adult, particularly since the washing out of the stomach has come into common use, has been completely neglected, not to say denied, in infants.

Nevertheless, in children more frequently than in adults, the alimentary canal is the source of numerous disorders; it is the axis about which gravitates all the pathology of the new-born child, if we except congenital and hereditary diseases.

The most notable fact accompanying his observations, is that the dilatation of the stomach in infants is habitually associated with rachitis.

This association is not fortuitous, there is between the two affections a relation of cause and effect; digestive troubles precede and predispose to rachitis.

The onset of the disease is insidious and its symptoms are those of a chronic disease.

The physical signs consist in an exaggerated development of the abdomen, of tympanism and of succussion.

The functional symptoms exhibit themselves sometimes in the digestive organs (dyspepsia), sometimes in the nervous system, (convulsions, insomnia), sometimes in the skin (eruptions, urticaria), and sometimes in bronchitis.

The prognosis is serious, because the dilatation may extend into the second stage of childhood, and even to adult life, as shown by several cases.

The unique cause of dilatation of the stomach in infants is bad alimentation; infants that are bottle-fed, that are given solid food prematurely, or that are weaned abruptly, are the ones who present this condition of dilatation of the stomach.

Nevertheless, it has been noted also in infants nursed at the breast, who suckle too freely or too often.

The prophylaxis consists in nourishment by the female breast as far as possible, and the restriction of the amount taken to within reasonable limits.

It is necessary to abolish the bottle, and to deny all feculent and other indigestible substances.

It is necessary to delay the period of weaning and gradually supplement the breast milk by an appropriate diet.

The dilatation once established, it is treated by diet; milk for the new-born; dry food for older children.

Frequently it is necessary to have recourse to washing out the stomach.

A CASE OF CHYLOUS DEPOSIT IN THE ABDOMEN.—Dr. Francis Nickerson, of Lowell, Mass., communicates a curious case of this character to the Massachusetts Medical Society (Medical Communications). The patient was 55 years of age, deaf and dumb, a carpenter or cabinet-maker. His father died of consumption. Height five feet three inches; weight 105 pounds. Fairly healthy in appearance, carriage erect and firm, movements quick and nervous. Figure not muscular, well-formed, with a rather full abdomen. Complexion light, hair white since 17 years of age; near-sighted; one testicle. General health good. On Jan. 15, 1877, was obliged to give up work and go to bed on account of a sudden attack of pain shooting from the lower part of his back directly forward through his abdomen, and accompanied by vomiting. On medical examination a tumor simulating a distended bladder was found. The catheter drew off only a few drops of limpid urine. Aspiration was then resorted to, which resulted in the extraction of about two quarts of milky fluid, with entire relief to the patient. After the aspiration the tumor collapsed to a level with the surface of the abdomen, and in a day or two the patient was about his work, apparently as well as ever. This experience was repeated March 21, Oct. 3, 1877, and July 28, 1878, except that every recurrence of the tumor was preceded by an exacerbation of pain lasting for about three days, while the quantity of fluid diminished so that at the last aspiration scarcely

twenty ounces were withdrawn. Some months after this the patient noticed a partial refilling of the tumor, and a subsequent retrocession thereof. The aggregate amount of fluid aspirated was about five quarts. After the first aspiration up to a year and a half ago he was subject to a dull ache in the lower part of the back, which was easily converted into a severe pain, shooting forward to the site of the tumor above described, by long walks or riding. This pain was also brought on when, having a desire to go to stool, he did not satisfy that desire at once. He had at times, also, some pain in the act of micturition. During the period just mentioned vomiting occurred at various intervals. The matter vomited consisted in the main of the same milky-looking fluid which was taken from the abdomen. Has an aversion to milk and dislikes fat. The pain and vomiting had been growing less marked up to a year ago last March (this paper was read June 11, 1884), when his last attack of vomiting took place while he was at work. This attack was accompanied by a loose discharge from the bowels, in which, as well as in the vomitus, the milky fluid, as he says, reappeared. Ever since this time he has been very well in every way.

A specimen of the fluid withdrawn by the first aspiration was examined by Dr. Nickerson a few hours after its extraction. Its general appearance was that of milk. After standing a few hours it exhibited a soft and generally diffused coagulum. After remaining a week at a temperature ranging from 60° to 68° F. there were no signs of decomposition. Odorless; mawkish taste; reaction alkaline; sp. gr. 1.018. Ether extracted from it largely a clear, yellow fluid, in which, on the addition of nitric acid, an albuminoid precipitate was thrown down. Under the microscope were seen large quantities of molecular granules, fat globules, occasional crystals of cholesterine and granular corpuscles of different sizes, in some of which nuclei were revealed on the addition of acetic acid.

An examination by Prof. Edes, of Boston, confirmed the foregoing, with the addition that the other extract not only precipitated with nitric acid, but also, after being boiled with an alkali, precipitated with acetic acid, which would assimilate it more closely to caseine. No trace of urea or anything like urinary pigment.

In his search for precedents to the foregoing case, the writer refers mainly to Prof. Bussey's published works bearing upon this subject, as being the most complete and satisfactory, but does not find analogous cases in them. He finds three cases in an essay on dropsy by Donald Monroe, Lond., 1865; a case in Percival's essays medical, vol. 1, Lond., 1788; a case by Quincke, *Deutsches Archiv für Klin. Med.*, vol. 16, p. 121; a case reported in this journal (*Jour. AM. MED. ASS'N*, vol. 1, p. 120), as taken from the *Gaz. Med. de Strassbourg*; and a case by Dr. Mastin, *Amer. Med. Weekly*, Louisville, Ky.—all of which suggest the idea that the fluid obtained from this patient was chyle from ruptured lacteals, and that this rupture may have been due to a strain in the abdominal region, possibly on vessels already distended. In only two instances does he find men-

tion made of the aseptic character of the chylous fluid, namely: Quincke's case, in which the fluid extracted by ether remained fourteen days without any change in looks or smell, and Dr. Weaver's case, *Med., Surg. and Pharm. Repository*, Aug., 1814, in which the milky fluid was kept for several weeks without any appearance of decomposition.

The symptom of chylous vomiting finds a single precedent, *New England Jour. Med. and Surg.*, vol. 12, p. 4. As to the symptom of chylous discharge from the bowels, there is only the testimony of the patient himself.

OBSTETRICS AND GYNÆCOLOGY.

A NEW TREATMENT OF PERIMETRITIS BY ELECTRICITY.—Dr. G. Apostoli (*Journal des Connaissances Medicales*) has used this method for the past two years to the exclusion of all other modes of treatment, in a number of cases which have all been benefited to a satisfactory, rapid and permanent cure.

The inflammation of the peri-uterine tissue, designated as perimetritis, or pelvic cellulitis, is very common and one of the most difficult to relieve satisfactorily. Electricity methodically applied gives great relief, either at its commencement in the acute form, to prevent suppuration, relieve pain and abort a commencing phlegmasia; or in its chronic form, to accelerate convalescence and hasten the resorption of an exudation. It can be used either by means of the induced or faradic, and galvanic or continued currents.

The faradic or induced current can be applied by two methods. The first is the old one of placing one pole in the uterine cavity and closing the circuit by placing the other pole on the abdomen above the pubis. The second method is that of placing both poles in the uterus by means of a sound. This latter has the advantage of being more readily applied, less painful, and more active, localizing the action of the current to the uterus, and allowing of a greater degree of intensity to the current. Between the electrical treatment of metritis and perimetritis a distinction should be made. In metritis the faradic current should come from a bobbin provided with a short, thick wire, from which the intensity is as strong as possible and continued from three to five minutes. In perimetritis on the contrary the bobbin should have a long and fine wire, to produce a slight stimulation which should be progressive and prolonged for some time. The rules laid down to aid in the application of this treatment are as follows:

1. Introduce the sound into the uterus as gently as possible, arresting it with the slightest obstruction.

2. The operation should never be painful, the patient should not feel the sound at all, and the current of electricity but very little.

3. In those cases where it is impracticable to introduce the sound into the uterus, there may be substituted for the double uterine faradization, a double vaginal faradization, by electrizing the vagina, one pole being upon the neck of the uterus and the other upon the wall of the vagina.

4. The current should be used at first with but slight intensity,—the writer uses a battery constructed by Gaiffe with two Lèclanche elements.

5. The application should be somewhat extended in time, lasting from five to thirty minutes, generally about 10 to 15, or until the patient declares of her own accord that she feels better.

6. Each application should produce its own benefit immediately; there should be a sensible improvement from the beginning, a greater facility in walking, a diminution of pain, but this relief will not be durable until after several applications.

7. This treatment is indicated even in the acute forms, where the affection can be aborted, if suppuration has not begun, and even then will diminish it considerably.

8. In the subacute and chronic forms it is not necessary to be so careful about regulating the strength of the current, and the intensity can be increased to a degree which would be dangerous in the acute form.

9. It is the simple chronic form where there is neither fever nor painful reaction, that the faradic current of tension can be combined advantageously with the current of quantity, applied for a short period of time to stimulate more briskly the muscular contractility, to increase the circulation, and to produce, as Tripier puts it, a true interstitial massage, to aid in a more active reabsorption of the exudations.

(b) The continued current, applied as an intra-uterine chemical galvanocæstic, may, in the subacute or chronic state, never in the acute, serve as a useful auxiliary to the faradization. It must always be used in small doses, 20 to 40 milliampères, and of short duration, lasting from three to five minutes, it must never be painful, be well supported, and stopped if the patient complains of it.

ELECTRICITY IN LABOR.—Dr. Kilner read a paper before the London Obstetrical Society on the use of induced currents during labor. The effect produced by the current consisted in a diminution of pain, tended to diminish the fatigue, and to prevent post-partum hæmorrhage, render the pulse more regular, increase the frequency and force of uterine contractions, and prevent vomiting. But it did not modify the pain resulting from constricted vulvæ, or that which came from the introduction of an instrument in instrumental delivery. Out of 300 cases, Dr. Kilner had only two of post-partum hæmorrhage. Moreover, the current did not bring on contractions in cases where there was urgent need of them.

When the induction current was used for an hour to an hour and a half, its sedative action was felt, and it did not increase the contractions. In several cases it produced violent and almost continuous contractions. In one case the contraction continued for 15 minutes.

To diminish pain, the induction current is preferable to anæsthetics, as its action can be controlled at will, and it does not cause vomiting. Dr. Kilner has never observed uterine rupture by the contractions, so frequently prolonged and produced by the current.

BACTERIA AS THE CAUSE OF SUPPURATION.—The latest report to the Scientific Grants Committee of the British Medical Association has been made by W. Watson Cheyne on Micrococci in Relation to Wounds, Abscesses and Septic Processes.¹ It is of interest, as although the experiments described were made to test the correctness of the views advanced by Dr. Ogston in regard to the same subject some time ago, they do not agree with his conclusions. Dr. Ogston has affirmed that micrococci are present in all acute abscesses, indeed wherever suppuration is present or imminent except when it is caused by burns or blisters. He also believes that the common micrococci that exist in the intestines are one and the same with the virulent forms that excite inflammation, but as they do not readily grow in oxygen and lose their virulence when grown in it, they do not always excite morbid action. If, however, they are grown in eggs without oxygen they regain their toxic powers. The same micrococci can, under certain circumstances produce septic intoxication, septicæmia, pyæmia, erysipelas, etc.

Whether or not the micrococci found in abscesses and wounds can thus be rendered harmless by the access of oxygen to them is a matter of much interest and importance.

Some years ago Mr. Cheyne published the result of some experiments which he then made in order to ascertain whether micrococci are present in all acute abscesses. He made his tests by cultivating or attempting to cultivate them in meat infusions. He obtained

micrococci in only seven out of thirty-two cases tested. His lack of success he seems now willing to assign to the imperfection of his method and to the lack of the methods of staining since pointed out by Koch.

In the present report he describes his more recent experiments.

They were made, however, with infusions, and before the method of cultivation on solid substances had come into use. In regard to the use of infusions of various kinds as media, Mr. Cheyne makes some very just remarks, which it may be worth while to quote: "My own experience with fluids leads me to think that the risk of contamination in these experiments has been much exaggerated since the introduction of solid cultivation materials, and that there is too great a tendency to underrate and reckon as worthless researches in which fluids alone are employed. No doubt researches with fluid media are much more difficult and laborious than with solid, but with care and judgment excellent work has been and can be done in this way."

The first series of experiments were made with micrococci from an acute abscess of the groin. Streptococci (or chains) were found in the pus, but they did not grow in meat infusion. Two days later micrococci were found, but no chains. This time meat infusion was successfully inoculated. The resulting micrococci were cultivated through several generations, and fluid containing them was injected into rabbits in various parts of the body. Nineteen experiments were made; in fourteen there was no effect produced by the injection; in three there was slight swelling and redness, which passed off; and in two there was found a slight amount of cheesy inflammatory exudate, containing micrococci. These rabbits died of an epidemic disease which was prevalent at the time.

Seven eggs were inoculated with the same infusions, following as nearly as possible the method of Dr. Ogston. In only one of these did the micrococci grow. These were injected into two parts of an animal, without producing any effect.

A second series of experiments was interrupted by the epidemic among the rabbits. The purulent matter was obtained from sinuses which had been scraped and washed out with zinc chloride, after an amputation for carious disease of the ankle. Micrococci were found and cultivated in infusions, which were injected into rabbits without effect. Eggs were also inoculated, but micrococci developed in only one of five trials. They proved innocuous on injection in animals.

¹British Medical Journal, Sept. 20, 1884.

A third set of experiments was made with micrococci obtained from a wound made in an excision of the ankle joint which was treated aseptically and followed an aseptic course. They grew well in meat infusions, but produced no ill effects when injected into animals. They developed better in eggs than had the micrococci in former experiments. Six out of eight eggs were affected. When the micrococci of the eggs were injected into rabbits no injurious effect was noticed. In four cases slight redness followed, but quickly passed off.

Several points of difference are noticed between these experiments and the conclusions arrived at by Dr. Ogston. In the first place, micrococci taken from wounds and abscess proved harmless to animals, whether first grown in infusions or eggs; and therefore cannot be the cause universally of suppuration, as Dr. Ogston asserts.

It appears, secondly, that the growth in eggs away from the air does not contribute to their virulence, nor do they grow as well there as in infusions. Indeed, Mr. Cheyne found that undiluted egg albumen is not a good nidus for the development of micrococci, whether oxygen was admitted to them or not. For when he inoculated eggs that were broken and the albumen exposed to the air, with proper precautions to obtain a pure cultivation if any, he did not succeed in propagating the micrococci.

These experiments we quote more to point a lesson of conservatism than for any other purpose. It is common to-day for many physicians to conclude as soon as bacteria are discovered in connection with a morbid process, that they are its cause. Such a conclusion should be adopted only after most careful experimentation by different persons, only when by repeated trials a disease is shown to occur uniformly after inoculation with bacteria. Mr. Cheyne's experiments may also be regarded as not settling the question both because not sufficiently numerous and on account of the methods of cultivation used, which may be called in question by some, though probably they are as accurate as the dry method. The uniformity of Mr. Cheyne's results makes his conclusions most probable, and at least, throws the question fully open as to the uniform generation of suppuration by bacteria.

MEDICAL SOCIETIES AND THEIR METHODS OF WORK.—There are three legitimate and important objects to be accomplished by the organization and maintenance of medical societies, namely, the mutual interchange of views and facts of clinical experience by which the observations of each become more

nearly the common property of the whole; the planning and execution of special investigations for the development of new facts, and the solving of problems requiring the coöperation of several observers working to the same end; and the cultivation of social intercourse, personal friendships, and the establishment of union and harmony among all those pursuing the same calling.

The first and last of these objects have hitherto chiefly occupied the attention of our numerous society organizations, while the second has attracted but little attention, although of more importance for the promotion of scientific knowledge than both the others. And even in the accomplishment of the first, the time is so far occupied by the reading of papers of which the members have little or no notice beforehand, and consequently can not be well prepared for discussing, that the real interchange of views and the eliciting of facts of individual experience are far more limited than is desirable.

But the time has come when much more of the time of all our medical societies, whether local, State or national; whether general or limited to some specialty, should be spent in devising well considered lines of investigation, directly calculated, on the one hand to induce a more general practice of recording facts and cases by all practitioners, and on the other, to institute original experimental investigation directly calculated to develop such facts as would reliably advance our knowledge in some department of the wide field of medical science and art. Some beginnings have been made in this direction, as seen in the work of the Standing Committee on the relations of atmospheric conditions to the prevalence of acute diseases, of the American Medical Association; in the work of the Committee of the British Medical Association on the collective investigation of disease, and in here and there items of special investigations in local societies. Of these latter the Suffolk District Society of Massachusetts affords one of the best examples in its work of the past year. Its investigations on the subject of contamination of waters by sewerage, the best practical methods of epuration of the same, the quality of the milk supplied to the people of Boston and the best method of transporting the same from the producer to the consumer, indicate an activity, and a considerate practical direction to its work that is worthy of imitation.

AMERICAN GYNÆCOLOGICAL SOCIETY.—The ninth annual meeting of this Society commenced in the Palmer House, of this city, on Tuesday morning, Dr.

Albert A. Smith, of Philadelphia, President, in the chair. The number of members in attendance was not large, but the time was occupied through the day in the reading of several important papers, and the discussion of the questions to which they gave rise. In the evening the members of the Society were entertained at an elegant banquet given by the Chicago Gynæcological Society. Dr. A. Reeves Jackson presided at the table, and the occasion appeared to be highly enjoyed by all present. We expect a full report of the proceedings during the several sessions in time for the next number of the JOURNAL.

SOCIETY PROCEEDINGS.

SUFFOLK DISTRICT MEDICAL SOCIETY.

SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.

ALBERT N. BLODGETT, M.D., SECRETARY.

June 7, 1884. The meeting was called to order at eight o'clock, Dr. E. M. Buckingham in the chair.

After presentation of a summary of the report of the previous regular and special meetings of the Section the reports of committees were called for.

The Secretary announced that the committee appointed at an earlier meeting to take into consideration the question of the milk supply of Boston had prepared a partial report, which was in the hands of the Secretary, who, by request, read as follows:

PRELIMINARY REPORT OF THE COMMITTEE APPOINTED TO TAKE INTO CONSIDERATION THE MILK SUPPLY OF BOSTON.

The committee appointed at the meeting of the Section on Feb. 27, 1884, "whose duty it shall be to report upon the whole subject of the providing of milk for Boston, and suggest the means of obtaining it pure for its citizens," have attended to that duty, and have held several meetings, at which all, or nearly all, the members of the committee have been present. They have visited the section of country from whence most of the milk supply of Boston is derived, and have endeavored to ascertain the manner in which it is treated at the farm where it is produced, and have followed its history as nearly as possible until it is delivered in the city. The committee has on several occasions had the benefit of the advice and counsel of those interested in the purity of our milk supply, and has considered the question of a change in the present methods of transportation and delivery, and has carefully examined several forms of cans for the transportation and delivery of milk, and has also made careful study and examination of many samples of milk obtained from different sources representing some of the various grades of milk sold for consumption. The committee has been so fortunate as to receive the of-

fer of every facility for the continuance of its work from the office of the State Board of Health, as well as from that of the City Board of Health, and has been promised the assistance of the Milk Inspector of Boston in its efforts to devise a means for improving the quality of milk supplied to the people.

A work of such magnitude as that which has been intrusted to your committee could not be concluded in the limited time since the appointment of the committee, and it is desired at this time to present a preliminary report of progress with the suggestion that the committee be continued and allowed to prosecute its labors, and report to the Section at some future meeting of the Society.

The labor intrusted to the committee seemed legitimately to commence at the source of supply, the farmer's stable, where the cows are housed, and consequently one member of the committee has made a personal inspection of the farms and dairies in several localities. The investigation was made in four towns in Worcester county. It is the usual custom of the farmers after milking one or more cows to strain the milk into the eight-and-a-half-quart cans furnished by the contractors, which, when full, are set in cellars during the winter months, and in warm weather lowered in springs, wells, or put in tubs supplied with running water. A can partially filled in the morning is mixed with enough evening milk, after it is cooled, to fill the can. A letter or mark with chalk on each stopper indicates from whose farm the milk is obtained. Just before the milk is called for by the collector the stoppers are put in place. During the evening it is transported to the railroad station and put on board cars especially designed for this purpose. In the winter a small stove is used to prevent freezing. In the summer the cans are iced with great care. The milk arrives in Boston early the next morning, and is delivered to the distributors during the day.

Many farmers are careless in cooling the milk, and as a result it is returned sour by the contractors. This is nearly a total loss to the farmer as he receives no pay, and often the cream has been removed.

Many of the cows were very dirty, their hind flanks were covered with manure an inch or more thick, which must often drop into the pail, and is, no doubt, the deposit so frequently found in the consumer's supply. The contractors often complain to the farmers for not being more careful in this regard.

If a farmer waters the milk it is immediately returned, and to every man who comes to the car it is whispered very privately that Mr. W. has been caught, and a "request not to say anything about it." In a few days all in the town know it, and if the man chances to be a church member his punishment seems to be adequate.

None but "grade" cows are kept for supplying "railroad" milk, and their food is such as to improve the quantity rather than the quality. In the winter English hay, shorts, cotton-seed meal, roots, and occasionally corn meal are fed. In the summer grass and corn fodder.

But very few of the farmers have silos.

The prime defect in the present system of milk

supply appears to your committee to consist mainly of two factors, namely, the employment of such a kind of can as admits of being opened without detection, whereby the milk may be variously manipulated, in the form of addition or subtraction, or both, and which gives to the consumer a deteriorated quality of milk, as the analyses of the State Board of Health conclusively show, the proportion of specimens which were found to be adulterated amounting to 90 per cent.

The other defect in the present system of supply is the habit, now almost universal, of keeping the milk received on one day until the next morning, thereby adding a considerable amount of time, sometimes as much as twenty-four hours, to the age of the milk when it finally reaches the consumer. This is a disadvantage in another respect, as it exposes the milk to whatever deleterious influences or infective processes may be contained in the place of storage, where it is necessarily exposed to the air in the process of mixing and putting into small cans for family service. The temptation to adulteration which here exists should not be forgotten, and it is at this part of its journey that by far the larger part of all adulteration is committed.

Any practical method of delivery to consumers immediately on the arrival of the milk in the city depots, and of avoidance of the process of mixing and recanning, would seem to offer a remedy for these two greatest dangers to which milk is exposed.

It might be said that it would only be inviting the farmer to adulterate the milk instead of allowing the retail milkmen to do so, but this would be less likely to occur, as any particular dairy could be easily identified, which is not possible under the present system.

Another disadvantage attending the prolonged keeping of milk, arises from the necessity of adding some chemical substance to prevent fermentation and souring. This addition may not be directly injurious, but it is an adulteration, and the addition of any foreign substance to milk should be condemned. It is also to be feared that the additions made to milk, particularly that sold in stores, are not always harmless.

The committee has examined several varieties of cans and glass jars for the transportation of milk from the source of supply. The system of glass jars has never been practically tried in this city, but from places where this system has been introduced it was learned that the loss by breakage is very considerable, amounting, on an average, to a complete renewal of the entire stock of jars once in three months. Your committee is unable to find any place where this system has long remained in operation except in the case of certain private individuals who carry on a limited business in milk, and charge an unusual price. This system seems entirely unsuited to the requirements of a general milk supply, and your committee cannot recommend it. A can holding sixty quarts was brought to the attention of your committee, and illustrated by a model. This can is of steel, made without solder, and is of strong and durable character. It is provided with a large opening for cleansing purposes, and may thus always be thoroughly freed from impurities before receiving milk. This

can is to be filled at the farm of supply, and when full a cover is placed in the opening and securely fastened and sealed with lead so that it is thereafter impossible to obtain access to the interior of the can until the seal is removed by an authorized person. In this can the milk is cooled and transported to Boston in the same manner as is now done with the ordinary can. The milk can be withdrawn as required, only by inverting the can, when it flows freely from a valve-opening, which closes automatically the instant the milk ceases to flow through it. It is practically impossible to tamper with the contents of this can after the cover is adjusted, and efforts to introduce water by the orifice for pouring out the milk were not successful. Air is allowed to enter the can to replace the milk as this is poured out by means of a second guarded opening, through which it is impossible to introduce any foreign substance whatever. The advantages claimed for this can are its imperishable nature, its ease of cleansing, its perfect protection of the milk from manipulation or contamination, the thorough mixing of the milk at every withdrawal by the necessary inversion of the can, the impossibility of removing the cream from the milk, and a saving of several hours of time in the age of the milk when it is delivered to the consumer.

The objection was raised that the adoption of this can would preclude the possibility of obtaining the milk of one cow separately for the use of infants or invalids. The committee considered this point carefully, and came to the conclusion that this constituted no objection inasmuch as the milk now furnished to the people of Boston is almost invariably brought to the city in large tin cans, and is put into service cans for family use at the milk sheds after its arrival in Boston. It is, therefore, practically impossible to secure the milk from one single cow for any purposes whatever. Your committee also came to the conclusion that one cow's milk presented no advantage to recommend it above the mixed milk from a dairy of several cows. Indeed the advantage seemed to be on the side of the mixed milk, as this constitutes a protection to a certain extent against the perturbations of health and of the quality of milk supplied by any one animal.

Your committee also desires to point out the fact that the majority of people taking milk from milkmen are not acquainted with the varying character of this secretion at different times of year and under different conditions of health in the cow.

During the months when the cows are fed on hay the milk is generally much paler and somewhat thinner than when the cows are at pasture. By demanding at all seasons of the year a quality in milk which exists in it at only one season the people unconsciously encourage adulteration of milk, and thus defeat their own best interests.

With the hope of placing a supply of pure and wholesome milk within the reach of the inhabitants of the poorer parts of the city, and especially of sick children and invalids, your committee would suggest the establishment of "milk stations" in accessible and well-known localities, possibly in connection with the district dispensary establishments, or at certain

drug stores, to which the poorer people, and particularly the sick, might be referred by physicians or others, and by means of a ticket or voucher obtain a supply of pure milk at a cost within their means, instead of buying, as is now too often the case, milk which has been diluted sometimes to the extent of 60 per cent.

It is in the poorer parts of the city that the greater proportion of adulterated milk is to be looked for, and therefore it forms the supply of those who most need a pure and wholesome article. There can be but little doubt that the rate of mortality among children might be materially affected if it were possible to furnish pure and fresh milk to the inhabitants. The "depots," as suggested above, seem to your committee to be a step in this direction.

Signed by the committee.

HENRY O. MARCY, *Chairman*,
HENRY J. BARNES,
E. W. CUSHING,
LLOYD F. ABBOTT,
ALBERT N. BLODGETT, *Secretary*.

The report of the committee was accepted, and, in accordance with the suggestions contained in the paper, the committee was continued, in order that its labors may be prosecuted still further, and the utmost benefit derived from the thorough investigation of an important branch of domestic supply, upon which the lives and health of a large proportion of our population are more or less directly dependent.

The hour being already somewhat late it was voted that the reading of the papers appointed for this evening, by Dr. P. C. Knapp, on "Observations on the Cutaneous and Tendon Reflexes;" and Dr. F. Minot, on "Three Cases of Distended Gall-Bladder," be postponed to the next meeting. The readers having expressed their approval of this arrangement, and there being no further business before the Section, it was voted to adjourn, at 9:15 o'clock.

CHICAGO MEDICAL SOCIETY.

The regular semi-monthly meeting of this Society was held in Parlor 44, Grand Pacific Hotel, on Monday evening, September 15, at 8 o'clock. The President, Dr. D. A. K. Steele, in the chair. Dr. L. H. Montgomery, Secretary.

Dr. C. W. Earle read a brief paper on "Congenital Malformation of the Stomach," reciting the case of an infant that lived twelve days. Its life was sustained by very minute quantities of nourishment, he, during the time, being unable to diagnose the ailment. And it was only by permission of friends that an autopsy was made, when the trouble was ascertained. It consisted in there being no continuation from the stomach through the pylorus to the intestine, nor was there any communication whatever between the stomach and duodenum. The child's biliary secretion seemed healthy enough and was passed from the bowels, as well as the meconium.

The speaker also read a report of a case of bony tumor of the female pelvis and exhibited the specimens of both the above cases. The latter's weight was 3½ pounds. Both of which were believed to be

rarely met with. They were accordingly, but informally discussed.

The Secretary, Dr. Liston H. Montgomery, presented the following resolutions and moved their adoption:

WHEREAS, From present reports and indications in foreign countries, cholera and yellow fever (both pestilential diseases) prevail, and as the latter especially is always assuming a threatening attitude toward us, and is not conducive to our national prosperity, nor to public health, and should, if possible, be averted with earnest and efficient sanitary measures, and

WHEREAS, Cholera may make its appearance on this continent ere another twelve months should elapse, and should likewise, if possible, be averted or restricted to the narrowest limits, therefore,

Resolved, That it is the sense of the Chicago Medical Society to have that department of the government relating to public health, recognize the services of able sanitarians who constitute the National Board of Health, for the purpose of coöperating with municipal, State, and other organizations of a similar kind, and that a committee of seven (7) members of this Society be appointed by the Chair to draft suitable resolutions in behalf of said National Board.

Resolved, Furthermore, that this committee present said resolutions to the Congress of the United States, memorializing that body to make a sufficient appropriation for the purpose of said Board for scientific investigation in the prevention and restriction of epidemic, preventable and pestilential diseases.

We believe this action should be promptly taken at the coming session of our national legislature, and that a thorough sanitary organization of the nation should be recognized, and with it absolute enforcement of the best means for the protection of her citizens, and the improvement of our inter-State sanitary condition.

The mover of the resolutions stated that, inasmuch as they had been published on the postal card announcements, every officer and member of the Society, which consisted of about 276 members, had (he presumed) become familiar with the object aimed at in presenting them. He desired a full discussion, and to hear the views of each member present, if time permitted. If they are adopted, broad-minded, philanthropic men in official life will see their value when the first case of cholera appears on our borders, which we trust may never occur, but which is by no means impossible by next June. Then we will wish that thorough vigilance and a more thorough organization had taken place. The time, therefore, for more effective measures to be taken, is to begin now—months before the probable advent of the disease. It seems to me that the scientific, sanitary and commercial interests of the nation all demand the perpetuation of its National Board of Health. The resolutions were promptly seconded by Drs. R. E. Starkweather and H. J. Reynolds, and after a lengthy discussion, which was participated in by many members, each of whom favored the object of the resolutions, the motion to adopt *unanimously prevailed*.

The President stated that he wished a little time to

consider the appointment of so important a committee as is called for by the resolutions.

Dr. Edmund Andrews offered the following motion, which was duly seconded by Dr. C. E. Webster: "That this Society hereby express its thanks to Dr. Vincent L. Hurlbut for the gift of a very valuable collection of books and pamphlets, consisting of 300 volumes, to the Library Committee of the Society, for the Chicago Public Library." In behalf of the Library Committee, the speaker continued by stating that there are on the shelves of the city Library 1,200 volumes for medical reference. The Library authorities have bound, at their own expense, 75 volumes. The report was considered a flattering one, especially when the project to establish a medical department by this Society, to the Public Library was inaugurated so recently as last spring. The closing remarks of Dr. Andrews elicited a hearty and unanimous vote of thanks for Dr. Hurlbut.

The chair announced the following gentlemen to constitute the committee as provided for in the resolutions previously adopted: Dr. O. C. DeWolf, Dr. R. E. Starkweather, Dr. L. H. Montgomery, Dr. John Bartlett, Dr. J. H. Etheridge, Dr. A. R. Jackson, Dr. J. H. Hollister.

Dr. H. A. Johnson asked to be excused from serving on the committee, for the reason that he was the representative from Illinois on the National Board of Health, his resignation not having been accepted by the President of the United States. He took pleasure in extending an invitation to the committee to call upon him at his library, and he would render to its members all the assistance he could, and impart any information he had received from his experience as a member of the National Board of Health. His library also was at the disposal of the committee.

Dr. J. H. Etheridge then moved that the committee be authorized to present their resolutions to the Society for a final consideration, and then submit them to Congress.

The motion was carried, and the Society adjourned.

L. H. M.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

The regular annual meeting of this Society, which had been called to commence its sittings in the Representatives' Hall of the State House in Springfield, Ill., at 10 o'clock A. M., of Sept. 23, 1884, did not organize for business until 2 P. M., on account of the copious rain and the small number in attendance at the morning hour. At 2 P. M., the Society was called to order by the President, Dr. B. M. Griffith, of Springfield. An opening prayer was made by Rev. R. O. Post, and in the absence of Gov. Hamilton, Judge Matheny welcomed the members of the Society in a brief and appropriate address. This was responded to in equally appropriate terms by Dr. Joseph Eastman, of Indianapolis. These formalities having been completed, Dr. Wm. A. Byrd, of Quincy, Ill., read an interesting paper on the nature of "Gall-Stones," and the most effectual means of prevention, and of treatment after they are already

formed. After some discussion, the Society adjourned until 7:30 P. M., when on reassembling, the President, Dr. B. M. Griffith, delivered the annual address. He pointed out with clearness the objects of the Society, the best methods of securing them, and the more important relations of the profession to the community. After the address, the members were cordially and elegantly entertained at the residences of Drs. Griffith, Million, and Buck.

Second Day.—The Society was again called to order by the President at 10 A. M., in the Senate Chamber. Dr. Archibald Dixon, of Henderson, Ky., read a paper on "The Work of the Past Year." Dr. R. E. Houghton, of Indianapolis, Ind., one on the "Relation of Nerve to Muscle, being the basis of Antipyretic Treatment in Fevers and Inflammations," and Dr. Amos Sawyer, of Hillsboro, Ill., one entitled "Thoughts on Evolution." The reading of each of these papers was followed by a discussion, in which many of the members participated with more or less interest and profit, yet without adding much that was really new to the stock of professional knowledge previously existing. The Society then adjourned until 2 P. M. On reassembling in the afternoon, Dr. Joseph Eastman, of Indianapolis, read a paper entitled, "An Enemy Came and Sowed Tares." Dr. H. B. Buck, of Springfield, presented the subject of "Electricity in Gynecological Practice." Dr. T. S. Galbraith, of Seymour, Ind., read a paper on "Perimetritis;" and Dr. Geo. B. Walker, of Evansville, one on the "Means of Relief in Difficult Labors."

These several papers were well written and each contained some facts of value, although their reading left but little time for general discussion. An evening session was held, to which the public generally was invited, and an address was delivered by Dr. H. A. Johnson, of Chicago, on "Preventive Medicine." The advancements in sanitary science; their importance in preventing disease, and especially in limiting the spread of epidemics, were discussed in a popular and yet interesting and eloquent manner. Like nearly all the sanitarians of the present day, he urged thorough *cleanliness* as the great desideratum to be attained by sanitation, both public and private. At the close of the address, a motion was adopted requesting the speaker to furnish a copy for publication in both medical and secular papers. The Society then adjourned to 9 o'clock the following morning.

Third Day.—The Society was called to order at 9 A. M., the President in the chair. Papers were read as follows: By Dr. H. C. Fairbrother, of East St. Louis, on "Repair of Bones;" by Dr. J. A. Sutcliffe, of Indianapolis, on a "Case of Malignant Disease of the Testicles;" by Dr. Wright, of Onley, on "Excision of the Radius;" by Dr. A. G. Bernays, of St. Louis, on "Chips from a Surgeon's Workshop;" and by Dr. G. N. Kreider, of Springfield, on "Dislocations of the Shoulder." From the little disposition manifested to occupy time in the discussion of the topics presented in these several papers, as well as from the unexpectedly small number of members present, it became manifest that this would be the last day of the session. After the reading of papers

was closed, the following officers were nominated and elected for the ensuing year:

President—Dr. F. W. Beard, of Indiana.

First Vice-President—Dr. A. B. Miller, of Missouri.

Second Vice-President—Dr. J. A. Sutcliffe, of Indiana.

Third Vice-President—Dr. E. H. Luckett, of Kentucky.

Secretary—Dr. G. W. Burton, of Indiana.

Assistant Secretary—Dr. H. J. B. Wright, of Illinois.

Treasurer—Dr. A. M. Owen, of Indiana.

Chairmen of committees as follows:

On Programme, Dr. A. M. Owen, of Indiana.

On Surgery, Dr. W. A. Byrd, of Illinois.

On Practice of Medicine, Dr. Arch Dixon, of Kentucky.

On Gynæcology, Dr. George J. Engleman, Jr.

On Obstetrics, Dr. G. B. Walker, of Indiana.

On Therapeutics and Hygiene, Dr. J. F. Hibbard, of Indiana.

On Ophthalmology and Laryngology, Dr. J. L. Thompson, of Indiana.

On Chemistry and Toxicology, Dr. J. G. Hynman, of Indiana.

On Legal Medicine, Dr. Jacob Gregory, of Missouri.

It was decided to hold the next meeting at Evansville, Ind., on the second Tuesday of June, to continue three days.

The business part of the annual meeting was then closed by adjournment. But many of the members assembled again in the State House in the evening to participate in a microscopical entertainment, in company with many amateur microscopists of both sexes. The occasion was one of much pleasure and profit to those in attendance, both in a scientific and social aspect.

F.

SECRETARIES OF STATE MEDICAL SOCIETIES.

The following list of Secretaries of State Medical Societies and their P. O. address will be found very convenient and useful in facilitating correspondence with such societies:

STATE.	NAME.	POST OFFICE.
Alabama.....	Dr. T. A. Means.....	Montgomery.
Arkansas.....	Dr. L. P. Gibson.....	Little Rock.
California.....	Dr. W. A. Briggs.....	Sacramento.
Colorado.....	Dr. G. W. Cox.....	Denver.
Connecticut.....	Dr. S. B. St. John.....	Hartford.

STATE MEDICINE.

AMERICAN PUBLIC HEALTH ASSOCIATION.

TWELFTH ANNUAL MEETING, ST. LOUIS, MO., 1884.

The American Public Health Association will convene at St. Louis, Mo., Tuesday, Oct. 14, at 10 o'clock A. M., and continue four days. The meetings will be held in Liederkranz Hall, corner of Thirteenth street and Chouteau avenue.

Papers have been promised for this meeting as follows: on

1. Hygiene of the Habitations of the Poor.—Major Samuel A. Robinson, Inspector of Plumbing of the District of Columbia; Chas. W. Chancellor, M.D., Secretary State Board of Health, Maryland; Wm. K. Newton, M.D., Health Officer, Paterson, N. J.

2. Hygiene of Occupations.—George H. Rohé, M.D., Professor of Hygiene, College of Physicians and Surgeons, Baltimore, Md.; Walter Wyman, M.D., Surgeon U. S. Marine Hospital Service; J. W. Chambers, M.D., Baltimore, Md.

3. School Hygiene.—Samuel W. Abbott, M.D., Health Officer State Board of Health, Lunacy, and Charity, Mass.; Edward M. Hartwell, M.D., Johns Hopkins University; Stephen O. Richey, M.D., Washington, D. C.; Felix Formento, M.D., New Orleans, La.

4. Adulteration of Food.—Hon. Erastus Brooks, Member State Board of Health, New York; Prof. H. B. Cornwall, Princeton College, New Jersey; Chas. E. Munroe, S.B., Professor of Chemistry, United States Naval Academy, Annapolis, Md.; Prof. V. C. Vaughan, M.D., Member State Board of Health, Ann Arbor, Mich.; J. Cheston Morris, M.D., Philadelphia, Pa.

5. Water Pollution.—Major Chas. Smart, M.D., Surgeon United States Army, Member of the National Board of Health; Henry M. Baker, M.D., Secretary State Board of Health, Michigan; Thad. M. Stevens, M.D., Indianapolis, Ind.

6. Disposal of Sewage by Irrigation or Chemical Action.—Henry P. Walcott, M.D., Chairman State Board of Health, Lunacy, and Charity, Massachusetts; Geo. N. Bell, C. E., Newport, R. I.; W. John Harris, M.D., St. Louis, Mo.

7. The Observable Effect Upon the Public Health of Official Sanitary Supervision.—Colonel George E. Waring, C. E., Secretary National Board of Health, Newport, R. I.

8. The Work of Municipal and State Boards of Health.—Reported by their Secretaries.

9. On Disease Germs.—Major Geo. M. Sternberg, M.D., Surgeon United States Army; L. Bremer, M.D.,

St. Louis, Mo.; W. W. Vinnedge, M.D., Member State Board of Health, Lafayette, Ind.; W. H. Stillwell, M.D., Humboldt, Tenn.

10. Cremation as a Sanitary Measure in Times of Great Epidemics.—John Morris, M.D., Baltimore, Md.; Rev. John D. Beugless, Chaplain United States Navy, Brooklyn, N. Y.

11. A Survey of the Present Sanitary Situation in St. Louis.—Being a series of short papers on leading public health topics, contributed by city officials and local sanitarians.

a. The Situation, Soil, and Surroundings of St. Louis, considered from a Hygienic Standpoint. By Col. Henry Flad, C. E., President Board of Public Improvements.

b. Organization of Health Department, Sanitary Legislation, and the Abatement of Nuisances. By John D. Stevenson, Esq., Health Commissioner.

c. Sources, Quality, etc., of the Milk and Meat Supplies of St. Louis. By Joseph Spiegelhalter, M.D., Member Board of Health, and J. C. Cabanné, Esq.

d. Street Paving and the Public Water Supply.—By Thomas J. Whitman, Water Commissioner, and J. W. Turner, Street Commissioner.

e. On the Average Temperatures and Prevailing Climatic Conditions of St. Louis. By Prof. F. E. Nipher, Washington University.

f. Public Sewerage and House Drainage. By Robert Moore, C. E.

g. The leading local (productive) Industries, and their Effect on the Health and Lives of their Operatives. By George Homan, M.D.

h. The Infant and School Populations and existing Causes unfavorable to their Health. By J. P. Kingsley, M.D., Professor of Physiology and Diseases of Children, Mo. Med. College.

i. The Chief Local Factors in the Causation of Disease and Death. By Robert Luedeking, M.D., Professor Pathological Anatomy, St. Louis Med. College.

Several papers have been promised in addition to the above, among which are: on Heating and Ventilation, Chas. O. Curtman, M.D., Professor of Chemistry, Mo. Med. College, St. Louis, Mo.; on Protective Spectacles, Adolphus Alt, M.D., Editor *American Journal of Ophthalmology*, St. Louis, Mo.; on Prevention of Syphilis, J. D. Gatch, M.D., Lawrenceburg, Ind.; on Hygiene of the Nervous System and Mind, C. H. Hughes, M.D., Editor of the *Alienist and Neurologist*, St. Louis, Mo.; on the Sanitary Management of Railway Cars and Stations, W. Thornton Parker, M.D., Acting Assistant Surgeon U. S. Army.

Full reports are expected from all Committees.

The headquarters of the Executive Committee will be at the Southern Hotel. The first meeting of the Committee will be held Monday, Oct. 13, at 2:30 P. M.

The Conference of State Boards of Health will meet at Liederkranz Hall, Monday, October 13, at 2:30 P. M.

The subjects for each day's consideration will be stated the previous day, and an official programme

will appear each morning. Ample time for discussion will be allowed under the rules of the Association, and all discussions will be stenographically reported. The morning sessions will be adjourned at 2:30 P. M. daily, to permit the meeting of the Executive Committee, Advisory Council, and Conference of State Boards in the afternoon, and to enable members to visit the Missouri State Fair, which will be open until October 18.

Applications for certificates to enable members and those intending to become members and their families to obtain the reduced rates offered by the various railroad lines to St. Louis, should be made without delay to the Committee of Arrangements: Dr. Joseph Spiegelhalter, Chairman, 1100 Chouteau avenue; Dr. George Homan, Secretary, 703 Washington avenue.

All papers offered the Association become its exclusive property, will be copyrighted, and can only be published by consent of the Executive Committee. All reports and papers must be in the hands of the Secretary by October 12, in order to receive the approval of the Committee. After October 5 all communications to the Secretary should be sent to Southern Hotel, St. Louis, Mo.

Clergymen, engineers, architects, builders and others interested in the practical work of the Association, are cordially invited to be present.

Ladies are especially invited to attend the evening meetings of the Association.

Per order Executive Committee.

IRVING A. WATSON, Secretary.

Concord, N. H., Sept. 27, 1884.

DOMESTIC CORRESPONDENCE.

"THE COMMUNITY OF ORIGIN OF DIPHTHERIA, TYPHOID FEVER AND SCARLATINA,"

EDITOR OF THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION:

In your JOURNAL of August 30, was published a paper upon the above subject, which had been read by Dr. E. O. Bardwell at a recent meeting of the Iowa and Illinois Central District Medical Association.

Dr. B. gave, as confirmative evidence of such a theory, examples of the prevalence of one or more of these diseases at different seasons in five different places more or less widely separated, and all in bad sanitary condition. They, if taken singly, might be held to support his theory, but studied collectively and *chronologically*, tend rather to uphold the opinions of the specificity and the propagation of the poisons of these diseases from one to another place.

Typhoid fever had prevailed in all of the places in previous years but failed to appear in any of them in 1882, and diphtheria was endemic that season. The first notice made of diphtheria was in the fall of 1880, when two cases were treated and one died at No. 2. Sometime in 1882 (the time of year was not specified) two cases occurred at No. 1. About March of the same year (and it is important to know whether this

case preceded those above) one case appeared at No. 3. No. 3 is the nearest of the four places to No. 2, where the disease originally showed itself. In September following, No. 5 furnished 15 cases, with four deaths, and in December and January, 30 cases developed, and six ended fatally at No. 4.

It is thus seen that No. 2, which alone was visited by diphtheria in 1880, was the only place that escaped having the disease in 1882. Also that 45 out of 48 cases in all, occurred in two places, (Nos. 4 and 5). The appearance of the disease in No. 5 was followed by its development in No. 4 *two or three months later*. The probability of the seeds of the disease having been conveyed from one of these localities to the other is also favored by their proximity. No. 5 is "a valley nine miles long, and reaches out nearly at right angles to the one just mentioned," *i. e.* No. 4.

So much for diphtheria. Scarlet fever occurred in Nos. 2, 3 and 4. At No. 2, a child contracted scarlet fever in the summer of 1880, "without having been away from home or having had visitors for three months." However this may be, it is a suspicious circumstance that scarlet fever occurred that year in but one other of the places (No. 3), and that is the nearest one—being only four miles from No. 2. The suspicion that some communication existed between Nos. 2 and 3 is strengthened by the fact that a case of typhoid fever developed at the former in the spring of 1881, and the summer of the same year the disease made its first appearance at the latter place. The scarlet fever at No. 4 was in a mild form, and followed a few months later the attacks of diphtheria in 1882.

Now, as Dr. Bardwell has failed, or it may be has not attempted to trace the propagation of these diseases from one to the other, within the limited space of the five different places, it is fully as reasonable to suppose that he has overlooked the sources from whence the first cases derived their germs from antecedent attacks of the diseases.

If the three diseases were developed from a common origin, the one or other being evolved from the same nidus according to the peculiar nature of the predisposing force, it is strange that this force should have brought forth nothing but typhoid fever season after season for some years before the appearance of either of the other two diseases. And this is the more strange since the conditions giving rise to the different diseases cannot be widely different from each other. This is proven by the coexistence of two or all of them in the same season.

Neither of the diseases was very exacting regarding the conditions necessary for its development, as winter or summer alike favored the presence of all.

H. D. FRY, M.D.

Washington, D. C.

FRACTURE OF THE CERVICAL VERTEBRÆ.

CAMBRIDGE, MASS., Sept. 25, 1884.

N. S. DAVIS, M.D., EDITOR:

Dear Doctor.—In your last issue of the JOURNAL, Sept. 20, 1884, on page 327, there is a report of a

case (by Prof. Küster, *Centralblatt für Chirurgie: Edinburgh Clinical Journal*) of complete recovery after fracture of a cervical vertebra, contrary though, as the author remarks, to all previous experience. This report calls to mind a case of fracture of the axis which occurred in my practice several years ago. The following is taken from my notes: J. C. C., a man aged 61 years, fell from a pear tree eighteen feet, striking his head upon the ground and sustaining a fracture of the axis through or near the articulating process on the right side. The fracture was oblique and downwards, evidently involving the body of the axis which supports the odontoid process. The patient was seen at the time by several physicians, none of whom doubted that the patient had sustained a severe fracture of a cervical vertebra. Dr. Morrill Wyman of this city, saw the patient with me several times in consultation. The accident occurred on the 23d day of September, 1872, and the patient was unable to leave his house until the following June, 1873. For nearly four months the patient was obliged to lie in bed on the left side and for several weeks was unable to turn or raise the head; and it was with the greatest difficulty the nurse or attendants succeeded in changing or arranging his pillows owing to the severe suffering attendant on raising his head even for a moment. No attempt at reduction of the osseous parts was deemed advisable, the patient, though suffering from symptoms of a reflex excitability, did not appear to suffer from any marked motor paresis. Morphia was freely used to control the pain, and hydrate of chloral for the nervous disturbance. Several weeks after the occurrence of the accident, the patient had an acute attack of phlebitis of the left leg and foot. This gradually yielded under appropriate treatment; the patient after his recovery from the fall, as was to be expected, had his head inclined to the left and though the parts were quite stiffly fixed, he experienced but little inconvenience. There was marked evidence of the fracture the patient sustained by the fall, in the shape of a callus or hard prominence of the osseous tissues. This was observed more particularly posteriorly and on the right of the axis. The patient at length recovered from all his nervous symptoms, and was in fair health until 1879, when after a series of reverses in his fortune he began to be troubled with cough and difficult micturition. He had enlargement of the prostate, and there was a residual sediment of the urine. In May, 1881, the patient began to suffer from a severe gastritis, which after a few months presented symptoms of malignant disease of the stomach. The patient became extremely emaciated, and died Dec. 9, 1881.

Autopsy revealed a large cancerous mass of the stomach in front of the pylorus; the stomach was very much contracted in size; the malignant mass was raised above the inner surface of the stomach. It was a sort of fungoid, darkish, and was the probable source of the hæmorrhage from which the patient suffered. Both lungs were extensively adherent; the heart was normal. There was only one kidney; this was on the right side. Positively there was none on the left, but there was a ureter on the left, but it was impervious. The peritonæum on the inside was thick-

ly dotted with little white points. The kidney was somewhat larger than normal, but showed no positive indication of disease. The liver and spleen were highly congested. The bladder was somewhat contracted but otherwise healthy. The prostate gland was larger than normal, but it was not excessively so. The spinal column was curved laterally. The body of the patient being so greatly emaciated evidence became conclusive of fracture. There was a marked osseous callus or protuberance (prominence) of the right lamina of the axis extruding through the articulating process, and into the body of the vertebra. The axis was not removed, but none of the physicians who attended the autopsy, including Medical Examiner Dr. A. T. Holt, who conducted the examination, had the slightest doubt that the patient had sustained a fracture of a cervical vertebra as above described.

Very respectfully, your obedient servant,
AUGUSTUS P. CLARKE, M.D.

BOOK REVIEWS.

SECOND ANNUAL REPORT OF THE STATE BOARD OF HEALTH OF INDIANA, For the Fiscal Year Ending Oct. 31, 1883. Cloth. 335 pages.

The report shows that the Board have given their attention to the sanitary condition of the school houses throughout the State, a matter of fundamental importance, and one in which school authorities are often criminally negligent. This is true not only of the neglected country school houses but also of the crowded city buildings, and it is a matter worthy of remark that it is generally in the simplest matters of hygiene that the fault exists. Surely this is due more to carelessness than to ignorance on the part of the school authorities.

Several contributors to this report call attention to the importance to public health of some effectual measure for the prevention of syphilitic contagion.

The apparent spread of this disease, its direct relation to the present and future strength of the nation, morally as well as physically, make these suggestions worthy of careful attention. The gross ignorance of the public respecting this subject; the consummate skill with which the unprincipled in medical practice turn this ignorance to personal gain; the sense of modesty as well as the personal unfitness which prevents alike the religious and secular teacher from raising his voice against this hidden evil, an evil still more dangerous because it is concealed, all make it incumbent upon some one, and who better than an impartial public board, whose function is that of guarding the public health, to take the matter in serious consideration with a view to inaugurating efficient measures for its suppression.

The latter half of the volume is occupied by the report concerning vital statistics of the State for 1883. It consists of copies of blanks sent out, of reports received, and of tabulated statements respecting deaths, births, and other matters pertaining to this department of the work of the board.

MISCELLANEOUS.

CLITROPHOBIA.

Not clitoriphobia (or clitorisphobia) which is a disease confined to gynæcologists, but clitrophobia, a term used by an Italian writer (*Revista Clin. de Bologna*) to designate three cases suffering from a cerebral affection resembling agoraphobia, and which consists in a marked horror of being confined in a close place. They suffer, when so confined, in an extremely painful manner, the head becomes hot, the temporal arteries beat forcibly, they become furious and make desperate efforts to open the door, try to get out of the window or to kill themselves when they find they cannot escape.

It seems to constitute a pure monomania, that is to say it may exist without any manifestation of delirium. At other times it is accompanied by other psychological affections.

THE ITALIAN QUARANTINE AS AFFECTING MEDICAL JOURNALS.

The *Journal d'Accouchments* tells us that everything going into Italy from France, individuals, merchandise and correspondence undergoes a rigorous disinfection. Dr. Koch on his return to Germany, was thoroughly disinfected at the Italian frontier, he should have passed by declaring that the germs might be in his intestines and therefore not reached by the disinfectants. It seems that two wagons, one loaded with chloride of lime and the other with phenic acid, were disinfected at Chiasso? The rule was that everything should be disinfected that passed the frontier, and it was done.

The *Progrès Médical* states that many of its Italian exchanges have desired a suspension of that journal during the prevalence of the epidemic, "the journals arrive all torn and reduced almost to their titles from the disinfection which they undergo." Many travellers have been nearly asphyxiated in the rooms used for disinfection, when they have been obliged to remain for any length of time, and have consequently been seriously affected.

THE MEDICAL DEPARTMENT OF THE CHICAGO PUBLIC LIBRARY.

The Chicago Medical Society wishes to inform the profession that there are now 1,200 bound volumes of medical books in the Public Library, in a convenient location to be consulted by the profession.

The majority of these works have recently been purchased by the Society Committee on Library. They embrace a carefully chosen collection of the best known recent medical authorities in English and foreign languages.

Most of the standard works on the leading specialties (including dental surgery) have been obtained, and also some books on pharmacy. The funds for this purchase consisted of an appropriation of \$500 from the Society treasury, supplemented by voluntary contributions from the physicians and druggists of this city.

Valuable contributions of older works were also received from some sources.

This collection is located in the southeast corner of the south room of the upper floor, and a large table and chairs have been provided for the convenience of physicians. The librarian of the upper floor will show the way to those desiring to consult the books.

By agreement with Mr. Poole, the books will not be loaned out, but kept in the Reference List for consultation, so as always to be found when needed.

There will also be found a good representation of American and foreign periodicals, which can be inquired for at the librarian's counter.

A large and valuable collection of old journals is not yet on the shelves, for lack of money to bind them. Most of these were donated by Dr. Vincent L. Hurlbut.

EDMUND ANDREWS, M.D.,
F. C. HOTZ, M.D.,
DAVID GRAHAM, M.D.,
Committee on Library.

TOBACCO AS AN ANTIZYMASIC.

M. Pecholier in the *Montpellier Medical* considers that the use of tobacco preserves one from an infinity of contagious diseases. He thinks that as typhoid fever is due to a ferment, the pullulation and life of which in the organism is the initial cause of the disease, tobacco is the most powerful destructive agent, and that its action is due to nicotine; he declares that a number of smokers have been protected from epidemic influences through tobacco. Perhaps it is for this reason that Willis recommends the use of tobacco in armies, as a preservative against certain epidemic diseases.

DECORATIONS OF MEDICAL MEN.

It would seem as if our foreign brethren *must* have decorations of some kind, to judge from the letter of a correspondent of the *Medical Press and Circular*, who tells us that one of the guests at the reception of the King of Denmark, at Christiansberg, during the meeting of the International Medical Congress, wore upon his breast the proud shield of "a bicycle club." The American delegate comes in for his share however, in the retort said to have been made by the King in reply to the assertion that "in America we are all Kings." "I am glad to meet a brother, all in the same business." Old, but still good and applicable.

A STATUE TO DR. GUISLAIN.

An effort is being made to secure subscriptions for the erection of a statue to *Dr. Joseph Guislain*. The members of the Society of Mental Medicine of Belgium are actively interested in promoting this object, and desire that all specialists in this department of medicine have an opportunity to subscribe, and that the statue represent the combined subscriptions of the specialists in mental diseases of the world, rather than any given district. To this end, subscriptions have

been received from England, France, Russia, Germany, Italy, Holland and Sweden, in sums varying from 5 to 25 francs. The United States is, as yet, not represented. We trust this notice may come to the eyes of medical men especially interested in this department of medicine, of which Dr. Guislain was so distinguished a member. We hope the subscriptions from America towards the erection of this statue will compare favorably with those of other countries. Subscriptions may be sent to Dr. B. C. Ingels, *Médecin de l'Hospice-Guislain à Gand, Belgium*.

All subscriptions are published in list form, and will be sent to subscribers.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM SEPTEMBER 20, 1884, TO SEPTEMBER 26, 1884.

Middleton, Passmore, Major and Surgeon, having reported from sick leave of absence, assigned to duty at Fort Leavenworth, Kan. (Par. 2, S. O. 188, Hdqr's Dept. of Mo., Sept. 19, 1884.)

White, Robert H., Captain and Assistant-Surgeon, ordered for duty as Post Surgeon, Fort Gaston, Cal. (Par. 2, S. O. 110, Hdqr's Dept. of Cal., Sept. 13, 1884.)

Wilson, Wm. J., Captain and Assistant-Surgeon, from Dept. of Dak. to Dept. of the East.

Gardiner, J. de B. W., Captain and Assistant-Surgeon, from Dept. of Ariz. to Dept. of the East.

Corbusier, Wm. H., Captain and Assistant-Surgeon, from Dept. of East, to Dept. of Ariz.

La Garde, L. A., Captain and Assistant-Surgeon, from Dept. of Mo. to Dept. of Dak. (Par. 1, S. O. 220, A. G. O., Sept. 19, 1884.)

Hall, Ino. D., Captain and Assistant-Surgeon, assigned to duty at Fort Townsend, W. T., to relieve Surgeon R. S. Vickery. Surgeon Vickery on being relieved, directed to report to commanding officer Vancouver Bks., W. T., for duty. (Par. 3, S. O. 140, Hdqr's Dept. of Col., Sept. 15, 1884.)

Birmingham, H. P., First Lieutenant and Assistant-Surgeon, leave of absence extended 20 days. (Par. 2, S. O. 116, Hdqr's Div. of the Mo., Sept. 22, 1884.)

Barrows, C. C., First Lieutenant and Assistant-Surgeon, granted one month's leave of absence with permission to apply to the proper authority for an extension of one month. (Par. 4, S. O. 86, Hdqr's Dept. of Ariz., Sept. 13, 1884.)

Diety, W. D., First Lieutenant and Assistant-Surgeon, assigned to duty at Fort Selden, N. M. (Post Surgeon.) (Par. 4, S. O. 187, Hdqr's Dept. of Mo., Sept. 18, 1884.)

McCaw, W. D., First Lieutenant and Assistant-Surgeon, assigned to duty as Post Surgeon, Fort Craig, N. M. (Par. 5, S. O. 187, Hdqr's Dept. of Mo., Sept. 18, 1884.)

OFFICIAL LIST OF CHANGES IN MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING SEPTEMBER 27, 1884.

Bloodgood, D., Medical Inspector, to Washington for examination preliminary to promotion, and as to qualifications for sea duty, Oct. 1, 1884.

Hord, W. T., Medical Director, as member of Naval Examining Board, Oct. 1, 1884.

Turner, T. J., Medical Director, as member of Naval Examining Board, Oct. 1, 1884.

Boyd, J. C., Passed Assistant-Surgeon, placed on waiting orders, Sept. 25, 1884.

Oberly, A. S., Surgeon, to Washington for examination preliminary to promotion, and as to qualifications for sea duty, Oct. 1, 1884.

ON OCCIPITO-POSTERIOR PRESENTATIONS.

BY ISAAC E. TAYLOR, M.D., OF NEW YORK.

Read before the Section on Obstetrics and Diseases of Women, American Medical Association, May 8, 1884.

MR. CHAIRMAN, AND GENTLEMEN OF THE SECTION ON OBSTETRICS AND THE DISEASES OF WOMEN:—Requested by your honored and distinguished chairman to present a paper at this meeting on some subject appertaining to the branch of the profession we are all interested in, I thought that a few remarks on the management and rectification of the child's head in the occipito-posterior position in difficult cases might not prove to be unacceptable.

I selected this subject in lieu of a paper on some gynecological topic, having understood that there were several papers in that department to be offered for our edification.

The subject I propose to consider is one which, at the present day, might appear to be almost superfluous and useless for any one to undertake, much less to offer anything different from that which is generally practiced respecting the management of the delivery of the child in these presentations. These presentations of the child's head are of an everyday occurrence, as we are all cognizant of and with.

The frequency, as well as the mechanism of this class of cases in midwifery, was not clearly comprehended by the profession until Nagele, Sr., issued his celebrated monograph in 1819, "On the Mechanism of Parturition," controverting and reversing almost entirely the views and opinions existing and prevalent at that time. Nagele announced in that essay "that the process by which the head of the child had been considered as a regular phenomenon was a deviation; and exactly that which had been esteemed a deviation from the usual course and rule, was perfectly regular," which is, that the third position of the vertex is after the first position by far the most frequent in occurrence of all the cranial presentations, the frequency being almost as 1 to 2, and that the second and fourth positions were exceedingly rare—the second more rare than the fourth.

Out of 1,244 cases, Nagele had seen only 17 cases in the fourth position. None in the second. Nagele considered that there was but two presentations of the

child's head occupying the superior strait at the commencement of labor.

The first position is when the occiput is located at the left foramen ovale, and the forehead looking to the right sacro-iliac synchondrosis.

The second is the very reverse of the first. With this view of the subject, according to Nagele, the right oblique diameter is principally and chiefly occupied by the child's head. Such was the high estimation at that time respecting the views and opinions of Nagele from his experience, that for many years they were considered as accepted truths, and his essay was styled the "Euclid of obstetrics."

Rigby, Sr., translated Nagele's monograph, and published it in England in 1829. He endorsed fully the views and opinions of Nagele. This is only 55 years ago.

The subject therefore as to the correct and true mechanism of the occipito-posterior presentations of the child's head, and their frequency, is not so very old as to preclude any further consideration and observation. Respecting the management and rectification of those difficult cranial presentations, which all of us are every now and then meeting with, I defer to such a scientific and learned assembly of medical gentlemen, coming from every section of this country. I trust we will not despise "the day of small things," in desiring to attain the object I have in view, nor that the older views, and experience of some celebrated obstetricians, which have in a great measure been proscribed, if not entirely forgotten, may be referred to, and claim some attention. Should they be instituted at any time, they may prove of benefit to both mother and child.

My paper I wish to be considered as simply a practical one, to illustrate the redressment of occipito-posterior positions of the child's head into face presentations, in some instances, instead of producing flexion.

The views of the French school on the positions of the child's head, in relation to the superior strait, and the relative frequency of each of them, were in the ascendant, when Nagele wrote his essay. They were accepted and taught by many, if not nearly all of the prominent French and German authorities. It is true that Saxtorph, of Copenhagen, and especially Solayres de Renhac, of Montpelier, as well as Johnston, of Dublin, were the exceptions.

Nagele admitted that they had preceded him, as to the rotation of the child's head from a posterior to an anterior one. Respecting the frequency Nagele was decided, and imperative on that point, as well as that

the rotation and delivery of the child was effected almost always by nature anteriorly.

He insisted also that the occiput did not rotate into the hollow of the sacrum, but maintained an oblique position in the pelvis, and if it did not move anteriorly, the child was delivered in that manner at its birth.

By some authorities these cases were termed face to pubes cases. This I think is an error, for it is not the face, but the upper and anterior part of the parietal bone, and part of the frontal bone at the pubes, face looking upwards. Sometimes it is the frontal bone at the pubes.

In other cases it is a true vertex presentation at the vulva, consequent on the extreme flexion.

Smellie, in 1744, recognized the movement of the head from a posterior to an anterior position. He however made the change, as he believed, by two fingers. He did not realize the frequency of this kind of cases, and that nature accomplished the rotation in nearly all of them.

John Clarke, of Dublin, 50 years after Smellie, stated that he had redressed 13 out of 14 cases by this method.

Our distinguished and justly celebrated Prof. W. P. Dewees, in reference to the occipito-posterior presentation, held "that no man was competent to practice obstetrics who could not detect, and change the position of a child's head from a posterior position to one anterior."

Prof. Henry Miller, one of the distinguished Presidents of this Association, clear and distinct in the enunciation of his practical views on this subject, informs us that he labored assiduously to promote the rotation of the child's head, and he concluded that he now allows nature to take her course in a considerable number of cases, and that it is accomplished as well without as with assistance.

The 17 cases which Nagele met with when the head disengaged posteriorly as face to pubes, were owing, as he says, to exceptional circumstances, such as amplitude of the pelvis, laceration of the perinæum, or flexibility and smallness of the child's head.

After the appearance of Nagele's essay, the profession investigated the subject anew. Among other prominent obstetricians, Dubois and Simpson from their investigations and experience, coincided with Nagele, as to the frequency of the presentation, the manner of the rotation, the obliquity of the child's head in the pelvis, and the delivery of it in the same position.

Other able, conscientious and experienced observers differed materially from the views and opinions I have referred to. They held that the fourth position instead of being so very rare and unusual, was decidedly more frequent than Nagele had reported.

Capuron entertained the very opposite view, and announced "that the posterior part of the child's head, when posterior was never delivered by rotation, but that it was always born as a face to pubes case." Guillemot was firm in the conviction "that the occipito-posterior cases were delivered as true face cases more frequently than when the occiput was moved round anteriorly."

Face cases Nagele considered were next in frequency to the occipito-posterior with the chin always anterior. He says, "he has never seen a case with the chin posterior. That is where the forehead had turned itself forwards and upwards, and brought the face at the inferior strait or aperture of the pelvis into a diameter contrary to the usual one, anterior." Madam Lachapelle coincides with this opinion. The frequency of Guillemot's face cases, from an occipito-posterior, were 1 to 3—only one-third more than Nagele's held the second occipito-posterior position to the first position, which is 1 to 2.

It may appear singular that such diametrically opposite and discordant opinions on such a practical and important subject in midwifery could exist, as to the frequency of the position of the child's head, the mechanism by which it is delivered through the pelvic cavity, and at its birth.

Verily the old saying on this subject is fully corroborated, "who shall agree when doctors disagree."

The three very distinct and positive views and opinions I have referred to respecting the mechanism of the occipito-posterior positions of the child's head, by faithful and experienced obstetricians, of nature's handiwork during the process of labor at the inlet, the pelvic cavity, and its outlet, should merit some consideration, even at this day.

Setting aside at the outset the opinion of Capuron, which time and experience has not verified, "that the head of the child passes directly into the hollow of the sacrum, and is delivered as face to pubes."

Some of us, however, will agree with this view, and that the manner of delivery is more frequently recognized than Nagele believed.

In many instances they are as easy, quick and as natural as though they had been occipito-anterior cases.

But what shall we have to say respecting the views of Guillemot as to the frequency of the occipito-posterior presentations becoming face? The frequency of this class of position being converted into face, few of us may not coincide with, but as to the fact there can be no question.

I do not desire to be discursive on this subject, by entering into any special details. I am fully aware that our time is pressing. I realize, nevertheless, that it may be well for the consideration, as also illustrative of the subject, to refer as briefly and as succinctly as possible to the manner by which the rotation of the child's head is effected, and which in those cases is deemed an absolute necessity, the *sine qua non* of the labor, especially in those cases which become tedious, and may, and do sometimes, necessitate craniotomy.

Occipito-posterior presentations are generally redressed from the backward position of the pelvis to the anterior, by the natural rotatory or spinal action of the uterus.

This singular, curious, and wonderful movement of the uterus, by which the occiput of the child's head when posterior, is changed anteriorly and reversely, when the frontal bone is anterior as in face cases, is moved posterior, has never as yet been satisfactorily explained.

Various theories have been advanced, while some authorities embrace the opinion, and I may say quite a considerable number, that the inclined planes conduce materially and principally to the important change of rotation consequent on the head of the child when reaching that part of the pelvis—others, that when this resistance is met with, the *vis vertens* of the uterus becomes unnecessary. Others again consider, that there must be a harmony of action of the uterus, and the body to be moved, but that the foetal spinal column is the direct line of communication to the occipito-atloid articulation, and that the head is thus directly impressed downwards, becomes flexed, and when meeting with the inclined planes, rotation ensues. Should there be, however, any defect at the superior strait, either by an equally faulty or the narrow conjugate pelvis, the spinal theory could not avail.

The delivery of the child's head is one of descent, through the parturient canal, whether it is synclitically or obliquely placed.

Flexion is considered as requisite in the anterior, as in the posterior presentations of the cranium. In some instances, however, the nature of the movement is changed, and the mechanism is reversed, the chin becomes extended, and the vertex is made a face presentation.

In the occipito-posterior cases, the rotation forwards is deemed of greater importance than the anterior to effect the delivery of the child. If the change is not made the rotation is believed to be at fault. The rotation, however, may not be at fault, because flexion has not taken place. Flexion is deemed as requisite therefore, and as important an element in the mechanism of the delivery of the child as rotation.

The movements of the child's head, whether at the superior strait, pelvic cavity, or the inferior strait, can be explained in another aspect, and that is by the uterine forces alone, acting on the vertex, or the antero-posterior direction of the child's head.

We recognize as a primary principle, and it must be admitted, that the result of the uterine contraction must, and should always coincide with the axis of the uterus. Movement and rotation can and only does occur on a fixed axis.

If the uterine forces pass through the axis solely, no rotation can be accomplished. If directed towards or through the posterior part of the head, flexion is the sequence.

If through the anterior or frontal part, the forehead will descend or lead, and if continued, a face presentation is the consequence.

Nagele considered rotation was effected principally by the uterine contractions. The head, he says, is moved by the pains forward; before it has made the rotation, it retreats, and it is then moved forward again, and this movement to and fro, continues till it has finally accomplished the quarter of a circle.

This description shows that the movement of a quarter of a circle does not depend on the inclined planes, but that the *vis vertens* is absolutely necessary and requisite.

In several instances I have noticed the rotation did

not take place during the contraction, but as soon however, as the contraction was passing away, the head glided forwards during the relaxation and eventually became established in its new position anteriorly.

The experiments instituted by Dubois on the cadaver, with a child's head, and which are sometimes referred to, were an artificial physical movement to show how rotation was performed in the pelvic cavity. They could not in any way illustrate the natural spiral action of the living uterus. They were made to show, as was supposed by some, the influence of the inclined planes.

It is true they describe a mechanical fact, an artificial physical force, but they do not conduce to the truthfulness of nature's movements by the uterine contractions.

What explanation according to this view is rendered, or has been advanced in those cases of face presentations with the chin tending posteriorly, resting as it does on the ilio-pectineal circle, or even partly in the superior strait?

Without this rotatory or *vis vertens* action of the uterus, the child will have to be sacrificed. Rotation and flexion are not, moreover, the only important elements requisite for the safe delivery of the child.

Extension of the child's head backwards becomes a positive necessity in some cases, in lieu of them, independent of the size, form, mobility and position of the head in the pelvis to be translated, and the capacity, form, and the resistance of the canal to be traveled, either naturally or by artificial aid to become face. Some authorities moreover recognize the fact that there are instances of occipito-posterior presentation, instead of the chin approaching the chest to become flexed, departs from it, and the anterior fontanelle and forehead gradually become more apparent and tend to the centre of the excavation. These kind of cases, however, prove favorable in some instances and nature redresses them by flexion, for they are only temporary. Now, whether the primitive position of the child's head is directly transverse at the superior strait at the commencement of labor or not, the head will in the course of labor come to the oblique diameter.

Should the head be well flexed at the superior strait even while it is in the cervix uteri, the contractions regular and efficient, the head will pass through in this manner, and in a short time the head will be rotated round anteriorly, and the child is delivered as easy and as quickly as in occipito-anterior cases. Should, however, flexion not have taken place, either in the cervix uteri, or in the pelvic cavity, we are likely to have a case of some difficulty, for the vertex is presenting, and rotation may not occur unless artificial aid is provided for either by flexion or extension—should it be a forehead presentation, the possibility is that we may have a face presentation, but if not, then it becomes a question whether it is not better to make it a face, instead of trying to produce flexion, or terminate the delivery by instrumental efforts.

Face cases are considered by some practitioners as more difficult and tedious to the mother, and especially unfortunate to the life of the child.

My own experience does not coincide with this view, but that they proceed usually without greater difficulty, and terminate quite as successfully, as occipito-anterior ones, for no unusual proportions of the pelvis are requisite.

This transmutation of the child's head into face, according to Guillemot, even while in the pelvic cavity, occurs after this manner: "The occiput being arrested by some point in the excavation, instead of advancing along the perinaeum toward the inferior strait, ascends in the curvature of the sacrum, by executing the movement of rotation backwards, and being at the same time thrown back upon the posterior part of the chest, while this is going on, the forehead and face descend behind the pubes, and pass downwards, and backwards, until the chin emerges under the arch, and the head, which is completely turned back, traverses the perineal strait, as in face presentations." Forehead presentations do not often enter the pelvis "*a plomb*," unless from some defect of the pelvis. When they do, they will then assume a position between the normal vertex and a face presentation.

Should this exist without becoming a face, or an occipito-posterior well flexed, in the translation of the head to the outlet, the forehead may present at the vulva, then the eyes, while the superior maxilla is fixed against the pubic arch, and the cranium sweeps over the perinaeum, but the superior maxilla, the mouth, and the chin do not appear from beneath the pubic arch until after the whole cranium has been delivered.

This description of another way by which the child is born as a frontal case, instead of becoming face in the pelvic cavity, shows us that nature may and does deliver even these extreme cases, without much flexion occurring. The success of the delivery in this class of cases, I believe, is consequent on the perinaeum being a short and yielding one, the head not much elongated and a small-sized occiput. Should, however, the perinaeum become very much extended, it would be utterly impossible for the head to escape over the perinaeum, as it has become a true vertex case. The frontal bone is then directly under and against the pubes, and the labor will have to be terminated by artificial means in some way. An illustration of which I will present, with some others of a different nature occurring in the pelvic cavity, and at the superior strait.

There are some patients who in nearly all their confinements have occipito-posterior positions. One of my families had four labors in succession of occipito-posterior positions. They all terminated favorably in the anterior position except one, which was instrumental. These children weighed 10 to 12 lbs. Pelvis ample. The shoulders measured respectively 20 to 22 inches in three of them. The last birth, a year ago, was a girl, the smallest of all; the delivery in that instance was only one hour, being a frontal presentation. In three of these cases, the head was in the left oblique diameter of the pelvis.

In Mrs. K.'s first labor the left oblique existed, and she was obliged to be delivered instrumentally, after traction at intervals of nearly two hours. Child living. Dr. Lusk assisting. It was thought at the

time, that there was some slight diminution of the pelvis. Vertex presentation. Child weighed 7 lbs.

In Mrs. K.'s second labor, last year, the posterior position prevailed, but this time it was the right oblique diameter. Immediately after the membranes ruptured, after four hours' easy labor, the child was delivered in fifteen minutes, occiput anteriorly; child weighed 7 lbs., Dr. Wells, of New Rochelle, being present till I arrived.

Swayne, of Bristol, England, from his investigations as to the frequency of the different positions of the child's head at the superior strait, affirmed that the left occipito-posterior positions were far more frequent than the right. My own experience coincides with this view and in other cases which have occurred to me, the last three years, they were nearly all in the left.

McDonald, in the October number, 1874, *Edinburgh Journal*, says one of his patients in three labors had occipito-posterior, and one face, all easy labors—another three cases and one brow. In a third, out of four confinements, there were three occipito-posterior and one face. Out of the 10 cases there were two face and one brow, which is not very far from being a true face, that is nearly one-third face presentations, four occipito-posterior cases becoming face.

Guillemot informs us "that we should not depart from the truth, by announcing that in every three occipito-posterior positions, one of them would give rise to a face presentation.

Causes.—The disproportionate large size of the child's head is supposed to be the principal cause in the general run of these cases, in its relation to the pelvis. We should not be unmindful that the diminution of the measurements of the pelvis, in all its diameters even of a quarter of an inch, conduces, as I believe, frequently as a barrier to the delivery. Large shoulders, although the head may be small, become a decided source of difficulty. This cause is but very cursorily alluded to in the obstetrical works in these kinds of positions.

In the cases of Mrs. S. and Mrs. G., which I will refer to, it was the chief cause, and although the forceps were used, and efficient, after careful traction was made, it became necessary to conduct the labor by other means.

It was formerly believed prior to Gerdy's exposition of the mechanism of the shoulders during labor, that the trunk of the child did not partake in the movements of rotation after the head was born, and that there was consequently a certain degree of torsion of the neck, and that the twist would remain so, until the shoulders changed their position, when the neck becomes untwisted. The accepted views of Gerdy, who considered and demonstrated that the body of the child must participate in the movement of the head, whether the head was in or out of the pelvis, and that the shoulders from being "transverse become oblique." I think we will coincide with this physiological fact at this day, and yet it is too frequently overlooked, where artificial aid is required. Some children may have been innocently sacrificed through forgetfulness of this important physiological fact.

In some of these difficult cases, therefore, it is an absolute necessity before the further descent of the head to the inferior strait, or should it have reached the perinæum, or even dilating the vulva, that the shoulders should have entered in part, or wholly the superior strait before rotation could or would ensue.

It is principally those positions, I believe, which Caseaux and Von Helly have incidentally referred to, where the occiput has only a few lines to ride over the perinæum in order to escape from the anterior perineal commissure, and when, under the influence of a new pain, the head rotates briskly, the occiput gains the front, the forehead rolls into the perineal concavity, and the labor is terminated immediately.

I have watched a few of this class for some time, presuming they would be born as face to pubes cases. I have, however, been agreeably disappointed to realize the change so quickly made to an occipito-anterior one.

In these positions no other or better explanation can be rendered, I conceive, than that of the uterine forces, the shoulders have just engaged in the superior strait, or if they were engaged, the *vis vertens* action of the uterus has accomplished the shoulder movement or rotation, and as a natural sequence, the child is delivered occiput forwards and not as face to pubes.

Various authorities could be cited who consider that face cases are as easy and quick in the delivery of the child as in any occipito-anterior presentation. Difficulties do and will occur in all cranial presentations. The general opinion of the profession is far more favorable than unfavorable respecting this occurrence.

Collins informs us, and others join with him, that the delivery is so rapid in some instances that they are not noticed. I have seen two instances where they were delivered in two pains, and one transversely in a single pain. As a general rule, also, he, as well as others, hold "that there is an impropriety for rash interference in these cases, as nature accomplishes them very easily."

Treatment.—Instrumental and manual aid are the requirements which become necessary to terminate the labor in this class of cases should nature not be competent to finish it. Some practitioners give the choice to the lever in preference to the forceps.

The English resort to it more than we do in this country. Prof. H. L. Hodge, however, was a strong advocate for its employment, and there are many illustrations exemplifying its application in his work, as well as the use of the fillet.

The forceps claim very justly more consideration, and are generally adopted. The long curved most usually. The long straight I prefer under certain circumstances. The short curved occasionally, if the head is low down, may be very serviceable.

While some will advise after the application of the forceps, that the head should be slowly rotated during the process of extraction so as to bring the occiput anteriorly, whether it is at the superior strait or in the cavity or inferior strait, others reject any effort at rotation, even while the head has descended to the inferior strait, and rest simply and solely on that

alone, allowing nature at this stage of the labor to effect the rotation, if possible, and the delivery to take place.

McDonald informs us that in all his twenty cases rotation took place, and that it was purely the result of direct traction efforts, believing that traction alone is sufficient to eventually deliver the patient—occiput anterior. I wish I could entertain as favorable a view, and had such fortunate results by rotation. It has not been my experience, for when the head has been brought down by the instruments, or come down naturally to rest on the perinæum, they have most generally been delivered as face to pubes, though, as I have stated before, the head has occasionally glided round even while it was *in extremis* on the vulva. I have always entertained a decided objection during traction to attempt rotation, unless nature gave evidence of aiding in accomplishing it.

There should be a perfect consonance of action existing with the uterine movement, and the body to be moved. Flexion taken place, the pelvis of natural standard measurement, and the shoulders, if the head of the child is low down, should have engaged in the upper strait, a requisite so important that if they have not, they will be a decided hindrance to the easy delivery by the forceps. Unless these requirements exist, any effort made to rotate at the same time traction is proceeding, serious injury to the child's head and neck will follow.

Should the child's head be oscillating in the pelvic cavity, even after traction by the forceps, then there could be no doubt that the shoulders were the cause of the delay if the pains are efficient; therefore there could not be any delivery of the child until that cause was overcome. It would be far better, under the circumstances, to lay aside the instruments, and address the further management of the case to entirely different procedures.

A distinguished authority is especially severe in his denunciation respecting rotation by the forceps. He says: "It is labor lost. It is a sin to attempt to promote this turn by twisting with the forceps."

I have never seen but two instances, after the forceps were applied and traction attempted, where rotation took place in the pelvic cavity. One of them was with my lamented colleague, Prof. G. T. Elliot. The rotation was so rapid, after slight traction, that the forceps and the head were rotated together. Fortunately, no unfavorable lesions or injury occurred to the soft structures of the patient. With all this, I have been informed by excellent practitioners that they have frequently accomplished it, and the instruments are easily removed.

Rotation of the child's head is not an isolated movement of itself. It is, and must be, consequent on the rotation of the shoulders at the same time by the uterine forces; and if they do not move with the forceps when the rotation is attempted, the child may be seriously injured as well as the mother. We do not take the blame to ourselves, but attribute the unfortunate event to a tedious and difficult labor.

I have preferred, as the instruments are an obstruction sometimes to the rotation being effected of the child's head, after the head has made some descent,

to remove them, and after awhile to reapply them, when realizing that considerable force and power would seem to be required. On their reapplication, the head having undergone some change for the better, either by further descent or flexion, I have then been enabled to accomplish the delivery with the slightest assistance lower down, and then removed them and allowed nature to complete the delivery, either as a face to pubes or possibly by rotation anteriorly.

When the forceps have failed in some instances, whether at the superior strait, pelvic cavity, or inferior strait or vulva, manual aid becomes an important and essential substitute, and an absolute necessity and benefit to conduct the labor to a more favorable issue, and it may be to save the child, particularly in the equally faulty pelvis. The hand is the natural and essential means to help us, for several purposes.

1st. To flex the head, which is the usual and generally adopted method, and to move the head anteriorly.

2nd. To produce extension of the child's head, and to make it a face presentation. The use of the hand has been advocated by several obstetricians of high repute. It has been severely criticised by some, bitterly denounced by others, resorted to by others for awhile, and rejected by them again. The chief object, as a general rule, has been either by the hand or two fingers to produce flexion, in a great variety of the irregular presentations of the cranium and face cases, considering that that important element in the mechanism of parturition is the most natural and correct course, and in this manner endeavoring to imitate nature according to her own way. All this is very true, and cannot be gainsaid. It is, nevertheless, not a law so imperatively impressed on the mind that its faithful execution has in all cases claimed its sustentation.

The presentation may be of such a nature that the attempt to flex the head proves a serious mistake, after having occupied much time, and careful manipulation by the hand or lever. By creating, however, extension of the child's head backwards, may occupy only a few minutes, and the labor may terminate in a shorter period of time.

The latest American authority, the lamented Dr. John S. Parry, of Philadelphia, was a decided advocate for "the use of the hand," to correct unfavorable or irregular positions or presentations of the head during labor.

1. To flex the head when partially extended in all its presentations.

2. To transfer the occipito-posterior into occipito-anterior positions.

3. To change presentations of the face with the chin behind into those of the vertex, with the occiput in front.

His paper was read before the Obstetrical Society of Philadelphia, Nov. 6, 1873, and published in the *American Journal of Obstetrics*, May, 1875.

Dr. Parry, at the close of his paper, remarks, "That the study of the literature of obstetrics, so far as the writer has been able to complete it, has failed

to reveal any account of the manipulations which he had described."

In this aspect of the subject, Parry has certainly overlooked the method so faithfully executed and sustained for years by Smellie, nearly a century and a half since (1744).

Prof. G. S. Bedford, New York, in 1870, was a firm believer, and very clear in his language how to execute with the hand, in the class of cases referred to, and the object he desired to be attained.

Some of the ancient authorities also advised its use. * * * * Smellie was very much averse to perform version, if it could possibly be avoided. Whenever there was any irregularity in the position of the head, shoulder or face, he resorted to its performance by the hand.

In these cases Smellie writes (Chap. 4, Article Premature Labor): "Let the hand open the os externum slowly during a pain, and when the os internum is sufficiently dilated by the descent of the waters and membranes, let him introduce his hand into the uterus, behind the womb and membranes, and bring the cranium of the head down." Smellie not only introduced the hand to rectify the irregular positions of the head, but in some cases after he had rectified the position, "he applied one blade of the forceps to the head, while the hand was in the cavity of the pelvis, then withdrew it, and adjusted the other blade." I have frequently, he says, attempted to change the head in this manner, and have likewise when the forehead was towards the groin aside of the pelvis moved it more backwards, and by this means the forceps could be applied. Sometimes the hand would fail and the head would return to its former position. Bedford, page 198, midwifery, footnote, writes:

"In order to correct the mal-position, it will be necessary to introduce the hand into the vagina, pass it up to the superior strait, and quietly place the finger on the side of the head, the other hand steadying the uterus through the abdomen. The hand thus placed at the superior strait will cautiously elevate the head, and at the same time incline the vertex downwards, thus converting the position into the ordinary one of the vertex." This method he also applied to the moving the head round from an occipito-posterior to an anterior one.

Smellie admits that sometimes the head was so large and slippery that he could not obtain firm hold on it.

Many of us will coincide with this experience.

* * * There are instances where the hand alone internally cannot fulfill the mission it was intended in effecting the rotation of the child's head, and the body at the same time, unless it is assisted or aided by external manipulation in moving the shoulders with the head, illustrating how necessary and important it is that the shoulder movement should occur, or else the case may prove an unfortunate one. This double manœuvre or manipulation, the external in combination with the internal, going hand in hand with each other, is not dwelt upon by obstetric authorities as much as it might be. Except *en passant*.

As one of the illustrations of the double movement or the combined external with the internal, the following is referred to:

CASE 1. Left occipito-posterior presentation, failure of forceps, and the hand internally to effect rotation; external with internal manual movement; forceps; child living; weight 9 pounds.

Mrs. U. S. G., primipara. Sept. 21, 1881, called at 3 A. M.; everything progressing favorably; head occupying the left occipito-posterior position; os uteri amply dilated. 6 A. M., head translated midway into the cavity of the pelvis; no change for two hours; vertex presentation; no flexion; head not decidedly arrested in the pelvis; easily movable. Dr. F. A. Castle was requested to assist me, and give the anæsthetic. 9 A. M., forceps applied, the head appeared to descend, while traction was made; forceps removed; no advance or descent apparent; a second trial for 20 minutes; no further success appeared possible unless very strong traction was attempted. There seemed to be no prospect of delivery by the instruments.

The hand was then introduced into the vagina, and the head during the cessation of pain was grasped, and slightly moved round, while Dr. Castle aided in moving the left shoulder more anteriorly. The head was retained in position in the pelvis, while the shoulders were gently and slowly changed at the same time. By this double manipulation, in a few minutes, the head was completely changed anteriorly. Forceps were then applied, and the delivery was over shortly afterward; child living; weighing 9 pounds; cause supposed lessening of all the diameters of the pelvis, and a well-developed child.

CASE 2. Frontal presentation; left oblique diameter; natural conversion into a face presentation; quick delivery; child living.

In 1855, while visiting at Bellevue Hospital in April, I was called by my house physician to see a woman who had been in labor for several hours. Primipara, aged 22, healthy appearance. On examination vertex on the left oblique diameter; anterior fontanelle could be defined; the left sacro-iliac synchondrosis space amply filled with the posterior part of the head; right foramen ovale space less occupied, and the finger could be moved freely over the front part of the head; the pains were regular and efficient. In half an hour the frontal bone was recognized dipping into the excavation. Shortly afterwards a face presentation was apparent. In half an hour the labor had terminated, child living and of usual size, as a face case.

This was the first time I had ever witnessed an occipito-posterior presentation become a face presentation. The delivery was easy; I had expected to have a tedious case of labor, and I was most agreeably disappointed at the favorable termination. It was a valuable practical experience at that time that further study and obstetrical observation has verified, that nature does so perfectly and so well accomplish her work in some difficult labors, when we little expect it.

It illustrated how correct the views and opinions of Guillemot were, and that there is a truthfulness respecting them which has been overlooked, in some

difficult cases, and which if not rectified, may have possibly proved unfavorable by other measures if they had been adopted.

CASE 3. Left occipito-posterior presentation; vertex at the superior strait; forceps failure; conversion into face; forceps delivery; child living.

During the spring of 1866, while visiting the Bellevue Hospital in company with a few medical brethren from the country, my attention was directed to a case of labor by the attending house physician. It proved to be an occipito-posterior position of the child's head on the left side, cervix amply dilated, vertex presentation. The posterior part of the head could not be reached, anterior easily recognized. The head had occupied this position for two or three hours. The forceps were used, traction for half an hour and then relinquished, even after decided efforts had been tried no progress was made. On the contrary, instead of any flexion, after the removal of the instruments the frontal bone was distinctly leading into the centre of the pelvic cavity. Recognizing the fact that nothing was to be gained by the reapplication of the forceps unless either flexion or extension was effected, I thought it would be better and more easy and simple to convert the frontal position into a face during the intermission of the contractions and retained there till after the contraction had ceased.

In the course of 15 minutes the face was well engaged in the pelvis, and slowly descending, the forceps were then applied, and in a short time the child was delivered living. This case has been introduced before in another published essay.

CASE 4. Left occipito-posterior presentation, vertex with the head well flexed. Forceps failure; vertex presentation at the vulva; manual conversion into a face by external manipulation on the perinæum; easy delivery; child living; weight, 9½ pounds.

Mrs. P. L., primipara, aged 22. Labor commenced March 10, 1882. I saw her with slight and irregular pains at 8 P. M. At 6 A. M. os uteri the size of half a dollar; labor progressing naturally; soft structures in excellent condition; head presentation, and believed to be an occipito-posterior presentation; pelvis appeared to be well formed. 8 A. M., head well flexed; os uteri two-thirds opened; occipito-posterior position well defined; membranes intact; during a pain the liquor amnii escaped, and the head passed through the cervix in that condition. 9 A. M., very little descent. 10:30 A. M., head has descended further down. I was in hopes that the labor would terminate very soon. 12 o'clock, no improvement.

Dr. Castle was sent for, and gave the anæsthetic; forceps applied; head brought to the inferior strait. The delivery required considerable traction. The instruments were then removed. Head slowly progressing, and well flexed, resting on the perinæum, with forehead against the internal part of the pubes; head entirely out of the osseous structures.

The perinæum, anterior and posterior, presented an extension from the coccyx to the fourchette, a measurement of 8½ to 9 inches, the width in keeping with the length. The fourchette was on a line with the lower part of the pubic arch. The appearance of expansion of the perinæum was certainly very for-

midable. The child's head seemed to be literally capped by the perinæum, very thin and tense. It looked as if the perinæum would be ruptured near the anus. Surgical anæsthesia produced. It was evident to Dr. Castle and myself that it was utterly impossible to try the forceps, owing to the excessive elongation of the perinæum caused by the extreme flexion of the head. The anterior fontanelle could be felt through the thin perinæum, an inch below the fourchette. Now, either nature had to accomplish the delivery by rotation, as it had in some of the cases I have referred to by waiting longer, or the attempt made to try and make it a face presentation.

During an interval of pain two fingers were placed on the posterior perinæum, just below the anus, when an effort was made to extend the head backward, performing the same evolution in the pelvis that the head does when it rides over the perinæum externally. The purchase obtained against the perinæum was retained during the contraction. After a few pains it was apparent the head was undergoing a marked change of rotation backwards. In a short time the eyebrows were felt, and on opening the vulva, the nose was recognized, and finally the chin escaped, and rolled under and over the pubic arch, and the child safely delivered as a face presentation; weight 9 pounds. There was not the slightest rent of the fourchette or perinæum.

No case could present a more clear illustration of the views of Guillemot respecting face presentations occurring from an occipito-posterior position, and to show how easy they may be converted into face artificially. Rectification by the two fingers on the frontal bone would have been impossible, owing to the extreme flexion. The marked extension of the perinæum precluded the use of the lever.

In contrast with manual aid in this and other cases being converted into face, and the application of the lever or forceps, and the time occupied, I would refer to Hodge, page 318, plate 23, figure 120, and to Woodale West's plates, in his essay on cranial presentations. I have no doubt that many cases of occipito-posterior presentations in the early part of the labor become face, and which nature redresses for the safe delivery of the mother and child, obeying in those cases the law, that when there is any active resistance, the head passes from that position, and assumes another, where there is more room and liberty by change of position as well as by flexion or extension.

Woodale West in his monograph on cranial presentations records an important case of this nature, although the flexion was by no means so great as some. As he was rebuked by his father for his officiousness in the management of the case, I will refer to it.

CASE 55, 1835. After severe pains for several hours, finally the orbit was at the pubes. I pulled down the head, and converted it into one of the face.

The labor was over in a few seconds.

West remarks: "I have often thought I was foolishly bold, being so young a man in practice. I should not now venture on such a plan. I would rather push the face back into the hollow of the

sacrum. My father, who was a practitioner, when I had related to him the circumstance, told me never to do so again."

A case previous to this occurred to West, which nature accomplished by making it a face. It was after the head had rested sometime with the nose at the symphysis pubis, the face itself came down, until the chin passed under the pubes, after which the labor was speedily over as a face presentation.

Other cases might be referred to.

On the contrary Caseaux informs us that he has seen the superciliary ridge just below the symphysis, and in another case he saw the eyelids, and these cases were delivered by rotation, the occiput passing over the perinæum. Several authorities among the more recent publications, tell us that the occipito-posterior presentations may possibly become face.

I am aware of no authority who avowedly advises the conversion of occipito-posterior presentations into face, instead of producing flexion, whether the head is at the superior strait, pelvic cavity, inferior strait or vulva in preference to flexion. It cannot, nevertheless, be called an innovation, for nature has instructed us, and we are only to imitate her teaching. The contour of the child's head, particularly the occipital part, and its size no doubt creates an advantage or disadvantage as to the prompt and easy delivery. Sometimes it may be elongated, and in other instances round and small, and the flexion in excess. Cases of brow and frontal presentation have by nature been converted into face.

In forehead presentation the prognosis is considered by some German authorities as very bad for the child. (No mention has been made specially to change this irregularity into a face, except in a cursory manner). The disproportion between the head and the pelvis by the long diameter of the child's head, and the duration of the labor, render in these cases the prognosis as equally unfavorable for the mother. If the forehead presents when the os uteri is sufficiently open, Schroeder advises, as well as others, to perform version. Hildebrandt insinuates that it is possible it might be converted into a face. In Massman's cases of forehead presentations out of 41 cases, 21 children were still-born.

Now what are the advantages or benefits arising from the manipulation and rectification of these occipito-posterior presentations, where the anterior part of the head is leading, and where there is only the slightest prospect of flexing the head, whether instrumentally or manually to make it an occipital presentation, as is usually done, than by converting it into a face presentation? Is the redressment unnecessary and more dangerous to the mother and child than by flexion. Why should this be the result? It is certainly more easy to accomplish the rotation by extension of the head backwards by the hand, or the two fingers on the frontal bone, than to attempt the rectification by flexion, when the occiput is farther back and looking upwards, and to make the rotation at the same time.

Extension may be performed in a few minutes. Flexion requires more time, and especially if instruments are used, with possible injury to the soft

structures of the mother. The argument that is adduced against converting these cases into a face, is equally as objectionable should flexion be attempted, for the fronto-occipital diameter prevails, as the head by either change will have to be rotated on the transverse axis of the child's head.

The form of the cranium and the face are nearly similar to each other. The obstetrical head is considered as entirely different from the anatomical, and the chin is the analogue to the occiput. The measurements of the different diameters are almost identical. When the head is extended the trachelo-bregmatic is half to three-quarters of an inch less, and when undergoing compression by the pelvic cavity may become still more so. The head differs but little when it is extended or flexed in its diameters. The fear and dread of face cases, is that the neck of the child may suffer from the extension should the labor be prolonged, and the congestion of the brain and face. I am not unmindful of the usually accepted view respecting the treatment of face cases.

Even at this day they are considered by some as being so unfavorable, that they resort to the redressment into occipital presentations in preference. The profession recognizes the correctness and truthfulness of Nagele's explanation respecting the frequency of occipito-posterior positions, and that they are as easily and as quickly, in the majority of cases, changed by nature into anterior ones.

With this view of the subject, when nature does not sustain the movement anteriorly of the child's head, they considered it was proper, legitimate and necessary they should attempt to correct the position by rotation by artificial means, whether by instruments or manually.

May I ask if it is not as correct, just as necessary, and judicious in the class of cases I have brought before you, to uphold the dictation of nature by redressing these presentations into a face, as by producing flexion, and which in many cases is so difficult, as various authorities have testified to from their own experience and efforts?

I fortify myself by the experience which nature has taught us, and from the writings of those authors I have referred to, as well as from my own practical experience after many years. The views and opinions I have presented may not coincide, but militate against the generally accepted doctrines and experience of the profession, that face cases are more unfavorable than the anterior or posterior cranial presentations, as 5 to 13.

Should this safe and prudent course of practice, as I firmly believe, be sustained in the class of occipito-posterior cases I have offered, and when the lever and the forceps have proved of no avail, craniotomy may have to assert her claim, unless the time is extended by trusting to nature, as we have seen in some particular instances, hoping that the head of the child may fortunately glide forward and terminate the labor, with, as I believe, faint prospect of success. It is only a "bird's eye view" I have presented on this important and practical subject. The time allowed for the reading of a paper is so limited, and very justly so, on such an occasion, that it necessarily precludes any

very extended and critical exemplification on such an everyday occurrence as the management of occipito-posterior presentations.

USE OF CHLOROFORM IN LABOR.

BY JNO. HERBERT CLAIBORNE, M.A., M.D., OF VIRGINIA.

Read in the Section of Obstetrics and Diseases of Women, of American Medical Association, May, 1884.

Since the introduction of chloroform by Prof. Simpson, of Edinburgh, nearly forty years ago, the use of that anæsthetic has not proceeded *pari passu* in obstetrical practice, with its use in surgical or even in general practice. I think I am safe in stating that the majority of the profession resort to its use only in severe or complicated labor, or in cases calling for manual or for instrumental interference.

From a study and record of more than two hundred cases of labor, mostly consecutive, in private practice, coming under my observation within the last few years, and in all of which chloroform was administered, I have derived the following conclusions:

1. The process of labor in all of its stages may be facilitated by the use of chloroform.
2. The duration of labor in all of its stages may be shortened by the use of chloroform.
3. The pains of labor in all of its stages may be entirely yet safely obtunded by the use of chloroform.
4. The accidents of labor in all of its stages occur less frequently under the use of chloroform.

That these conclusions, at least in their entirety, do not embody the views of the teachers of the profession is apparent in the last edition of Playfair's *Midwifery*, 1880. On page 288 of that book we read: "A common error is the administration of chloroform to an extent which materially interferes with uterine contractions, and predisposes to subsequent post-partum hæmorrhage." Again, on page 290—"we do not think of chloroform until the os is fully dilated, the head descending, and the pains expulsive." In other words—"we do not think of using chloroform until the second stage of labor has begun," and on page 291, "Bearing in mind the tendency (of chloroform) to produce uterine relaxation, more than ordinary precautions should be taken against post-partum hæmorrhage, in all cases in which it has been freely administered."

These views I entertained myself at one time—and the very conclusions which I have formulated for discussion in this paper I felt it my duty to combat in a public discussion before the Medical Society of Virginia some ten years ago.

I then believed that labor was oftener delayed than otherwise by the use of chloroform, and that the danger of post-partum hæmorrhage was always greater after the administration of that anæsthetic. And I was upheld and endorsed by more than one of the eminent medical men present on that occasion.

I now desire to confess and recant the error which I then held and promulgated. I came into practice just when the God-given boon had been first used and commended to the world by Simpson. I heard it denounced by a distinguished and revered preceptor as dangerous, cruel, and a criminal contravention of the Divine curse: "In sorrow shalt thou bring forth children." (Genesis iii, 13.) And though I used it at as early a date as any of my compeers, I used it for a time only in bad cases, and I used it hesitatingly—and as it were under protest—accepting it as an evil, but of less magnitude than the fearful complications of labor which called for its relaxing and obtunding effects. Since then I have learned to accept it as a boon—a benefaction beyond all computation, and now I believe that the conditions and circumstances should be very rare and very peculiar which would justify a practitioner in withholding its blessing from a woman in the agony of childbirth. Nothing gives me so much pleasure as the promise of that Lethe to the expectant mother when the fearful hour draws nigh, except the fulfilment of that promise, and her grateful expression of returning consciousness—"Is it indeed all over, and is my baby born?"

I cannot recall any accident which was the result of the use of chloroform in any case of labor in my own practice, nor do I remember to have seen recorded any such case in the practice of others, nor any fatal case of labor in which the untoward result was attributed to the use of that anæsthetic.

I regret that I have not a complete record of my own cases from the commencement of its use, which would now number many hundreds.

But several practical questions arise in discussing the propositions that I have submitted—and amongst them:

1. Should chloroform be administered in *every* case of labor? I reply, no. There are some cases of labor in which the pain is insignificant; some in which there is no pain. I have patients in my clientele who, in repeated labors have assured me that the process in no stage was painful; that the sensation amounted to nothing more than an operation from the bowels when somewhat constipated. In others the pain is so slight as to require no alleviation, and the process of delivery so prompt as to call for no interference. Such exceptionally happy cases need no further blessing. But such cases are indeed exceptional. As a rule, the act of parturition may be fitly termed, as it has been ever termed, an *agony*, from the Greek, a struggle as if in the pangs of death. Such pain appeals to every human heart for help, and every human instinct compels us to render it. Not only so, but the rational requirements of sound practice demand that we arrest at once this fearful suffering, this terrible irritation of the terminal nerves of that tender organ, which in the woman is the throne of the sympathies. *Ubi irritatio—ibi fluxus*; and what fatal changes wait upon those processes so easily and so rapidly converted from the physiological into the pathological! Dr. Dickson, of Charleston, used to say that he always tried to kill pain wherever he found it, as he always tried to kill a snake. Both are the enemies of the human race, hereditary, traditional,

implacable and mortal. Kill the pain and cure the patient. And what will kill pain so quickly, so thoroughly, and so efficiently as chloroform? Not only so, but in an instant you transport the patient from the throes of martyrdom into the ecstasies of the blest.

But secondly. Another practical question arises. At what time or at what stage of ordinary uncomplicated labor should we commence the exhibition of chloroform? Certainly not until labor has surely and unequivocally set in—not until the lips of the os uteri have thinned out, and the process of dilation unquestionably begun—not for those dragging, nagging pains—aggravating and distressing but not genuinely the pains of labor, only the precursor of those pains, and partaking of the nature of neuralgia of the sacral plexus and its diversified connections. Chloroform would nullify these pains too—as it does all other pain when pushed to its limits. But we do not propose to administer chloroform for mere neuralgia. For these pains we rely upon bromide of soda or potash, and the hydrate of chloral, twenty grains of each every hour until a drachm of each is taken, if so much be necessary to secure relief; the former agent for its especial action upon the spinal centres, and the basic ganglia; the latter for its effect upon the higher centres of cerebral origin, a combination of rare power and one which has rarely disappointed me. Chloroform administered under these circumstances, doubtless does retard labor, and postpones all of its processes. But withheld until the process of dilation has clearly begun—or better, until the circumference of the os has attained to the size of a half dollar, and the use of the anæsthetic will not only facilitate, but will hasten the act of opening to completion. More than that, it will obtund and render enduring those trying pains that inaugurate and accompany the first stage of labor, and which many women declare to be more harrowing than the agony and throes of the second stage.

And in the first stage it is not always, indeed it is not often necessary to push the anæsthetic to the induction of unconsciousness. Administered even in very small quantities, it assuages these pains to an extent which enables a woman to bear them with patience. In this stage it is best that it should be given intermittently—be given as the pain comes on and be taken away as the pain goes off.

Should the os, however, prove especially stubborn and refuse to dilate, then chloroform to the extent of inducing complete anæsthesia, will often relieve the difficulty by bringing on relaxation of the circular fibres. It will generally do so, and thus may often obviate the necessity of antimony or venesection, even in the plethoric and full-blooded. It will very rarely fail to do so, if preceded by a full dose of chloral and bromide of potash.

But now, when the first stage has terminated, when the os is fully dilated, and the head of the foetus commences its descent through the pelvic passage, a condition of things which the experienced accoucheur can often recognize without vaginal examination, by the subjective symptoms, by a change in the character of the complaint made by the patient, or by a sort

of a lull in the storm—the woman realizes as a rule, a temporary relief, and often falls into a short sleep—very short it may be, but very refreshing. In this state, what shall we do with the chloroform? may be asked as a third question.

Take it away, of course. Dispense with the anæsthetic for a shorter or longer time, according to the urgency of the recurring pains. Some women, in whom the expulsive pains of the second stage are merely expulsive efforts, and no pains, and who do not dread this stage of labor at all, call for the chloroform no more. In such cases no anæsthetic is necessary, and if not necessary, its administration, of course, is not judicious. But unfortunately for humanity, these painless cases of labor are not often seen in the obstetric chamber. Generally, when the hard head commences its downward career through the pelvic arc, pushing along, crushing along against the irritated nerve plexus lining that sensitive channel, and caught by a resistant perinæum is hurled back time after time, then the true agony is begotten, which calls for human sympathy, and demands human help. What heart so hard as to withhold chloroform in that hour of bitterness and despair! And in that last fearful pain, invoked by a long-suffering perinæum, just as its last attenuated fibres are stubbornly yielding to the force of those final throes, which threaten in their violence, the very dissolution of nature, who can stand idly and unmoved, and yet know that he holds the remedy for it all in his own hand? Not I. Nor am I satisfied now to assuage the suffering. I abolish it. Chloroform then, as the bleeders say, *ad deliquium animi*. I give it to full unconsciousness. Nor have I ever seen it arrest or delay the labor in this event. I have often thought it gave full play to, if it did not help the expulsive efforts at the last. At the same time it relaxes the perineal tissues, and diminishes the danger of rupture. I have never, except on one occasion, seen a torn perinæum under the full influence of chloroform, and that occurred from the careless handling of a pair of long forceps.

I can only account for this fact of muscular relaxation and tissue relaxation under the use of chloroform, and yet persistent and increased uterine action, on the ground that the diminished sensitiveness of animal function more readily permits if it does not increase organic or ganglionic action.

I have had a patient say to me more than once, "Doctor, give me enough chloroform to *prevent* my feeling the pain, and I can bear down better. I can't help bearing down." What does that mean, and what does that teach?

The most striking illustration and the most positive proof which I ever had of this fact, I derived from the case of a lady whom I once attended in a condition of intoxication. She had had at two previous labors most painful and tedious delivery—under use of instruments—and some wise person had told her that if she "would drink half a pint of the best whisky, just as her next labor begun, that she would not get drunk, and yet that she would not feel her pains!" I was called to her some 15 minutes after she had taken the whisky, and was told by the nurse what had occurred. She was even then too much

under the influence of the potion to recognize me or to speak to me, and soon after passed into that semi-comatose state known as dead-drunk. An examination revealed the os dilating. I remained by her side for six hours, and during that period every stage and process of labor was consecutively and regularly developed and completed, and the child born alive and well! Yet, with the exception of uterine dilatation and contraction, and general muscular contraction attendant on the expulsive effort, there was no more manifestation of life in the woman than could be seen in the delivery of a manikin!

Not one sound or cry was made, nor was there the slightest facial expression of pain, or of any other emotion, during those six long hours, nor for six hours afterwards; nor when, after some difficulty, she was finally restored to consciousness, did she remember or could recall one single incident of her accouchement, except, that "on a friend's advice, she had drunk the liquor, after preparing her bed." I had attended this lady before, and I have attended her in several consecutive confinements, but I have never known her to have so safe and so unexceptionally a normal labor as on that occasion.

I do not, of course, intend by these remarks to endorse the use of the anæsthetic which she adopted, or to commend the use of any anæsthetic to the extent to which she carried it, but draw the logical and inevitable conclusion that *anæsthesia, even to the utter abolition of all signs of sensibility, may be safely induced, and that it does not necessarily arrest or retard the obstetric process. More than this—it does not prevent, but does, in my experience, incite firm uterine contraction, sometimes to an unpleasant extent in the third stage of labor, thereby diminishing the risk of post-partum hæmorrhage, by expelling uterine clots and facilitating uterine involution.* I mean by this statement to say that, in many cases in which I have used chloroform most freely, in the first and second stages of labor, the third stage was marked by unusual and persistent uterine action—the patient exclaiming in several instances: "Doctor, I cannot stop bearing down; I feel as if I should be compelled to force the womb through the pelvic 'passages.'"

And now arises another practical question: Should the use of chloroform be continued in the third stage of labor? As a rule, I answer, no, but in exceptional cases, yes. In puerperal convulsions, for instance, it is the sheet anchor of the accoucheur, and I know of no remedy which can replace it. Venesection in the plethoric and chloral hydrat. in all cases, are most valuable adjuvants in such complications; but, if confined to one sole remedy, I should select chloroform. Theoretically and practically it meets every indication. In cases of retained placenta with rigid closure of the os, and in cases of hour-glass contraction I can conceive of circumstances which might justify or demand its exhibition. I have no experience of its use in either case. Finally, that, in all cases of complicated labor, demanding manual or instrumental interference—turning, or the use of forceps, or perforation, anæsthesia is imperatively demanded, admits of no question. All are agreed, I presume, upon that subject.

It only remains to enquire what form of anæsthetic shall we adopt. In every instance in which I have used the word I have wished it to be understood that I meant *chloroform* pure and unmixed, such as that prepared and furnished the profession by Dr. Squibb, of Brooklyn. I think it vastly better than sulphuric ether in obstetric practice for the following reasons: 1. It requires a much smaller quantity of the agent to induce the same amount of anæsthesia. 2. It produces the same degree of anæsthesia in a much shorter time. 3. It acts with much more certainty. 4. It is not followed by the nausea and vomiting which are so frequently the results of the use of ether. 5. It does not act so often as a stimulant, inducing the peculiar intoxication or hysterical excitement which is common in the exhibition of ether.

I have been surprised, however, to read in a note by the American editor of Playfair's *Midwifery* (last edition, p. 291), that "In the United States chloroform is rarely used in obstetric practice, as compared with pure sulphuric ether, and anæsthesia is much less practiced than it was soon after its introduction." This certainly does not accord with my observation or experience. I cannot undertake to speak as he does for the whole "United States." But I am sure that when he speaks for the geographical section of that country which I have the honor to represent, he speaks without the book. In general surgical practice we use less unmixed chloroform, preferring in many instances either the washed ether, or a mixture of that with chloroform and alcohol—something like the Vienna mixture; but we have not discarded the use of chloroform even in general practice by a large majority. In obstetric practice I do not know of one physician who substitutes chloroform by ether. I have occasionally used it, for the reason that it was not convenient to procure the chloroform and the ether was at hand; but I can see no especial advantage in the use of ether, but the marked disadvantages which I have enumerated. Besides, if, as the editor before referred to contends, inertia of the womb occasionally follows the use of chloroform, it must also follow the exhibition of ether likewise, (*loc. cit.*, p. 292), and we are not the more apt therefore to have post-partum hæmorrhage after the one than after the other. In addition, though under the one of chloroform in general surgical practice many a death has occurred, or rather been published, who has witnessed or recorded a death from the use of chloroform in obstetrical practice?

Now, whilst I am unwilling to array myself anywhere in this discussion, anywhere except on the side of safety and conservatism, yet, before the announcement of the American editor of Playfair's *Midwifery* be accepted as authority, I would urge that the profession at large earnestly and generally enquire into the truth of the propositions which I have had the honor to submit for the consideration of this learned body.

And if woman is to be robbed of this inestimable boon in her hour of agony, and the lying-in chamber is to be reconverted into the hall of torture, let me meet her there with the painful and sorrowful as-

surance that wiser men than I have decreed that she must submit to the irremediable and the inevitable.

30 Union St., April 25, 1884.

DISCUSSION.

Dr. Robertson, of South Carolina.—Mr. Chairman: I would like to ask Dr. Claiborne as to the effects of chloroform upon the fœtus. Does the fœtus ever suffer?

Dr. Claiborne.—I have never seen any instance, sir, in which it did.

Dr. Robertson.—I have seen it, undoubtedly.

Dr. McKenzie, of Illinois.—Mr. Chairman: My experience with the use of chloroform is in perfect accord with that paper. I would like to ask the author of that paper whether he has noticed the effect of chloroform in promoting the secretion of the parts, thereby converting what is termed a dry labor into a moist? That has been my experience.

Dr. Claiborne.—I think that is so; a softening of the parts occurs.

Dr. Jepson, of West Virginia.—Mr. Chairman: I hail from the western part of the State represented by the gentleman who has read the paper, and in an experience of 15 years in the new State, I have not found a case of an agony such as has been described so eloquently and pathetically by that gentleman. [Laughter.] On the contrary, every year I practice medicine I am the more impressed with the ease with which a large majority of my patients give birth to their children, and the very short time that is required for the obstetric physician to be present with his patient. It is a common thing to be called to attend a woman and to find upon arrival at her house, that the child has been born.

Now, sir, I commenced my career by the use of chloroform in labor, and I find that sometimes chloroform does induce hæmorrhage, and sometimes lessens the uterine contractions. I remember one case where the patient said to me, after inhaling chloroform for a very brief period: "Why, doctor, what is the matter? I cannot bear down;" and the experience was repeated every time the patient inhaled chloroform. And as you all observe, there is a certain class of cases where chloroform cannot be given because it interferes with the delivery.

From my brief experience I have found that there are cases where the use of chloroform is necessary, but I would limit its use to those cases where unusual agony is endured. I would say, in conclusion, "Let Nature do her perfect work." She is competent to do it, and my patients are perfectly willing that she shall do it. And before I sit down I would like to ask the gentleman who read the paper what was the condition of the child that was born as he has described?

Dr. Claiborne.—I stated that the child was born alive, and it lives yet.

Dr. H. C. Ghent, of Texas.—Mr. Chairman: I did not desire or intend, a few moments ago, to make any remarks upon this subject; but I cannot allow, sir, the time to pass without making a few remarks upon this, one of the most important subjects that

can engage the attention of the American Medical Association, or that of any other country.

I do not know, sir, what kind of pains the women in West Virginia have, but I want you all to know that the women in Texas suffer the same old pains during parturition!

Having been taught by Dr. Charles D. Meigs, of Philadelphia, not to use chloroform, for a number of years after I began the practice of obstetrics, I was afraid to have a bottle of it in the house. [Renewed laughter.] But, after many years of labor in this field, in which I had been the witness of so much pain and anguish during parturition, I at last ventured on the use of this anæsthetic in some of the most painful cases of childbirth. The early teachings of the illustrious Henry Miller, of Kentucky, had something to do with this test. I used chloroform, at first, gradually, advancing a step at a time, until now (and for the past fifteen years) I use it in every case of labor, whether natural or preternatural, unless the woman positively refuses to take it.

When the woman has passed the first stage of labor and says, "Doctor, can you do something for me?" I always thank God that, through the science of chemistry and the discovery of Sir James Y. Simpson, whose name is immortal, I am enabled to reply "Yes!" and to carry her safely through the agonies of her parturition! [Applause.]

Now, sir, a great deal has been said about post-partum hæmorrhage. I desire to say that the most frightful cases of this character I have ever had to contend with occurred in my practice before I began the use of chloroform, and that no serious or alarming case has ever taken place since I began its exhibition. My honest convictions are that, if chloroform were more frequently resorted to in this branch of practice, the gynæcologist would have much less work to do in this country, for there is no doubt in my mind but what chloroform does tend to prevent lacerations of the perinæum; and I therefore most heartily endorse nearly the whole of the valuable paper just read by the gentleman from *Old Virginia*! [Applause.]

Dr. Parsons, of Pennsylvania.—Mr. Chairman: I want to say that I agree with the gentleman from West Virginia, who is opposed to chloroform in parturition, except in instrumental cases, and in cases where there is a great deal of suffering. I infer from the remarks of the author that he is in the habit of using chloroform in every case of labor. I want to ask him whether, in a case where there was disease of the heart, he would first make an examination; whether, if he suspected there might be fatty degeneration of the walls of the heart, he would still use chloroform with impunity.

Dr. Claiborne.—The gentleman has misunderstood me. I said there were cases in which it should not be used.

Dr. Jepson.—Mr. Chairman: I wish to say another word, in order to disclaim the charge of abusing chloroform. On the contrary, I never attend a case of labor without a bottle of chloroform in my pocket for emergencies.

Dr. Van Annem, of Missouri.—Mr. Chairman: I

would like to ask this question: Who is to administer the chloroform? I usually find in my management of cases of labor that about the time the final throes come on, when the head is about pressing on the perinæum, and the last agony is upon the woman, I have about all I can do to attend to the woman, and it is rare indeed when you have an assistant in the shape of a lady or the woman's husband that, at that critical period, is competent to administer chloroform.

The ground I take in the administration of chloroform in labor is this, and it is probably a question of policy on my part, you might say. The great public has not been educated up to the point that chloroform ought to be used in all cases of painful labor; and in those cases where you ought to administer chloroform, if there should be any exceptional trouble afterwards, some meddlesome person in the neighborhood will assign the whole trouble to the use of chloroform and blame the doctor! [Laughter.] I administer it carefully after labor has commenced, but I would not positively insist upon any woman taking it, but if asked, I would advise her to take it, provided there was nothing the matter with the heart. I have found that in every case the use of chloroform facilitated the labor. My experience is that no bad results have ever followed in any case the administration of chloroform in labor; and no woman has ever taken chloroform in my practice that did not desire to take it again.

Dr. Wathen, of Kentucky.—Mr. Chairman: If I understood the author correctly, he stated that chloroform, in his experience in a great many cases, has never retarded labor; that the woman "bore down" better, as he expressed it, and that it always prevents rupture of the perinæum. I am an advocate of the use of chloroform in labor, but I do not see how any one with an extensive experience in the use of chloroform, will say that labor is never retarded. I have had cases where the uterus had contracted well and regularly. After I gave chloroform, the uterus almost entirely ceased to contract. I stopped the chloroform, and the uterus again contracted well. If I began the use of chloroform again, the contraction ceased. And I am sure that cases of this sort have been met with in the practice of most obstetricians. I do not see how these patients can "bear down" better. Certainly, chloroform, when given to an extent that will prevent the pain of labor, partially paralyzes the contractile powers of the auxiliary forces.

That chloroform in labor tends to prevent lacerations of the perinæum cannot be disputed, but no one of extensive experience will deny that lacerations may and do occur, where the anæsthetic is judiciously and scientifically used.

Dr. Danford, of New Hampshire.—Mr. Chairman: I would like to ask of the gentleman who read the paper if, in anæmia of the brain, he would give chloroform, or to prevent congestion, in combination with the iodide of potassium.

Dr. Claiborne, in reply.—I am certainly very much obliged to the gentlemen who heard me so patiently,

and who have criticised me so leniently; and I am sorry if I should have been misunderstood in some of my remarks. Possibly I was, and as far as practicable, I will right myself now in a very few words.

I do not wish to be dictatorial or dogmatical. I am seeking for the truth, as I believe you all are, in the interest of that great humanity whom we represent. I was very anxious to appear before this body, and take the opinion I have taken to-day, because, as I have announced, I had ten or twelve years ago taken a different opinion, when my experience was less large and I had not used this anæsthetic to the extent I have now used it.

And, first addressing my remarks to the lady (Dr. Danford, of New Hampshire), who did me the honor to ask a question of me, I should say that the use of the iodide of potassium —

Dr. Danford.—I thought you spoke of the bromide of potassium.

Dr. Claiborne.—Well, I understood you to ask me whether I would not use chloroform in combination with the iodide of potassium. However, I will say that I would prefer, in the case of cerebral anæmia, neither bromide of potassium nor chloral.

As to the question of the gentleman from Pennsylvania (Dr. Parsons), I would say, that where there is heart disease, valvular disease or excessive dilatation of the heart, or enlargement of the heart, of course in a man's professional practice he is apt to be apprised of those facts, and an intelligent practitioner will apprise himself of those facts before he administers chloroform.

As to the question of the gentleman from Missouri, (Dr. Van Annem), I might say that I generally have experienced nurses, and it is to their hands that I ordinarily give the administration of chloroform, but I should not hesitate in the final throes to administer it myself. I can do it with my right hand;—I might say here that, in the case of labor, my left hand never comes off the womb until the birth of the child.

And as to the question of the gentleman from Illinois (Dr. McKenzie), I will say that I have seen dry labor converted into moist by the use of chloroform.

Dr. Wilson, of New Jersey.—Mr. Chairman: I would like to ask the gentleman if he would follow the use of the bromide of chloral in the first stages of labor, with the use of chloroform, and, if so, if there is not danger of paralysis of the heart. I ask this question, because I have seen bad results;—where the bromide of chloral caused paralysis of the heart and immediate death. And I think, sir, that it is a dangerous thing to establish a custom of giving that deadly drug, bromide of chloral, and then to follow it by the use of chloroform. I think the profession cannot be too careful on that subject.

The Chairman here announced that, in consequence of the lateness of the hour and the number of papers yet to be read, he was forced to close the discussion.

MEDICAL PROGRESS.

MATERIA MEDICA AND THERAPEUTICS.

CAMPBOR INHALATIONS IN CORYZA.—Dr. G. E. Dobson writes to the *Lancet* advising the following: About a drachm of camphor, coarsely powdered, or shredded with a knife, is placed in an ordinary shaving jug, which is then filled with boiling water. The patient having made a paper cone (out of a sheet of brown paper or an old newspaper) large enough to surround his face by its wide extremity and the mouth of the jug by its narrow end, proceeds to respire freely, at each inhalation drawing the steam into his nostrils, and at each exhalation forcing it up against the outer surface of his nose and adjoining parts of the face. A twofold action is produced: the camphorated steam acts internally in a specific manner upon the whole extent of the mucous surfaces, and externally, produces profuse diaphoresis of the skin covering the nose and sides of the face, these acting as a derivative from the inflamed Schneiderian membrane. The jug should be surrounded by a woollen cloth in order to prevent the water cooling, or, better, if a tin shaving-can be used, a small spirit lamp or heated iron may be placed beneath it, so as to maintain the heat of the water and the vaporization of the camphor. The patient should continue his respirations (keeping the margins of the base of the paper cone closely applied round his face) from ten to twenty minutes, and this should be repeated three or four times in as many hours, till entire freedom from pain is experienced. Great relief is usually felt even after the first application, and three or four usually effect a cure.

MILK DIET IN GASTRIC ULCER. M. Debove has lately lifted up his voice against the common practice of putting patients with ulcer of the stomach upon an exclusively milk diet. He argues that the quantity of fluid required is so great that a dangerous dilatation of the stomach is produced, thereby leading to hæmorrhage, and cites one case of death so caused. His plan is to give about six drachms of beef powder with two and a half drachms of bicarbonate of sodium. This, he found, is passed directly into the intestine, undergoing no change, and causing no irritation in the stomach. In addition about a quart of milk with saccharated lime is allowed each day. M. Debove states that this mode of treatment has given him great satisfaction in a number of cases.—*Gazette des Hôpitaux; Practitioner.*

ON THE TREATMENT OF PHTHISIS PULMONALIS BY THE MULLEIN PLANT.—We have already referred to Dr. Quinlan's views on this subject in the previous pages of Medical Progress, *vide* vol. 2, p. 234, JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION. Now we find that he has read a paper before the International Medical Congress, in which he gives cases and treats of the subject somewhat *extenso*. It is published in the *Dublin Journal of Medical Science*.

From time immemorial the Irish peasantry have re-

garded this plant as an unfailing cure for consumption; and thus it is that an herb, which in England, France and Germany is a mere wild weed, is in Ireland carefully cultivated on a very large scale. It is in constant demand, it is advertised in all the journals, and, in fact, forms an article of ordinary commerce. There are five mulleins, all belonging to the natural order of *scrofularaceæ*; but the one in question is the *Verbascum* Thapsus, or great mullein, which is known in France as the *motène bouillon blanc*, and in Germany as the *kleinblumiges Wollkraut*. The best results are obtained with the green leaves, which can be procured during seven or eight months of the year; but excellent effects are produced by the dried leaves also.

The method employed by the Irish peasantry is to take 100 grammes of the fresh green leaves (or about 30 of the dried) and place them in rather more than one litre of fresh cow-milk. This is brought to a boil, and allowed to stand for 10 minutes. The hot fluid is then filtered, is slightly sweetened, and is drank while warm. This whole quantity is taken twice or, in some cases, three times a day. It has a soothing pectoral effect, and, after a little time, is much liked by the patient.

Dr. Quinlan has treated 127 cases with the mullein leaf solely, with one trifling exception. Previous to commencing treatment, each patient was carefully weighed, and this weighing was repeated every week, with great attention to uniformity of conditions as to time, clothing, meals, etc. The symptoms and physical signs of each patient were accurately noted, and the results tabulated. This has led to the following conclusions:

1. In the early and pretubercular stage of pulmonary consumption mullein has a weight-increasing and curative power greater than that of cod-liver oil, and nearly equal to that of Russian koumiss. It has been experimentally proved that this is due to the mullein, inasmuch as the milk alone fails to accomplish the same results.

2. In cases in which tubercles are well established, or cavities exist, the mullein has a great power in relieving cough. In fact, such a patient taking it requires no cough mixture at all, and every practical physician will recognize the great boon which this power confers on the phthisical sufferers, whose stomachs are often hardly able to receive alimentary sustenance. Indeed, the mullein milk is looked on by them more as a food than as a medicine. In persons of very feeble digestion heaviness is often experienced after so much milk. This, however, can be completely relieved by allowing the boiled mullein milk to cool down to 50° C., and adding a teaspoonful of pancreatic fluid. It should then be left under cover for 10 minutes.

3. Phthisical diarrhœa is completely obviated by the mullein. This is, no doubt, aided by the milk, but also occurs when the mullein is prepared with water.

4. All the symptoms of pulmonary consumption can be combated by the mullein, except colliquative perspirations. Over them mullein had no influence, and the hypodermic injection of the atropia sulphate

was used. This is the sole exception in the mullein treatment.

5. Mullein smoke applied directly to the respiratory passages has a great effect in relieving irritation and spasmodic coughs, and coughs in general. The dried leaves of the mullein are broken up fine, and are smoked in an ordinary pipe, either pure or mixed with a little tobacco to flavor them. Very elegant cigarettes are prepared for this purpose. These are of two kinds: (1) mullein, flavored with a little Turkish tobacco; (2) for those to whom tobacco is disagreeable, mullein, flavored with a little oil of cascarilla.

It is worthy of remark that very young mullein leaves have a dangerous resemblance to young foxglove—so much so that an experienced gardener has been known to put a young plant of the latter into a mullein bed. Full or even half-grown mullein and digitalis are not the least like each other. Dr. Ernest Knowling reports a case where belladonna leaves got accidentally mixed with mullein, and produced serious, but happily not fatal, results.

MEDICINE.

ON THE ACTION OF A SECRETION OBTAINED FROM THE MEDICINAL LEECH.—Prof. John B. Haycraft has given in the Proceedings of the Royal Society some very interesting results of his investigations into this subject. It has long been a difficult problem to solve in the study of the coagulation of the blood, as to why the blood stripped from the leech after his application to man in "leeching" should remain fluid, and why there should be a tendency to the oozing of liquid blood from leech bites. Dr. Haycraft acted upon the idea that probably the leech secretes some ferment-containing juice which antagonizes the blood ferment, thereby preventing coagulation within its body, and enough remaining around the edges of the wound to prevent the outflowing blood from clotting until the leech ferment is all washed away.

To decide this question, the gullets and buccal cavities of leeches were taken, cut in small pieces and placed in a salt solution, resulting in an extract of leech of a faint greenish-yellow tint and an alkaline reaction. This was found, when applied to freshly drawn blood, to prevent coagulation. The extract was then boiled, but its characteristics remained unchanged, showing that it was not a ferment? Its active principle is insoluble in chloroform, ether, benzole and alcohol, and could not be separated in a pure form.

The blood-coagulating ferment was then separated carefully from blood, and one part (*a*) treated with distilled water, the other part (*b*) with leech extract. On being added to hydrocele fluid *a* produced a satisfactory clot, *b* not producing coagulation. Hence the action of the leech extract is to destroy the blood-coagulating ferment.

Fresh blood mixed with leech extract and placed under the microscope showed that while coagulation was prevented, the corpuscles were not influenced, the red forming rouleaux as usual, and the white ex-

hibited the normal amœboid movements. Careful microscopical examination of the parts of the leech involved failed to show any glandular structure. The secretion is probably derived from the epithelial cells lining the sucker and buccal cavity; it may be that unicellular glands of the sucker share in its production.

The injection of this leech extract into the veins acts similarly to the injection of peptones in the non-coagulability of the blood, acting on dogs and rabbits alike. In the coagulation of milk it has no influence, but it hastens the coagulation of myosin, and probably when it causes loss of contractility in a muscle, it is due to this fact inducing rigor mortis, the essential phenomenon of which is clotting of the myosin.

A FACT IN HYPNOTISM.—M. Beaunis, Professor of Physiology to the Faculty of Medicine at Nancy, records an extraordinary case under the above title. The patient was a girl aged 12½, and was suffering from her fifth attack of chorea. M. Beaunis had been informed by Professor Birnheim of the result of hypnotism in a similar case, and decided to have it tried. A Dr. Siébault was the agent to hypnotize the patient. The result was that as soon as the child was hypnotized all choreic movements ceased, and when asked to write, instead of meaningless scrawls, her writing was steady and legible. The seances were continued for some days, and the child was cured completely. M. Beaunis says the facts require no comment.—*Gaz. Med. de Paris, Edin. Med. Jour.*

DOES REFLEX PARALYSIS OCCUR?—Dr. C. J. Nixon has read a very interesting paper on this subject before the Academy of Medicine in Ireland (*Dublin Journal of Medical Science*), in which he claims the following:

1. That those cases of paralysis of the orbital nerves and of amaurosis following affections of the fifth nerve, which have been adduced as instances of reflex paralysis, arise either from an extension of neuritis from nerve to nerve, or are instances of coincident affections of different nerves.

2. That we cannot admit the occurrence of paraplegia in urinary disease as a result of spasm of the blood-vessels of the spinal cord.

3. That if reflex paralysis have any existence, it is a paralysis by inhibition.

4. That there is no necessity for the admission of such a phenomenon as reflex paraplegia, as the cases recorded as such belong to forms of either neuritis or myelitis. The fact that many such cases recover rapidly is no argument against this view. There is no reason why a process of rapid repair cannot take place in nervous as in other tissues.

5. That the three conditions of peripheral irritation which give rise to paraplegia of the lower extremities are diseases of urinary organs, dysentery, and certain affections of the womb.

6. That these conditions give rise to paraplegia in three different ways. (a) by an ascending neuritis which sets up a myelitis; (b) by extension of inflammation to the cord along the veins from the primary

source of disease; (c) by the occurrence of a descending neuritis starting in the sacral plexus, and extending downwards along the sciatic nerves.

AGUE IN THE FŒTUS.—Dr. Rudolph Albrecht, Prosector to the Obuchoff Hospital, St. Petersburg, describes in the *St. Petersburger Medicinische Wochenschrift* (*British Medical Journal*) two cases of ague in the fœtus. Both were in the seventh month of uterine life; and in one case the mother had been seized 12 days, and in the other 38 days, before confinement, with high fever, rigors, and profuse perspiration, with intervals of defervescence lasting several days. In each case the spleen of the fœtus was enormously enlarged, and very hard and brittle. In the first case, a great number of motionless spirochætae were found in the blood. The infection of the fœtus, and consequent development of one of the chief pathological features of ague, was thus evident; and the presence of the special organism made one case complete. Dr. Albrecht believed that the spirochæta might have passed in its perfect form through the placental vessels into the foetal circulation, but that it more probably entered the fœtus as a spore. Careful comparison of the two cases led him to the conclusion that the ague first seized the mother after the usual five to eight days of incubation; and then, giving her the power to infect her unborn offspring, it thus passed to the fœtus, which also passed through a separate period of incubation.

SURGERY.

EXTIRPATION OF GOITRE BY MEANS OF THE ELASTIC LIGATURE.—Dr. S. Usiglio reports the case of a patient, aet. 56, who had enlargement of the thyroid body due to hyperplasia of the left lobe, in which the enlargement was removed by means of the elastic ligature. The part came away in five days and the patient recovered easily. Two months previously, in March, 1883, Dr. G. B. Masta had successfully employed the same means for the removal of a pedunculated tumor. De Vecchi and Castelleone have also reported cases. An incision is made into the skin, in which the ligature is placed, the wound being disinfected and the ligature tightened daily.—*Gazzetta degli Ospitali; Practitioner.*

RENAL SYPHILIS.—Dr. Negell, in his inaugural thesis (*Journal of Cutaneous and Venereal Diseases*), gives an admirable resumé of this subject.

1. Syphilis in any of its stages, may affect the kidneys; the same is true of hereditary syphilis, in infantile or adult life.

2. Certain renal complications are precocious, others late. The first, only studied within the last few years, manifest themselves in the first months after infection with all the characteristics of the nephritis of the infectious fevers; when the *début* of the chancre dates back several months, the clinical history of the affection is similar to cases of glomerulonephritis which are seen in scarlatina, for example.

3. Syphilitic nephritides occurring in the second-

any stage, are always grave accidents, nevertheless they are curable, not only in the acquired syphilis of adults, but also in the hereditary syphilis of childhood. Their gravity appears to bear a certain relation to the age of the syphilis, and the time which the patients have been subjected to specific treatment.

4. Albuminuria being the principal symptom in the examination of these renal accidents, we understand how specific nephritis may pass from view before the other secondary accidents of syphilis.

5. When œdema appears and is sufficiently marked to attract the attention of the patient and physician, another cause is generally assigned to it, so that syphilis is readily eliminated from the diagnosis.

6. These albuminuric patients being improved under the influence of specific treatment, and taking no further care of themselves after the secondary accidents have disappeared, the renal lesion may slowly pursue its course, and when later the patient comes under the care of the physician, it is more than probable that his suspicions will be directed to another cause than syphilis, especially since it so often happens that the patient declines to confess to a disease which he has every interest in concealing. It is necessary then, when a patient comes under the physician's care with all the symptoms of an acute or chronic nephritis, and the etiology generally adopted proves doubtful, to think of syphilis and institute specific treatment. If the patient bears any traces of syphilis (either upon the organs appreciable to view, or in the viscera, nervous centres, liver, etc.), these accidents only confirm the diagnosis of a syphilitic renal lesion.

7. Precocious syphilitic albuminuria is generally persistent and of quite long duration. There remains a question of extreme importance to be resolved: what will be the outcome, in a time more or less remote, of the secondary syphilitic nephritides considered as cured? The presumption is probable that a certain number of cases of Bright's disease may be the recurrence or later termination of this primary disease of the kidneys (precocious syphilitic nephritis).

8. Specific treatment gives the same results as in the other precocious accidents of syphilis. Milk diet should be regarded as a simple adjuvant but not recognized as a necessity.

9. Renal complications occurring in an advanced stage of syphilis (tertiary and quaternary accidents) exist, presenting sometimes the character of acute or chronic Bright's disease, sometimes the characters of amyloid degeneration; in the last case, he thinks with Wagner, and contrary to the opinion generally held, that the amyloid kidney is a consequence of syphilis, and not of a concomitant suppuration or of a mercurial or venereal cachexia, for cases occur in which there is no suppuration, and the patients, far from being cachectic, are on the contrary quite vigorous.

10. These specific renal alterations are more grave than those which appear in the first years of syphilis. Nevertheless they may be benefited by specific treatment, the sole condition being that the renal lesion

be not too far advanced; for, as in the case of the nerve-centres, we cannot rebuild the tissues.

11. Gummata of the kidneys, although quite rare, exist; but no pathognomonic symptom reveals their presence during the life of the patient. It is probable that anti-syphilitic treatment would have the same results as in gumma of other viscera.

CERVICAL HERNIA OF THE LUNG.—Dr. Mariani reports the following case in the *Revista de Medicina y Cirurgia Practicas*; *Journal d'Accouchements*, of a man 45 years of age, lymphatic, tall, in good health. When at rest his neck looked natural; but when taking active exercise or coughing, a globular tumor presented itself at the right latero-inferior portion of the neck (supra-clavicular region) which increased in size with each profound inspiration; particularly in the paroxysms of coughing did it become longer and larger, extended toward the median line, and involved the opposite side until, after repeated efforts at coughing, the neck was swelled to the size of the head. After cessation of the provoking cause, the neck resumed its normal dimensions. This singular phenomenon commenced to show itself at the age of fourteen years.

RAPID CURE OF SIMPLE CHANCRE.—Dr. Barthélemy gives in *L'Union Médicale*; *Jour. de Med. de Paris*, the method employed by Hebra, of Vienna, and which consists in washing carefully the penis of the patient with warm water, oil and soap, so as to remove all traces of previous treatment, and such topical applications as might form caustic combinations with salicylic acid. Then the salicylic acid is applied so as to cover only the chancre and a very small peripheral zone, this is kept in place by a thin layer of wadding, and covered by a strip of adhesive plaster. The application is made once daily if suppuration is not very abundant, if it be, twice daily, morning and evening. By the third day an eschar is formed which is deep enough to destroy all the evidence of the ulceration; then the salicylic acid is stopped and a simple ointment, such as adeps prep., is used spread on linen. Ordinarily the eschar comes away in half a day, leaving behind a simple lesion deprived of all virulence and healing in two or three days.

OBSTETRICS AND GYNÆCOLOGY.

THE INFLUENCE OF AGE ON PREGNANCY, LABOR AND INFANTS.—M. H. Courtade publishes an article on this subject in the *Archives de Tocologie*, which he sums up as follows:

Pregnancy.—1. Delay in the first conception often has for its cause a sort of paresis of the genital functions, as demonstrated by the tardy establishment of the menses, and by their irregularity.

2. Possibly the vices of conformation of the pelvis and of the vertebral column, most frequent in the older primiparæ, may be a cause of this delay, in the sense of constituting a material or moral obstacle to coitus.

3. Twins are frequent with the older primiparæ, and seem to increase in frequency with age.

4. Morbid complications occurring during pregnancy, which are either accidental or due to gestation, attain their maximum of frequency with the older primiparæ.

5. This is true particularly of renal affections and of simple œdema, dependent upon disturbances of the blood and circulation.

6. Eclampsia is more frequent in the older primiparæ.

7. Premature delivery is also more frequent.

Labor.—8. Labor is longer with the older primiparæ, and, with the exception of contracted pelvis, is due to:

(a) The weakness of the uterine contractions.

(b) To rigidity of the soft parts.

(c) In a restricted number of cases to ankylosis of the coccyx.

9. The delay in the labor is carried through its three stages, but is principally apparent during the dilatation of the cervix.

10. Interference is frequently necessary from the causes mentioned, and more particularly from the frequency of pelvic contractions.

11. The mortality increases with age.

12. Maternal morbidity, whether it be purely puerperal or extraneous, is correspondingly increased.

13. In consequence of a want of elasticity of the soft parts, rupture of the perinæum is most frequent, and increases with age.

Children.—14. The influence of age upon the sex and weight of children is still problematical.

15. Vicious presentations are more common with advancing age.

16. The mortality of the children increases with age, from the frequent interference, the long duration of labor, the frequency of malpresentations, and the maternal morbidity.

WOUND OF THE ABDOMEN, UTERUS, PLACENTA AND FŒTUS AT TERM BY A PIECE OF GLASS—NATURAL DELIVERY—CURE.—Dr. Martinelti (*Annali di Ostetricia*, *Jour. d'Accouchements*) records the following case: Seamstress, 34 years of age, fourth pregnancy, good health, panniculus adiposus but little developed. Menstruated last, August 20, 1883. On May 19, 1884, while coming down stairs with a carafe of water, tripped on her dress and fell, breaking the carafe, by which she was cut and bled freely, which blood was mixed with a large quantity of water. On examination there was found to be a wound of the abdomen, through which several folds of the intestine escaped. While waiting for the doctor, those about her replaced the intestine. The doctor found a wound which commenced a finger's breadth from the umbilicus and extended for three centimetres towards the left anterior-superior spinous process of the ileum. Between the lips of the wound he found a portion of the greater omentum. There were no symp-

toms of visceral lesion; the uterus was deviated obliquely to the right, two finger breadths from the wound. The wound was carefully dressed and closed by three sutures. For the three following days there was a slight febrile movement, but nothing special, except that the uterus seemed to be a little smaller. On the fourth day there was no fever. On the fifth day (May 24, the 277th day of pregnancy) labor set in, vertex presentation. Labor and delivery regular and normal, except that there was but very little amniotic fluid. The infant presented in the right scapular region, a finger's breadth from the inferior angle of the scapula, a recent wound, which was about three centimetres long, having scarcely involved the derm. A similar wound was found on the border of the placenta. The lying-in was satisfactorily completed, but little fever or meteorism during the fifteen days.

Fifty days later Prof. Chiara examined the patient, and found, besides the cicatrix of the abdominal wall, traces of a circular parametritis, with an intense pain in the culs-de-sac of the vagina, particularly the right.

At the time of the accident the woman had on a linen gown that was very thin, a flannel petticoat, a cotton petticoat and a chemise.

THE TREATMENT OF LUPUS.—Schwimmer (*Wien. Med. Wochenschrift*, 1884, Nos. 20 to 22) strongly advocates the employment of pyrogallic acid and mercurial plaster for the treatment of lupus, and he gives a series of cases in which these remedies were followed by excellent results. The peculiarity of his plan is that the remedies are used in sequence, the action of one being supplemented by that of the other. He first applies vaseline to the diseased part till all crusts are removed, after which a 10 per cent. ointment of pyrogallic acid and vaseline is applied, the dressing being changed two or three times a day and continued for from four to eight days, according to the activity of the process and the effect produced. Vaseline is then again used for a few days until the irritant effect of the acid is moderated, and then the mercurial plaster is applied and worn for from ten to fourteen days, the plaster being changed two or three times a day if there is much discharge, otherwise only once a day. After two weeks, if any nodules are seen in the cicatrix, the same cyclus of treatment is repeated, beginning with the vaseline as before, but using the pyrogallic acid this time for only three or four days. Generally, the writer states, two courses will be enough to cure the disease, though in some cases a third may be required. The duration of the treatment by this method is said to be from three to four months.—*N. Y. Med. Jour.*

PUBLISHED WEEKLY.

THE EDITOR of this JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information, should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE..... \$5.00.
SINGLE COPIES..... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 65 RANDOLPH STREET,
CHICAGO, ILLINOIS

SATURDAY, OCTOBER 11, 1884.

We postpone our usual supply of editorial matter, for the purpose of giving place to the following full and interesting report of the first day's proceedings of the American Gynecological Society, during its recent annual meeting in this city. An equally full report of the proceedings of the two remaining days of the meeting will be given under the proper head, in the next number of the JOURNAL:

AMERICAN GYNÆCOLOGICAL SOCIETY.

Ninth annual meeting, held at the Palmer House, Chicago, September 30 and October 1 and 2, 1884.

This meeting of one of the most exclusive and respected societies of this country, was interesting and profitable to those present, on account of the scientific and practical character of the papers presented, as well as by reason of the general and spirited debates. The attendance, both of the Fellows of the Society and of the physicians resident in Chicago, was only fair. The following is a list of the officers for the year 1883-84: President—Albert H. Smith, of Philadelphia; Vice-Presidents—James R. Chadwick, of Boston, and Samuel C. Busey, of Washington; Secretary—Frank P. Foster, of New York; Treasurer—Matthew D. Mann, of Buffalo; other members of the Council—T. Gaillard Thomas, of New York; Fordyce Barker, of New York; R. Stansbury Sutton, of Pittsburgh; Thaddeus A. Reamy, of Cincinnati.

The morning session of the first day began at 10 o'clock, President Smith in the chair. An appropriate address of welcome was given by Dr. Wm. H. Byford, in the course of which he spoke of the great loss which the Society had sustained in the death of its chief, Dr. Marion Sims. The regrets of absent Fellows were then received.

The first paper, Moot Points in Regard to Inver-

sion of the Uterus, was presented by Dr. John C. Reeve, of Dayton, Ohio. The progress of knowledge of inversion has been slow, on account of the rarity of the occurrence of the accident, and also because many cases must have been unrecognized by ignorant midwives or unprofessional attendants. The etiology of the condition is now much clearer than formerly. It is not always due to an unskilful removal of the placenta, as was once supposed, but it is sometimes idiopathic. The object of the paper is to state certain facts not generally recognized. On account of the rarity of the accident it is legitimate to reason on the subject as well as to give the argument of cases.

The first question considered is, Can inversion occur independent of pregnancy, or of the presence of a polypus? It is, of course, generally due to these causes. It may be due to a tumor, as to a hydatid, one such case being on record. The question is, however, Can inversion occur without the presence of a fetus or tumor connected with the uterus, but simply by reason of some condition in the uterus itself? It is admitted that inversion cannot take place if the uterus is healthy. But in a soft, flabby condition of the organ, the possibility of the accident must be recognized, and unimpeachable cases are now recorded, one in a nullipara. The negative argument of Duncan, that the accident is impossible on account of the thick walls of the uterus, is begging the question, for the real point in dispute is whether the uterus may not be so dilated, and its walls so thin, soft and flabby, as to permit the accident. Baudelocque gives one case of a patient 15 years old. Thomas mentions Parker's case, where the uterus was removed for a supposed polypus. In the last case the trouble was recognized as due to efforts made in playing tenpins.

The second question discussed is, does inversion always begin at the fundus? This is the general assumption, but there is a possibility that it may begin at the cervix, and such a claim is made by Thomas. The probability rests upon the analogy of inversion to prolapsus of the bowel. The uterus must be soft and flabby, and in a condition favorable to a gradual rolling out of the wall in a way similar to the process of intussusception. Three cases in proof of this are given by Dr. Taylor, and one more case is added by Dr. Keene. A study of these cases brings the conclusion that inversion may begin at the cervix.

Does puerperal inversion occur except at or immediately after delivery? is the third important question discussed. May it be due to sudden rising from bed, or to straining at stool? No satisfactory answer has been given. No doubt the discovery of inversion is often delayed, but cases are on record which show that very probably the condition is occasionally not produced till some time after delivery. The first case happened in Chicago 20 years ago, and is of special interest from the fact that it led to a libel suit, which resulted in much pecuniary loss to Dr. Fisher, the attending physician. There was some flooding attending labor, but it was controlled without difficulty. There had been pain in the right side before delivery, and this continued after the expul-

sion of the placenta. After 10 days Dr. Fisher's visits were discontinued. One month later inversion was discovered.

The second case was in the practice of Dr. Sayles, and is given by Delamater. It was a second labor. No difficulty was experienced till after the birth of the placenta, when there was flooding so that the patient fainted. On account of the hæmorrhage Dr. Sayles was particularly careful to see that the uterus was contracted. No further complication occurred till the tenth day, when the woman, straining at stool, felt something give way. Then inversion was discovered.

In the third case, a twin birth, the patient did well till the eighth day. Then she got up and a slight flooding occurred. After this there was occasional bleeding till the twenty-first day, when the uterus was found inverted.

In the fourth case inversion did not occur till the ninth day, while in the fifth case it probably happened at the end of forty-eight hours.

In the sixth case the uterus was examined on the sixth day, and the inversion was discovered on the thirteenth day. Two more reliable cases are reported. The conclusion drawn from the consideration of these cases is that relaxation of the uterus may occur some hours or days after labor, and at this time inversion may very probably occur.

The fourth mooted point is thus stated as a question: May inversion occur without symptoms to attract attention? Generally the symptoms are prominent and the accident is mostly fatal within 72 hours. But there are recorded cases which answer the question in the affirmative. In many of the cases given in the last paragraph there was no pain nor other suspicious symptom. Two others have been collected by Dr. Reeve. In the first the patient was in labor eight and one-half hours. Ergot was given. There was no hæmorrhage till after forcible extraction of the placenta, when there was some flooding. Inversion followed the extraction of the placenta by traction on the cord, but there was absolutely no shock. In the second case the foetus and membranes were born suddenly. Inversion occurred, but attended with no pain nor hæmorrhage.

These questions are important, both from a legal and diagnostic standpoint. It is believed that the cases have never before been collected. The importance of the last question in the diagnosis of polypus is emphasized. The possibility of the presence of an inverted uterus should never be forgotten in any case of suspected polypus.

In the discussion of the paper, Dr. Scott, of San Francisco, spoke of an interesting case which came to him last year. The placenta came away suddenly after traction on the cord had been made. Hæmorrhage, which continued three weeks, followed. Inversion was recognized by the attending physician, but it was not reduced. Later a second physician was called in. He also recognized the condition, but made no attempt at reduction. For seven months the patient had an inverted uterus with no hæmorrhage after the first three weeks. The symptoms were pain and a dragging sensation in the back and pelvis,

and leucorrhœa. In the eighth month the baby was weaned; then hæmorrhage began. At this time the patient came to Dr. Scott. He found the inverted uterus not very large nor soft. He accomplished the reduction without much difficulty in about twenty minutes, but during the process he distinctly felt some of the circular muscles tear. After the reduction the uterus was patulous so as to admit four fingers to the fundus. After a time iodine and hot injections were used in the cavity. In three weeks after the reduction menstruation came on and with it hæmorrhage. The bleeding continued for ten days, and was so severe as to be alarming. At the end of this time the uterus was as patulous as before. Dr. Scott then, perhaps unjustifiably, introduced sutures into the cervix. A severe attack of cellulitis followed which, happily, terminated by resolution.

Dr. Byford, of Chicago, had seen nine or ten cases of inversion. He gave a short account of a case which he had published in 1870. The case had a bearing on the third and fourth points of the writer's paper. Dr. Byford attended the patient in her second labor. The labor was not remarkable in any way. There was no hæmorrhage or other symptoms. After delivery the uterus was felt in position through the abdominal walls. At subsequent visits the uterus was found in position by abdominal examination. Three months later the uterus was found inverted. As no vaginal examination had been made after delivery, the possibility of an unrecognized inversion is admitted. The only other fact having a bearing on the case, is that the baby was weaned two or three weeks before the inversion was discovered.

Dr. Browne spoke of a case which was supposed to be due to the patient's rising from bed on the ninth day. Hæmorrhage, which with other symptoms had previously been absent, followed the effort. In this case there was laceration of the cervix.

Dr. Dunlap related the history that had been given him by a competent surgeon who had attended a case of chronic inversion. The labor was normal, but continuous hæmorrhage followed. Vaginal examination showed the os and cervix in position. Some months later, by repeated examinations, the doctor found the os gradually dilating and the uterine walls rolling in, and finally the inversion became complete.

Dr. E. W. Sawyer, of Chicago, spoke of a fatal case of puerperal inversion, occurring in his own practice, which was interesting on account of the unusual distension of the uterus. The pains were feeble, but the labor short, and a very large amount of amniotic fluid escaped. After removal of the placenta by traction on the cord, the uterus reached above the navel. Five minutes later alarming hæmorrhage occurred and ergot was given. Then the uterus was found to have disappeared, and a vaginal examination showed the organ inverted. In fifteen minutes the uterus was ergotized and replacement impossible. At the autopsy the remains of a large circular placental attachment were found on the fundus, and it was thus shown that gravity had caused the fundus to drop on account of its weight.

Dr. Howard, of Baltimore, spoke of a case of inversion due to the delivery of a large fibroid, and of

another case where the inverted uterus had been mistaken for a polypus.

Foreign Bodies in the Abdomen after Laparotomy, by Dr. Henry P. C. Wilson, of Baltimore. Sponges and instruments are probably left in the abdomen more commonly than is generally supposed. These foreign bodies may be a not unfrequent cause of death and it is quite probable that, in many cases, the accident is not fatal. Before relating, in full, the history of a case of his own, Dr. Wilson gave a short account of twenty other cases that he had, with difficulty, collected. Only five of the twenty cases have been published. Six of the twenty-one known cases have happened in America. The foreign body in one of these cases was a pair of forceps and in five cases a sponge. Of the foreign cases one was in the practice of Lawson Tait. It was fatal in four days. Sir Spencer Wells has had two cases. In one the loss of a sponge was discovered after several hours. The next morning the abdomen was opened and the sponge found and removed. In the other case a pair of forceps was missed two hours after the operation. The wound was opened the next morning and the forceps found. Karl Braun and Gustav Braun have each had a case where a sponge was found at the autopsy.

On February 20, 1884, Dr. Wilson removed from a pregnant woman, through an incision four inches long, a dermoid cyst of the ovary whose weight was twenty pounds. On account of considerable vomiting the operation lasted forty minutes. After the operation there was a great deal of pain but no shock. On the following days there was considerable nausea and pain, but the temperature did not rise above 100° F. March 1 the sutures were removed; there was pain in the right groin. From this date till March 9 there was some increase in the temperature and pulse and very great pain. March 9 there was a miscarriage with an easy labor and no hæmorrhage. For the next seven days there was very severe pain with some tympanites. March 16, a cake-like tumor was discovered about the navel. No fluctuation could be felt. The tumor increased in size till March 23, when it broke, discharging a purulent fluid through the upper angle of the original incision. From this time the patient improved, until April 16 she went home. There was still some pain and discharge from the wound. About the middle of June a piece of sponge came away. The opening was then enlarged and fragments of sponge continued to be thrown out till in August the last piece was found. Since then the patient has completely recovered.

As the sponges were, as usual, carefully counted after the operation, Dr. Wilson could give no cause for the loss of the sponge except the conjecture that a piece had broken off from one while it was in use. He invited the discussion of the Society on the means of preventing the accident and stated his own rules. First, all instruments and sponges should be counted before the sutures are introduced. Second, the operator should do his own sponging. Third, very few instruments should be used.

In the discussion, Dr. Thomas, after commending the paper for its frankness and value, gave a case of his own which happened three years ago in the Wo-

men's Hospital. At the patient's request a small exploratory incision was made to confirm the diagnosis of cancer of the spleen. Dr. Hunter was the only assistant, and only one sponge was used. The operation was quite trivial, but no secretion of urine followed and the patient died. The stoppage of the action of the kidney was attributed to ether which was used, its danger in renal diseases not, at that time, being recognized. At the autopsy a small piece of sponge was found in the abdomen. Its presence could be accounted for only by supposing that a small piece had broken off during the operation.

In regard to the means of prevention, Dr. Thomas differed with Dr. Wilson in holding that the operator can not do his own sponging with advantage. He would hold one good assistant responsible for the sponging. The other rules he agreed with but in addition he had been in the habit, for several years, of tying a piece of tape six inches long to each sponge. This did not interfere with its use and would tend to prevent its loss. He also condemned the practice of leaving instruments on vessels for any length of time.

Dr. Jackson knew of three cases in Chicago, in two of which sponges and in one forceps, were left. All were in ovariectomies. Dr. Jackson makes a written list and compares the instruments with it before finishing the operation.

Dr. Dunlap handles his own instruments and does his own sponging.

Dr. Howard described the method employed in the Samaritan Hospital in London. Two nurses have charge of the sponges, of which fifteen are used. At the close of the operation each counts the sponges as they are handed from one to the other. This method was adopted on account of a case where a sponge was lost. In this instance the sutures were removed, the sponge found and the patient recovered. At another time a sponge was thought to be missing. The sutures were removed, but no sponge was found and the patient died.

Dr. Engelmann, of St. Louis, added a case to the list, one occurring in his own practice, where the loss was due to the officious interference of a visitor, a prominent gynecologist, who usurped the duties of the assistant who had charge of the sponges. Before closing the abdomen a sponge was found missing. Dr. Engelmann searched for it carefully, examining especially the cavity of the pelvis. As it could not be found it was supposed to be in some waste that had been thrown out. Some time after the operation the patient became demented and later died. The post-mortem showed the sponge between the omentum and a fold of the intestine high up on the right side. The sponge was clean, there had been no inflammation and only slight congestion.

Dr. Mundé pointed out the moral of several cases by calling attention to the danger of using friable sponges. Also, a sponge should always be cut and not torn. He would always use a holder for each sponge.

Dr. Wilson, in closing, said that his number of cases had been increased to 28. Six had been added by the speakers and one he had learned of on his way to the meeting.

In the afternoon session the first paper read was by Dr. C. D. Palmer, of Cincinnati, entitled: Abdominal Section; its Value and Range of Application in Diagnosis and Treatment.

The writer first emphasized the importance for proper therapeusis of a correct diagnosis, and called attention to the unusual difficulties in distinguishing the pelvic diseases of women. As an aid to diagnosis the surgical rival of an exploratory incision, tapping, has a limited value for the following reasons: First, the dangers of tapping are greater than those of abdominal section except in cases of ascites and unilocular ovarian cyst. Second, it increases the danger of a subsequent operation two per cent. Third, the physical characters of the fluid are not characteristic. On the other hand exploratory section is a completely reliable means of diagnosis, and in suitable cases it may be extended to a complete operation. If the patient is in danger from the disease, and the treatment uncertain, and if there is no malignant disease, section is justifiable.

The following summary of the cases where incision is especially applicable is given: First, ovarian cysts complicated with ascites, etc. Second, interstitial uterine fibroids which produce hæmorrhage. The fact that these fibroids sometimes cease to grow makes this rule somewhat doubtful. Third, some cases of acute and chronic peritonitis. Fourth, intestinal obstruction which may be due to adhesions between the intestine and peritonæum. Fifth, some cases of pelvic abscess where drainage through the vagina is not sufficient. Sixth, extra-uterine pregnancy after the fourth month when puncture of the sac or electricity cannot kill the foetus.

After the reading of the paper both Dr. Engelmann and Dr. Mundé agreed with the writer that section had been too little used in diagnosis. Dr. Mundé said that statistics showed against tapping a mortality of 25 per cent., a result which proved the greater safety of exploratory incision.

Dr. Wilson related a case of his own which showed the superiority of incision to tapping. There was a doubt between the diagnosis of amniotic dropsy and pregnancy with ovarian cyst. He found against the abdominal parietes the thin uterine walls, which would have been punctured by tapping. The woman was delivered safely.

Dr. Maury gave two cases which showed the importance of incision in diagnosis. Dr. Dunlap mentioned a case of psoas abscess that had been mistaken for malignant disease and impacted colon. Dr. Scott gave a case which illustrated the importance of opening early a pelvic abscess.

The Hygiene of Pregnancy, by Dr. Samuel C. Busey, of Washington; and Rapid Dilatation of the Cervical Canal, by Dr. William Goodell, of Philadelphia, were read by title on account of the authors' absence.

Cervical Fibroids as a Cause of Dystocia, and their Removal by Vaginal Enucleation, by Dr. Paul F. Mundé, of New York, was next presented. Fibroids generally exist in the body of the uterus; they are found in the cervix in only about ten per cent. of all cases. In pregnancy they may be dangerous by pre-

venting the expulsion of the foetus even after craniotomy. Sometimes the difficulty may be obviated by premature delivery. Tapping a soft tumor may suffice. If the tumor have a pedicle its removal is not difficult. In large sessile tumors we have to decide between Cæsarian section and enucleation. The great fatality of the former alternative shows the value of Thomas's serrated spoon which makes enucleation possible.

The writer gave a case in his own practice which proved the feasibility of the operation for very large tumors. The patient had bled considerably for five or six months and had become very emaciated. The pelvic cavity was filled with a large tumor which was a fibroid in the anterior lip. Pregnancy was diagnosed by ballottement. The foetus was thought to be living. Two methods of treatment presented themselves. The first was to wait till term and then, according to the indications, perform Cæsarian section, vaginal enucleation or Breisky's method of intra-abdominal enucleation. The second method was to wait one or two weeks for recuperation and enucleate through the vagina. By the last method the child would probably be sacrificed, but the condition of the mother and the fear concerning the progress of the tumor determined its adoption. On the day set for the operation the patient had uterine pains and rupture of the membranes. The tumor was removed in an operation lasting three-quarters of an hour. The difficulty in the removal was due to the impossibility of grasping the tumor securely by any instruments of prehension. There was not much hæmorrhage during or after the operation. The foetus was delivered and the uterus contracted well. In two weeks the patient left her bed. The tumor, which was exhibited, measured at the time of its removal eight inches in length, six inches in breadth and two and one half inches in thickness, and its circumference was about twenty and one-half inches.

This case disproves Playfair's statement that only small tumors can be enucleated. Schröder reports a case where the tumor was smaller than in the one just given; in other respects the cases are very similar. He allowed the case to progress to term, when he enucleated the tumor and saved both mother and child. Noma relates eight cases of enucleation, in all of which, however, the tumor was smaller than in Dr. Mundé's case. In all of these cases the mother lived. Five of the children were saved. Comparing these results with those of Cæsarian section, we see the value of the operation.

The discussion of the paper was postponed to the following morning. In the evening a banquet was given to the visitors by the local Gynæcological Society.

Wednesday morning the discussion of Dr. Mundé's paper was taken up.

Dr. Jenks had had one case of a cervical fibroid which interfered with labor. He incised and enucleated it.

Dr. Wilson held that enucleation is the correct practice when the tumor is accessible.

Dr. Byford thought that the surgeon should not interfere till labor came on, for enucleation would

then be as easy as at any other time and the tumor might be pushed out by the contractions of the uterus without injury to the child. He had had two cases where the tumor was pushed out before the child. In one the tumor weighed about eighteen ounces and in the other it was about as large as that presented by Dr. Mundé.

Dr. Dunlap believed that there might be cases where enucleation at labor would be dangerous. In Dr. Mundé's case most of the tumor was enclosed in a capsule and only a small part of it was intimately connected with the muscular tissue of the uterus. But if more were attached the difficulty would be much increased.

Dr. Van de Warker related a case which illustrated the superiority of enucleation to its alternative. He was called to a case thirty hours after labor had begun. A solid mass, attached to the posterior cervical wall, filled the pelvic cavity. He favored enucleation but Cæsarean section was made by the advice of the other consulting physicians. The child was saved, but the mother died. At the autopsy it was shown that enucleation was feasible.

Dr. Reamy told of a case where a tumor was attached to the posterior wall a little above the os internum. The diagnosis was at first obscure, but when the tumor finally presented it was found to be sessile. He incised and enucleated and then delivered the child. Both child and mother did well. He believes it is best to wait to labor for two reasons. First, if the tumor is not large so as to distend the parts well, enucleation is much easier when the passage is dilated by labor. Second, the physiological state of the system is such as to render the liability to septic infection much less at term than before.

Dr. Mundé in closing contended that the time of removing the tumor depended upon the condition of the patient in each case, on the size of the tumor when first seen, and on the rapidity of its growth. He considered the spoon saw invaluable, but in his tumor there was only one place where it was needed. A better forceps for traction was quite essential. In reply to Dr. Dunlap, he believed that a tumor could be removed if there were many adhesions, but of course the difficulty of the operation would be much increased.

Before presenting his paper, Dr. Thomas exhibited to the Society an interesting relic which he had picked up during his summer vacation in a Long Island village. There he met a gentleman who was heir to an old French estate, and who had in his possession several old trunks filled with curious heirlooms, duelling weapons, old dresses, etc. In the bottom of one of these trunks was the curiosity exhibited, a *cincture de Venus*, made of metal joints, covered with velvet, and with the waist and perineal bands fastened behind with a lock, which was sealed with wax, on which was stamped an armorial design. It differed from the one shown in the Musée de Cluny, which had an ivory ball for the vulvar shield. In this both the anal and vulvar shields are fenestrated, the fenestra being protected by projecting metal points.

His paper, entitled *A Further Report upon Extra-Uterine Pregnancy, embodying Six Cases*, was next

read. This paper was a supplement to one read at the meeting of the Society in 1882, when 21 cases were reported. According to the statistics of Bandl, out of 60,000 patients in the Vienna Lying-in Hospital, there were only five cases of extra-uterine pregnancy. Hence the writer must consider himself very fortunate to have seen so many cases.

It is only within the last 10 to 15 years that the subject has received much attention. The keynote to the management of the cases is early certain diagnosis. Even after foetal movements this diagnosis is difficult on account of the occasional existence of a uterus bicornis, or of a thin-walled uterus, or of a combined extra and intra-uterine pregnancy. Dr. Thomas has seen all kinds of tumors confounded with it from a fecal tumor to a phantom tumor of the abdomen. Yet modern methods of study make us cast aside the maxim of Depaul, that diagnosis is not possible before the fourth month. As regards treatment, Dr. Rogers, 20 years ago, advised removal as soon as the diagnosis was made. In 1883 and 1884 Tait reported five cases operated on, four of which recovered. Briddon in 1883 operated in one case.

Before describing his own cases, the writer gave a short account of some experiments on rabbits by Leopold. Small living embryos of different ages were put into the abdominal cavity. Many of the animals died from peritonitis. When this was not the result the embryos became encapsuled.

In a report of cases Dr. Thomas considers a detailed account of symptoms very important. If a case recovers under treatment there will always be a doubt concerning the diagnosis unless the details be given with sufficient fullness to enable any one to form his own judgment.

CASE 1. Mrs. T., aged 27 years, nullipara; menses had once ceased for a period of four months. Four weeks after the stoppage of a menstrual flow she received a severe shock while stepping from a car. Great pain and nausea followed. The pulse was 130 per minute, and she had the symptoms of a hæmatocele. She was anæsthetized, in order to examine the pelvic organs. A tumor was found behind the hæmatocele, and a diagnosis of extra-uterine pregnancy was made. To lessen suffering, aspiration was performed below the navel, and a straw-colored liquid was drawn off. After the patient recovered from the anæsthetic her pain was very severe, and she died that night. The post-mortem examination showed the uterus large and dilated, and the surrounding tissues filled with much lymph. A foetus of eleven months was found in Douglas's pouch. The examination made it evident that laparotomy would have been fatal. The sac must have been ruptured by the movement of the car. This was Dr. Thomas's fourth case of aspiration.

CASE 2. Mrs. G., aged 32 years. Married seven years. Has had no children. Since marriage her menses have been twice delayed. The uterus is retroverted. Her menstrual period was due on the 1st of December, 1883. December 23 she had a painful flow. The doctor who was called enjoined rest, and the symptoms subsided. On the 24th of December she had a worse attack of pain, accompanied with

chilliness and fainting. The uterus was found retroverted and increased in size. December 29 there was slight hæmorrhage, which gradually increased till January 2, when it subsided. On the latter date the pulse was 108° and the temperature 100.2° F. As the discharge now became fetid the cavity of the uterus was explored, decomposed clots brought away, and the uterus washed. All went well till the 7th inst., when there was a flow of bright red blood. On the 9th the uterus was of the size of three months of pregnancy. No tumor could be seen outside of the uterus, and the question of interstitial pregnancy was raised. On the evening of the 9th pain reappeared. At 9 o'clock temperature 101° F., pulse 120; morphia was given. At 10 o'clock there was more pain, and collapse. Pulse was 160, and very weak. She was kept up with stimulants and morphia. On the next day tympanitis developed. January 15 a large tumor was felt at the right of the uterus. Interstitial pregnancy, with rupture of the sac, was diagnosed. Dr. Thomas was called, and confirmed the diagnosis, and decided not to operate. Five days later the use of the electric current was begun. One electrode was placed in the rectum, and the other over the tumor. The bowels began to move well, and the tumor grew firmer. In May the patient left town, and in June she had quite recovered.

CASE 3. Mrs. H. Married 18 months. Had had two miscarriages. She menstruated in September. About the middle of January she had nausea and pain in left iliac region. After the middle of March she could not leave her bed and suffered much from pain in the abdomen and back with attacks of syncope. There was no increase of temperature. March 27, Dr. Thomas was called. He found a tumor the size of a fist and diagnosed extra-uterine pregnancy. On the next day the electric treatment was begun. The manner of using the electric current has been described elsewhere. Essentially it consists in applying a galvanic current for a short time, then, after a short interruption, a weaker Faradic current. In this case he began with a galvanic current of 17 cells from Kidder's battery for five minutes, and a Faradic current of ten cells for one minute. The application caused great pain but the tumor continued to increase in size. The strength of the current was gradually increased, some of the applications being made with the patient under the influence of ether. April 28, she was anesthetized and a current of 40 cells with 60 interruptions per minute was employed. This course was adopted only as a last alternative to abdominal section. From this time the patient improved. May 18 a menstrual period began which lasted three days. When last heard from, on the 13th of September, she was much improved, but there were occasionally slight paroxysms of pain and the tumor could still be felt. It is admitted that the diagnosis in this case was not positive. The case resisted the current more than any other that Dr. Thomas has seen, and this fact more than anything else causes the doubt in the diagnosis.

CASE 4. In 1882 an Irish lady came to Dr. Thomas's hospital to be treated for sterility, which was due to uterine catarrh. In a few months she was

discharged "cured." In 1883 she had nausea and some hæmorrhage. Dr. Lambert, the physician who had charge of the case, diagnosed pregnancy at the fourth month and advised rest and quiet. Later she had further attacks. From the first to the middle of January, 1884, her pain was very severe, and she was finally carried to New York on a bed. Dr. Thomas found symptoms of pregnancy and a tumor behind the uterus. At a consultation of four physicians, one man agreed with Dr. Thomas in his diagnosis of extra-uterine pregnancy, while the other two differed. On January 23 a current of seventeen cells was used. The number of cells was gradually increased. In forty-eight hours the symptoms had greatly improved, and in ten days the woman went home. One month later she began to work, and August 22 she was reported quite well.

CASE 5. Was one of supposed rupture of the tube in a case of tubal pregnancy. Dr. Briddon operated and found the condition diagnosed, but the patient died.

CASE 6. Patient aged 23. Married 6 years. Has had one child. She had symptoms of pregnancy for nine months. At the end of that time she had the symptoms of labor and called her physician. He found the labor pains regular, but the os did not dilate. On the next day the patient was anesthetized and abdominal pregnancy diagnosed by the finger in the uterus. Dr. Thomas was called and decided to postpone any operation on account of the cessation of labor pains. For the next three months the patient did well, but then she became worse, and in June an operation was performed. Through an abdominal incision a foetus weighing nine pounds, three pounds of amniotic liquid, and four pounds of a huge placenta were removed. The placenta had very extensive attachments, including the ascending, transverse and descending colons. As it could not with safety be torn from the bowel, Dr. Thomas found it necessary to introduce the hand under the placenta and pass a cobbler's stitch through the whole attachment, about an inch and a half from the intestine. Then that portion of the placenta was cut off and the rest was puckered up into a pouch, the mouth of which was sewed to the abdominal wound. This operation was well characterized by the expressive phrase, marsupialization of the woman. The operation was done with antiseptic precautions and the marsupial pouch was well irrigated. In twenty-four hours the patient had violent acute septicæmia. The temperature was 104.4° F., and the pulse 150. The sac was washed every two hours, and in four days the symptoms improved. The recovery was then rapid, and in six weeks the patient felt as well as ever. The upper and lower parts of the wound had healed, and the sac was closing from the bottom by granulation.

The delay of three months Dr. Thomas considered very important, for such a large placenta could not have been removed at term. This is his fourth case of extra-uterine pregnancy that went beyond term. All recovered.

In the discussion, Dr. Mundé said that he had had four cases. One of them illustrated the value of the electric treatment.

In reply to a question, Dr. Thomas said that he used whatever current would kill the child.

Dr. Harvey asked a question concerning the size of the uterus. In a patient of his at fifteen months of extra-uterine pregnancy the uterus was normal in size. Dr. Thomas replied that involution occurred after the death of the foetus.

In reply to a question concerning the time to use electricity, Dr. Thomas made the following answer: Before five months use electricity. After that time if the child is alive it is probably in the abdominal cavity, for the tube is ruptured earlier; let it go to term and perform laparotomy. If the child is not alive at the end of nine months wait in order to let the placenta shrivel.

Dr. Howard had a case where the uterus did not contract after the death of the foetus. He also related a case of Keith's where a supposed tumor was found to be a foetus which had remained in the tube during a normal uterine pregnancy.

(*To be continued.*)

BOOK REVIEWS.

TRANSACTIONS OF THE MEDICAL SOCIETY OF THE STATE OF CALIFORNIA DURING THE YEARS 1883 AND 1884. Paper, 293 pages.

This volume presents much interesting matter, and is singularly free from trash of all sorts.

Besides the ordinary reports, the following papers are presented: Old and New Codes; Hawaiian Leprosy; Experience of a Country Doctor; Causes Modifying the Climate on the Pacific Coast of the United States and British Columbia; Fracture of the Neck of Condyle of Lower Jaw.

As the Society, by its vote, ordered the general distribution of 500 copies of Dr. Wilder's paper, "The Old and New Code," that document is worthy of more than a passing notice.

After a historical review of the break in the profession in New York, he proceeds to consider the causes of this rupture. He shows that it is due to homœopathy, and that homœopathy is due to the weakness of the regular school in the department of therapeutics. Respecting this he says: "Unless serious and determined efforts be made to give this subject greater importance, both in practice and in the curricula of our medical schools, we need never expect to demolish homœopathy."

As a remedy for the present difficulties he proposes to establish a national examining board, on the following plan: Let the American Medical Association select three men, the Medical Corps of the Army and Navy each one, the five to constitute the Central Committee or head of the various State Examining Boards, these latter to be appointed by the respective State Societies.

The graduate of *any school* is to be allowed to present himself for examination, but all successful candidates are to be bound to use no other title than Doctor of Medicine. "The carrying out of this plan

would result in the establishment of a *caste* in the profession and give an opportunity for the better class of medical men to occupy a higher position."

The fundamental idea of this plan seems to be that the profession by purifying and strengthening itself is to become able to crush out all opposition. The fallacy of all such measures rests in this fact. No examination can positively determine a man's fitness to be a practitioner. His success in the actual conflict with disease is the only true criterion by which his merit can be judged. All organization and legislation fall short of the ideal, and it must be so, for in the future as in the past, quacks will thrive when fools require their services. A gradual purification of the profession and a gradual education of the people are the only means of eventually harmonizing their mutual relations.

LECTURES ON THE PRINCIPLES AND PRACTICE OF MEDICINE. Delivered in Chicago Medical College, Medical Department of the Northwestern University. By NATHAN SMITH DAVIS, A.M., M.D., LL.D., Dean of the Faculty and Professor of the Principles and Practice of Medicine, etc., etc., etc. Jansen, McClurg & Co., Chicago: 1884.

The volume comprising these lectures is excellent in appearance. The features which, after a careful perusal, attract one's attention especially, are: first, the distinction which the author clearly points out between the functional derangements of living matter that are manifest in the diseased state and the result of these which is ordinarily described as morbid anatomy. Second, the fullness and completeness and detail with which the treatment of disease is described, and third, the insertion of metric measures in all prescriptions. He, however, adds in brackets the apothecaries' measure.

So much attention has been devoted by pathologists to the study of morbid anatomy, both gross and microscopical, that it has come to be considered almost synonymous with pathology. The fact that morbid anatomy is the result of disease, not strictly speaking the disease, is ignored. The author in his first chapters which treat of the principles of medicine, points out the functions or attributes of living matter in general, as they are recognized by biologists, and attempts to explain the phenomena of disease by the increase, diminution or perversion of these primary functions or attributes.

The theories advanced to explain the phenomena of disease are interesting, and from their novelty when we compare this with other modern text-books, pleasing and instructive.

The author has attempted to do just what Dr. Greenfield in his recent address to the British Medical Association as Chairman of the Section on Physiology and Pathology, has urged ought to be done. The latter writer says: "It is only as means to an end that morbid anatomy and histology are essential, and that end is the tracing out of the processes of disease and making possible a rational application of physiology in abnormal conditions."

Dr. Stokes, in an address a few years ago before the same body has said: "There are differences—

and for want of a better name we may call them vital—which more intimately relate to life and health than to the anatomical or chemical changes produced by disease; and these are to be reached by the study of the living phenomena of the body and of the influences of agents upon them."

In the nearly half century of most extensive clinical experience which Dr. Davis has had, the phenomena of life or the vital activities of tissues as modified by disease and therapeutical agents has been impressed upon him. He has therefore formulated in his discussion of the principles of medicine some of his observations in this direction.

In the discussion of the treatment of disease he appreciates the fact that students and general practitioners need, and wish, detailed explanations of the methods adopted and of the results to be expected from them. Dr. Davis first explains the indications for treatment, then indicates the drugs that may be used, and points out especially those that he has found in his own extensive and varied experience most useful. He gives also numerous formulæ, for, as he says in one of the early chapters, we get often as characteristic an effect from a combination of drugs as from an individual drug, and almost always the effect desired is obtained best by combinations.

The spirit of his teaching, however, is that all students and practitioners should be so familiar with therapeutics that they need not be dependent upon others for combinations or set formulæ.

Not only does he thoroughly discuss the therapeutics of each disease, but also the hygienic requirements.

Many of the pages treating of etiology show most careful observation and research.

The metric system of weights and measures he recommends, and to assist in its introduction he has incorporated them in his work. However, in order to make the volume useful to those not familiar with the system he has added the other.

The volume will surely prove acceptable to the medical public, for it embraces the ripe fruit of many years of experience and observation by one who has been known to the profession of this country as one of its most clear, logical and original thinkers and accurate observers.

VISIONS OF FANCY, a poetical work, by N. M. BASKETT, M.D. Commercial Printing Co., St. Louis: 1884. Cloth, 109 pages.

Dr. Baskett's fancy, like that of many medical men, is a little morbid. His rhymes are hard and meters faulty. "That Yearling Brindle Steer" is the gem of the collection. It is not a vision of fancy, but certain matters of fact respecting the loss of that animal, and also an old Missourian's opinion of a Yankee.

MEDICAL ANNALS OF BALTIMORE from 1608 to 1880, Including Men and Literature. By JOHN R. QUINAN, M.D. Baltimore: Press of Isaac Friedewald. 1884. Paper, 275 pages.

This is a chronological and biographical index of the subjects considered, well arranged for reference with a systematic general index to the whole work.

NECROLOGY.

N. S. DAVIS, M.D., EDITOR JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION:

Dear Sir:—A recent number of the *Pennsylvania Magazine of History and Biography* has among its notes and queries an inquiry from Howard M. Jenkins, relative to Doctor Enoch Edwards of the Revolution. The inclosed sketch, taken from the manuscript Biographies of the "Medical Men of the Revolution," contains the information desired. And as the doctor was a patriot in the Revolution, a scholar and a man of note in the community in which he lived, you may deem it worthy of a place in the JOURNAL.

Very respectfully,

J. M. TONER.

EDWARDS, ENOCH, a surgeon of the Revolution, was born in Philadelphia Co., Pa., in 1750; died in Frankford, Pa., April, 1802. The name of this physician appears in the records of a meeting of the Philadelphia Co. Committee of Inspection and Observation, held March 21, 1776, in Philadelphia, at which Colonel William Hamilton presided as Chairman, and Dr. Enoch Edwards served as Secretary (*American Archives*, 4 Series, vol. 5, p. 442).

The subject of this sketch was the son of Alexander Edwards, Justice of the Peace, a farmer in Lower Dublin, Philadelphia Co., whose will was made April 22, 1777, and which was probated May 27, 1777. He left to his son Enoch a farm in Byberry of 51 acres, and to his son Evan, "the plantation in Lower Dublin, where I now dwell." The doctor succeeded his father as a Justice of the Peace.

Alexander Edwards was a man of good understanding, a member and Elder of the Baptist Society of Pennepal.

His son, Enoch, was designed for the ministry, and was educated under the immediate supervision of Dr. Jones, of Pennepal, but having a greater fondness for medicine, ceased the study of Divinity, and became a student of medicine under Dr. B. Rush. After completing his studies, he settled to practice in Byberry.

His brother, Major Evan Edwards, held command and served with distinction throughout the war for independence.

The doctor took an active and influential part in the support of the rights and liberties of the colony, as we see by his attending the meeting in March, 1776, already referred to. His name appears again in the report of the proceedings of the Provincial Conference of Committees of the Province of Pennsylvania, held at Carpenter's Hall, in Philadelphia, June 18, 1776. (*American Archives*, 4 series, vol. 6, p. 195); also, (*Pennsylvania Archives*, 2 series, vol. iii, pp. 636, 638).

The Philadelphia County Committee resolved, July 13, 1776, to raise their part of the Flying Camp; and at a public meeting chose their officers, among whom was Dr. Enoch Edwards, as surgeon. From papers filed in the Pension office at Washington, it appears that in January, 1777, Dr. Edwards was serving as aid-de-camp to Lord Sterling, along with Colonel James Monroe, afterwards President of the

United States. Subsequently to this date Dr. Edwards was appointed senior surgeon in the hospital department at Princeton.

In 1777 he was captured by the enemy near Bustleton and taken to Philadelphia, and shortly after released on parole. (—, Comly's sketch of Byberry, Pa., Hist. Society, vol. ii, p. 97). Dr. Edwards was united in marriage Oct. 26, 1778, to Frances Gordon at Philadelphia.

His connection with the hospital terminated in 1780. Shortly after this Dr. Edwards settled on a plantation in the vicinity of Philadelphia, near where he was born. He was fond of rural life and its pursuits, and particularly earnest in his efforts to advance the interests of agriculture. He was a man of property and influence in the community. Besides his real estate in 1783 he was returned by the assessor as owning two slaves valued at \$133.33 each. In 1786 the assessments showed him to have been the owner of seven slaves, assessed at \$200 each. (Martendal's History of Byberry and Moreland, p. 125). Dr. Edwards was chosen a member of the convention which framed the first constitution adopted by Pennsylvania after the Revolution.

His habits of thought and familiarity with public affairs, rendered him a valuable associate in that body.

He deserved and enjoyed to the fullest extent the confidence of the community in which he lived. The records of the Supreme Executive Council of Pennsylvania, which met in Philadelphia, Jan. 26, 1786, contains the following minute: "A petition from sundry inhabitants of the township of Oxford, Lower Dublin, Moreland, and Byberry, in the county of Philadelphia, praying that Dr. Enoch Edwards be appointed a justice of the Court of Common Pleas for said county, was read, and Mr. Edwards was commissioned accordingly." (Pennsylvania Colonial Records, vol. xiv, p. 609).

Although disliking party politics, and seldom taking part in them, yet he did not conceal his opinions, where he deemed it necessary, or to take a position, when a principle was involved.

His mind tended rather to the philosophical and practical, than to the theoretical affairs of life.

Dr. Edwards was, therefore, popular in the community in which he lived, and with the leaders and influential men of both parties, during and after the Revolution.

He was noted for his beautiful farm, and for his extensive orchards and superior fruit, and frequently entertained the leading statesmen and prominent actors in the Revolution at his house, when they happened to be in Philadelphia on public business.

He corresponded on agricultural and other subjects with General Washington, Adams, Jefferson, Madison, Monroe and many others of the leading and influential men of his day.

He published some very interesting papers on agricultural subjects. An able charge which he delivered to the grand jury, while on the bench, was published in the *American Museum* in 1788.

In 1793-4 Dr. Edwards with his wife visited Europe, and carried with him letters of introduction

from General Washington to some of the most successful agriculturists and other prominent men in England. Some years before his death (1792) he built himself a commodious house at Frankford, a few miles from Philadelphia, where he spent the closing years of his life. His wife survived him many years, but he left no children. From 1810 Mrs. Edwards resided in the family of James Robertson, President of the Bank of the United States, whose first wife was a cousin of Dr. Edwards.

Mrs. Edwards was living in 1844, at the age of 82.

J. M. T.

LOVE, ALBERT CLARENCE, M.D., was born in Lounds County, Mississippi, on December 2, 1851; died of typhoid fever at his residence in Darrowville, La., July 29, 1884, aged 32 years and 8 months.

At an early age Mr. Love entered school at Cooper Institute, Mississippi, where he received a liberal literary education preparatory to entering upon the arduous studies of the profession he had singled out for his life's labors. It was at this institution of learning that the author and subject of this sketch first met and formed the tie of friendship, which grew stronger as the years passed, and which was broken only by the ruthless hand of death. It was here, too, that the author watched and saw develop, year by year, in Mr. Love all of those true and ennobling traits of heart and mind that go to make up the great and good man.

Mr. Love had a retentive memory, acquired knowledge rapidly, and soon gave evidence of great literary promise. After his course of study he was frequently summoned by the Faculty of his Alma Mater to deliver an address at the Commencement exercises, or chosen as orator on the occasions of the reunions of the members of the Philomathean Literary Society, of which he was, while pursuing his literary course, a most zealous member.

At the age of 22 years he took a course of lectures in Mobile Medical College, Mobile, Ala., after which he repaired to the Louisville Medical College, Louisville, Ky., where he graduated with distinction in the spring of 1875, and was elected by the unanimous vote of the class to deliver the salutatory address on that, to him, memorial occasion. The doctor then returned to his old home in Mississippi, where he located and practiced his profession with great satisfaction to his friends and patrons, and with beneficial results to himself until the fall of 1877, when he left his field of labor, went to New Orleans, and during the ensuing winter and following spring pursued his studies, clinically, at the great Charity Hospital, and didactically in the Medical Department of the University of Louisiana. In the fall of 1878, he removed to Darrowville, where he gained the love and confidence of all who met him, and soon acquired a large and lucrative practice. He was a young man of great research, and believed in progression, not only in his profession but in every way that appertained to the development of mind and advancement of his fellow-man.

He contributed articles of interest to the local papers of his community, and occasionally produced

articles for medical journals. One of his favorite studies was the "prehistoric relics" of any community in which he lived. He had collected many peculiar relics, and wrote in an interesting manner on the subject. In the summer of 1881 he wrote a synthesis on the fever which was at that time prevailing in his section of the State. It was of a type resembling yellow fever in many respects, and was being investigated by a committee representing the National Board of Health. This article was published in a Louisville medical journal, and was read with interest and profit by many of the profession in this section of the malarial district. In the spring of 1882 the Faculty of Louisville Medical College elected him to deliver the charge to the class which was then to graduate. This honor he complied with, in a most befitting address. He was a member of the Louisiana State Medical Association, Health Officer for the parish in which he lived, President of the Board of School Directors, a member of the Knights of Honor, a member of the Knights of Pythias, the Guild of Ascension, the Ascension branch of the Sugar Planter's Association of Louisiana, and the Democratic Parish Executive Committee. The resolutions adopted by these several organizations, on learning of the death of this distinguished member and great and good physician, speak in unmistakable language of the great loss that they feel they have sustained. Pall-bearers were selected from members of these various associations, and the Knights of Honor and the Knights of Pythias escorted the body across the "Father of Waters" to the Episcopal church in Donaldsonville, where funeral services were conducted by the Rev. R. S. Stewart. From the church the remains were followed by one of the largest funeral processions ever seen in the town, to the Protestant cemetery, where, after the reading of the burial services of the Knights of Pythias, the body was entombed.

In the death of Dr. Love the community in which he lived is bereft of one of its most useful members, and our profession, which he loved so well, is deprived of the valuable services of an inquiring mind.

J. J. BLAND, M.D.

Houma, La., August 11, 1884.

MISCELLANEOUS.

OFFICIAL NOTICE.

ANNUAL DUES from members of the Association—*Five Dollars* per annum—are payable directly to the Treasurer. Such payment entitles them to receive the JOURNAL of the Association for one year.

SUBSCRIPTIONS TO THE JOURNAL from those who are not members should be forwarded to the office of publication, Chicago.

BACK VOLUMES OF THE TRANSACTIONS may be procured, at reduced rates, by addressing the Treasurer.

THE INDEX to the 33 Volumes of Transactions will be forwarded, postpaid, on receipt of *One Dollar* by the Treasurer.

According to a resolution passed May 9, 1884, at the Washington meeting, continuous payment of Annual Dues is required, to retain permanent membership.

RICHARD J. DUNGLISON, M.D.,

Treasurer.

Lock Box 1274, Philadelphia, Pa.

OFFICIAL LIST OF CHANGES IN MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING OCTOBER 4, 1884.

Stewart, Henry, Surgeon, granted leave of absence for one year, with permission to leave the United States, Oct. 15, 1884.

Edgar, Jno. M., Passed Assistant-Surgeon, detached from the "Nantucket" and placed on waiting orders, Sept. 29, 1884.

Harmon, G. E. H., Passed Assistant-Surgeon, to the Naval Academy, Sept. 30, 1884.

Bertolette, D. N., Passed Assistant-Surgeon, from the Naval Academy to the "Dolphin," Oct. 4, 1884.

Rogers, Benj. F., Passed Assistant-Surgeon, to the Naval Academy, Sept. 30, 1884.

Cooke, Geo. H., Surgeon, from the Naval Academy, and placed on waiting orders, Oct. 2, 1884.

Whiting, Robert, Passed Assistant-Surgeon, from the Naval Academy, and placed on waiting orders, Oct. 4, 1884.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM SEPTEMBER 27, 1884, TO OCTOBER 3, 1884.

Bentley, Edwin, Major and Surgeon, granted two months' leave of absence, with permission to apply for two months' extension, to take effect upon assignment to duty in Dept. Tex., of Surg. F. L. Town. (S. O. 121, Hdqrs. Div. of the Mo., Sept. 30, 1884.)

Bartholf, John H., Captain and Assistant-Surgeon, assigned to duty at Fort Ringgold, Tex., as Post Surgeon. (Par. 5, S. O. 129, Hdqrs. D. of Texas, Sept. 25, 1884.)

White, R. H., Captain and Assistant-Surgeon, assigned to duty as Post Surgeon at Fort Winfield Scott, Cal., relieving Assistant-Surgeon A. S. Polhemus, who, upon being relieved, will report to commanding officer Alcatraz Island, Cal., for duty. (Par. 1, S. O. 113, Hdqrs. D. of Cal., Sept. 19, 1884.)

Tesson, L. S., Captain and Assistant-Surgeon, directed to report to Commanding Officer Ft. Stockton, Tex., for temporary duty. (Par. 3, S. O. 127, Hdqrs. D. of Texas, Sept. 22, 1884.)

Gibson, R. J., First Lieutenant and Assistant-Surgeon, assigned to duty as Post Surgeon, Fort Winfield Scott, Cal., relieving Assistant-Surgeon A. S. Polhemus.

Polhemus, A. S., First Lieutenant and Assistant-Surgeon, upon being relieved, to report to commanding officer Fort McDermitt, Nev., for duty as Post Surgeon.

White, R. H., Captain and Assistant-Surgeon, to report to commanding officer Angel Island, Cal., as Post Surgeon, relieving Assistant-Surgeon C. K. Winne.

Winne, C. K., Captain and Assistant-Surgeon, upon being relieved, to report to commanding officer Benicia Bks., Cal., for duty as Post Surgeon, relieving Surgeon C. C. Byrne. (Par. 1, S. O. 115, Hdqrs. Dept. of Cal., Sept. 23, 1884.)

Maddox, T. J. C., First Lieutenant and Assistant-Surgeon, directed to report to commanding officer post of San Antonio, Tex., for duty. (Par. 5, S. O. 127, Hdqrs. D. of Tex., Sept. 22, 1884.)

Barrows, C. C., First Lieutenant and Assistant-Surgeon, leave of absence extended one month. (Par. 6, S. O. 97, Hdqrs. Div. of the Pacific, Sept. 19, 1884.)

Everts, Edward, First Lieutenant and Assistant-Surgeon, granted leave of absence for one month, with permission to leave the limits of the Dept. (S. O. 145, Hdqrs. Dept. Col., Sept. 24, 1884.)

ORIGINAL ARTICLES.

PUERPERAL SEPTICÆMIA.

BY THEOPHILUS PARVIN, M.D., PHILADELPHIA.

Read in Section of Obstetrics and Diseases of Women, American Medical Association, May, 1884.

Pajot has said that the term puerperal fever ought to be consigned to the museum of antiquities. Certainly the profession generally replace it by puerperal septicæmia, a disease analogous to surgical septicæmia.

It can be defined an acute, contagious, febrile disease affecting women in childbed. This definition may seem to some not broad enough, for it does not include cases where the unborn infant is affected with a septic peritonitis, or where the undelivered woman has the disease, or where nurses attending cases of puerperal fever are attacked; and those still more extraordinary cases reported nearly 40 years ago by Mr. Storrs, where male subjects were affected by the poison of this disease, and died with peritonitis and pleuritis. But whether the facts referred to have been, as suggested by some, badly observed, or whether they are true, the field is wide enough without a definition which would include them; the term puerperal necessarily excludes their consideration.

Certain conditions favor the occurrence of the disease, they are predisposing causes. The building stored with, or partially constructed of inflammable materials, is swiftly consumed when the fire comes, and the gunpowder explodes at the touch of a spark. So physical and moral distress, primiparity, protracted, and especially artificial, whether manual or instrumental labor, crowding of obstetric wards, and cold weather predispose to the disease, but do not create it; they furnish material for the flames, they are the gunpowder without the spark. But whence the fire, and what is the spark? Here two opinions are presented. The disease is autogenetic, or heterogenetic; or it is always heterogenetic. Autoinfection suggests that the house makes the fire, the powder magazine furnishes the spark, explodes itself. It is the doctrine of spontaneous generation—a self-created poison imperils life, a blind and merciless fate dooming to disease, and often to death. The doctrine of autogenesis is a confession of ignorance—ignorance of the source of the poison—a confession which we have many times to make in regard to other forms of contagious disease. There are cases of scarlet fever

where we cannot learn time and place of exposure to the scarlatinal poison—we cannot tell whence the disease came—but do we ever then conclude we have a case of autogenetic scarlet fever, an example of autoinfection? To ask is to answer the question.

Autogenesis may be a doctrine full of comfort to the obstetrician when isolated cases of puerperal septicæmia occur, and the lying-in room is but the vestibule of the grave, but is it not a simple hypothesis founded upon our ignorance, an hypothesis which we will not tolerate in similar diseases, and which is contradicted by those cases where we can distinctly trace the origin of the malady? The doctrine of identity of disease with multiple causes is not worthy of acceptance.

It seems more probable, more rational to conclude that puerperal septicæmia is always and everywhere heterogenetic. Such doctrine further commends itself by its practical results, and these are of especial interest and importance to doctors. We will be more careful and more successful in guarding the life of the puerperal woman accepting it.

The unity of the poison of puerperal septicæmia is coming to be a fixed article in the creed of most obstetricians. If this poison be not one, how happens it that sporadic cases of the disease present the same symptoms as those where the infection can be traced plainly to an external cause, and these sporadic cases likewise may beget similar cases? Moreover, multiplicity of causes may lead to inefficient prophylaxis, and various and vacillating therapeutics.

Still, in observing the genesis of a number of cases of puerperal septicæmia, we find one where cadaveric poison was the obvious cause, another where it originated in epidemic erysipelas; others where a case of uterine cancer was in the obstetric ward, and students making digital examinations of this patient afterward examined women in labor, until finally 14 lying-in women were infected; and similarly, a midwife had living with her mother suffering from uterine cancer. She used daily vaginal injections for her, and had her general care—all the women whom this midwife attended in labor were infected; or, take the cases where sewer-gas, or the miasm from decaying animal matter, from butcher shops, from cess-pools seemed the cause of the disease. Consider the remarkable case given by Charpentier, where a physician, immediately after visiting a patient having phlegmonous inflammation of the thigh, wishing to learn the condition of uterine involution in the case of his wife, then at the seventeenth day after her delivery, made a digital examination, and the result was she had fatal septicæmia. These, and many other

instances of apparent multiplicity of causes, are to be interpreted as showing that the one cause was in all, that the apparent causes were the bearers of the true cause.

An illustration of the consequences of a retained placenta fell under my observation during my recent service in the obstetric department of the Philadelphia Hospital. A woman was delivered of her child but the placenta not passing off in the usual time the interne, following the common, but I believe dangerous practice, a practice not to be adopted unless hæmorrhage demands such violent interference, introduced his hand into the uterus, and took away in fragments all that he could of the placenta, but fragments also were left behind; in three days she had an offensive discharge, then fever, abdominal swelling and tenderness, arrest of uterine involution; and the women lying on each side of her also had septicæmia. Plainly the second and third cases were examples of heteroinfection, but was the first autoinfection? No, the operator either carried the disease germs upon his hands, or, and this is more probable, they were borne in by the air admitted in his manipulations, and finding suitable soil for their development, infection followed.

But is not multiplicity of causes indicated by the different forms which the disease presents? In one case it strikes as with the terrible power and suddenness of the thunderbolt, and in another the malady is mild and brief, and in a third is protracted through many days, or even weeks. But scarlatina may kill in a few hours, or again be so mild as to be scarcely an indisposition; in some families it is a grave, in others a slight malady; some epidemics of the disorder are marked by great, others by small mortality. But the essential nature of the disorder is unchanged in its numerous and diverse manifestations. In puerperal septicæmia the disease may differ because of the quantity of the poison entering, the avenues by which it enters, the parts primarily or secondarily affected, and above all by the inherent susceptibility, the receptivity, the greater or less vital resistance of the subject.

It is hardly necessary at this day to insist upon the contagiousness of puerperal septicæmia. Woe to the man, woe to the households he enters as an obstetrician, who does not accept this important truth demonstrated by so many hecatombs of women perishing in childbed.

Single and contagious as is the poison of puerperal septicæmia, according to the belief of most, we are still met by the question as to its essential character. The parasitic nature of this poison is accepted by most obstetric authorities. Delore, *Traité Pratique de l'Art des Accouchements*, Paris, 1883, remarks that puerperal fever has for its primary cause the introduction into the organism of the puerperal woman of bacteria which produce septicæmia. Charpentier, in the second volume of his *Traité Pratique des Accouchements*, Paris, 1883, referring to the cause of puerperal fever, adopts the views of Pasteur, regarding this agent as a proto-organism, and this organism not being single, but existing in numerous varieties, the several forms of affections, of accidents observed

in puerperal women are explained. Spiegelberg, in the last edition of his *Lehrbuch der Geburtshülfe*, states that everything tends to regard the spherical bacteria as the bearers of the poison, to look upon them as a *contagium animatum*. Kleinwächter, *Grundriss der Geburtshülfe*, 1881, refers to puerperal fever as an infectious disease depending upon a specific poison, the real bearers of the poison being low plant-like organisms found in putrid fluids. In a word, the doctrine most generally accepted to-day is that without microbes puerperal septicæmia is impossible. Further, the fever frequently observed in connection with the establishment of the milk secretion, so commonly known as milk fever, and by some called traumatic fever, is really a mild septicæmia; and so too phlegmasia alba dolens is simply one manifestation of septicæmia—in short almost all the affections of women in childbed have a septicæmic origin.

Magrier, *Des Formes Diverses D'Epidémies Puerperales*, Paris, 1883, referring to the fact that Pasteur found in the lochia of women suffering with septicæmia a very great number of low organisms, while in other cases he could by an examination of the lochia predict the invasion of the disease, the event verifying the prediction, and that the blood of women dying from the disease presented the same organisms, these microbes penetrating into the blood-vessels cause the infection. "But before Pasteur, Delore in 1869, Orth in 1872, Heiberg especially in 1878, have seen numerous parasites in the lochia, and in the peritoneal exudates. Heiberg has traced them into the veins, and into the lymphatics." Fluids containing these microbes have been injected into the uterus, or into the peritoneal cavity of inferior animals, and septicæmia resulted.

To enter into the argument, to answer the objections made to the Pasteurian theory, viz.: microbes come from the diseased organism, and not from without; they have no action, but are simply an epiphenomenon of the disease; microbes do not act directly upon the tissues or upon the blood, but indirectly by soluble septic products which are made at the expense of these same tissues—objections which have been so well answered by Dr. Paul Bar, *Des Méthodes Antiseptiques en Obstétrique*, Paris 1883,—would involve too long a discussion. Besides, it is a question chiefly for those expert in microbiologic researches, and therefore I acknowledge my incompetence.

Passing from this general consideration of puerperal septicæmia, I will now present some illustrations of the disease as it occurred at the Philadelphia Hospital the first three months of the present year, during my service as a member of the obstetric staff of the hospital. In this time seventy-two women, including, however, one case of miscarriage at six months and a half, were delivered, and twenty of these had septicæmia, three dying. Such puerperal morbidity and mortality will not surprise any one who knows the wretched sanitary condition of the obstetric wards. In the winter months the wards are crowded; they are badly ventilated, without bath-rooms, and water-closets, the very walls diseased by the many epidemics of childbed fever, so that the poison seems to have found a permanent lodgment, remaining in

spite of disinfection, and defying antiseptics. But, I am happy to say, although this Carthage is not to be destroyed, new maternity wards are in process of construction, and when this is accomplished the percentage of disease and death among lying-in women forced to take refuge in the hospital, will be greatly lessened.

The first fatal case of septicæmia was a colored girl, sixteen years of age, unmarried, and a primipara. She was delivered on January 12 of a female child weighing eight pounds, after a labor of nearly twenty-four hours; the presentation was pelvic. Her convalescence seemed to be uninterrupted until fourteen days after her labor when she complained of pain in the abdomen, and had some fever. The next day she was transferred to the fever ward; her pulse was then 120, and her temperature 102, the abdomen tender on pressure and somewhat tympanitic. The symptoms of peritonitis were well marked. No chill occurred at the beginning or in the course of the disease. In three days pleuritis was evident, and death took place on the first of February, the seventh day of illness, or the twentieth day of puerperality. The following were the post-mortem conditions as given by Dr. Shakespeare, one of the pathologists of the hospital.

Mahallah Price, colored, æt. 16.

External appearance.—Evidence of blister over epigastrium and lower aspect of each mamma. Shows abrasion of an area of about three square inches. Nothing else noticeable.

Thorax.—Very extensive adhesions of both sides, consisting of recent, mainly dry lymph of a yellowish color. The same material also binds the lobes together. The thoracic cavity contains a considerable amount of serous fluid. The pericardial cavity also contains considerable fluid, and there are numerous minute ecchymoses on the parietal pericardium, especially near the origin of the vessels, and extending along the anterior surface. The visceral pericardium, particularly on the anterior surface, shows similar ecchymoses.

The *heart* is of normal size, consistence and color. The right ventricle partly occupied by a clot mainly chicken-fat in character, which toward the pulmonary orifice assumes a fibrous consistence, and extends far into the pulmonary vessels. The left ventricle is of normal size and contains a very small clot, fibrous in character, which does not extend beyond this cavity. The valves and ascending aorta normal.

The left lung is completely solidified, but not appreciably swollen. The cut surface appears smooth, semi-translucent and not at all granular. In the lower lobe there are one or two wedge-shaped areas characterized by a difference in color from the surrounding tissue, and in them are slight appearances of granulation. They are mainly superficial and probably embolic in origin. No emboli are seen in the vessels comprised in the area, yet the vessels occupy the central portion of these areas. No such appearances of embolism are noticeable in the upper lobe. The right lung shows the two upper lobes normal in appearance, as are also the lower lobes. The latter, however, are slightly congested and contain little air.

The bronchial glands of right side contain some points of cheesy and others of calcareous degeneration. These glands are not softened. The glands on the left side are considerably softened, but contain no caseous points.

The *abdomen* contains considerable serous fluid, with many large floating flocculi, yellowish in color. Adhesions are numerous between the coils of intestine, omentum and abdominal walls, particularly marked over liver and pelvis. Adhesions are easily torn, consisting of recent unorganized lymph.

The *uterus* is about 5 inches in length, $3\frac{1}{2}$ –4 in breadth and 2 in thickness at the fundus. The external surface is covered with lymph, especially well-marked in the posterior cul-de-sac, and over the ovaries. No abnormal appearance is noticed in the walls of the uterus or in the lining of the uterine cavity.

The *liver* weighs $4\frac{1}{2}$ pounds, somewhat enlarged, surface smooth where there are no adhesions. It is of a deep red color, and the capsule of Glisson readily strips. The gall-bladder contains but little fluid, and this of a dark, grumous character. No calculi. The right lobe thickened from above downward to the extent of about four inches. Cut surface natural color, dark red, and presents no visible abnormality. The substance, however, is easily mashed and torn by the finger, but the organ is not flabby.

The *spleen* is but little, if at all enlarged, and weighs six ounces. Surface normal. Organ somewhat flabby, the pulp is dark red in color and somewhat lessened in consistence. No other noteworthy appearance.

Substance of the *pancreas* normal.

Kidneys of normal size and appearance. The capsule readily strips, leaving a smooth surface. The substance of the organ firm and not visibly altered.

Cause of death.—(Puerperal?) plastic inflammation of the serous cavities with left-sided pneumonia.

E. O. SHAKESPEARE,
Pathologist.

Here is a fatal septicæmia involving the great serous membranes which gave no indication of its presence until fourteen days after labor, and its advent was not marked by a chill—nature gave no cry of alarm. These facts are certainly remarkable. My friend, Dr. Shakespeare, expressed the opinion that such extensive disease probably indicated a longer duration than the record showed. Another point of some interest in this case is that the temperature never rose higher than $103\frac{1}{5}$, and that elevation occurred just before her death.

The second fatal case was a colored woman, 22 years of age, the mother of four children. Her labor, occurring at term, lasted a little more than six hours. She was doing well until the third day, when without any preceding chill, her temperature rose to 102. She became delirious the afternoon of that day, attempted to kill her child; jumped out of bed, running about the ward, and it was only after repeated doses of chloral she was quieted. I saw her the next morning, when she was quite rational, but she still had fever, the lochial discharge was scanty and very offensive, the uterus was tender to the touch and

larger than it should have been at the fourth day, and she was removed to the fever ward. That evening her temperature was $105\frac{3}{5}$; it gradually lessened until the evening of the day before her death, which occurred on the sixth day of the disease, it fell to 101 , but rose the evening of her death to $106\frac{1}{5}$. Her pulse varied between 120 and 150.

The post-mortem was made by Dr. Formad, and the report of it is as follows:

Thorax.—No effusion in the pleura. Lungs highly congested and filled with oedematous fluid colored by decomposing coloring matter of the blood; otherwise natural. Pericardium contains some increase of fluid—also discolored. Heart very much softened, congested, and muscular tissue friable, giving signs of acute atrophy; otherwise size and condition of organ normal.

Abdomen.—Signs of a recent peritonitis, but not of a purulent character, the serous membrane being only congested, and no exudate of any kind visible. The mesenteric glands are all enormously enlarged, and upon section show cheesy infarction, and to some extent purulent contents. The lymphatic glands are also enlarged, some of them reaching the size of a walnut.

Uterus.—This is the size of a child's head, and on section the muscular walls show a thickness of about one inch. The mucous membrane is in a state of acute inflammation accompanied by gangrenous change. There appear to be some fragments of placenta with some necrotic change adherent to mucous membrane.

Ovaries.—These are normal.

Liver is in a state of acute yellow atrophy, being soft and friable. The parenchyma gives evidence of acute softening change. Gall-bladder filled with normal bile. Weight of liver 2 pounds 6 ounces. Spleen is completely disintegrated, being only a pulpy, semi-fluid mass, held together by the capsule. Kidneys completely softened by septic changes; otherwise normal in size. Rest of organs all softened, and give evidence of acute septic change. A good many of the changes must be attributed to post-mortem causes, the examination being made 30 hours after death, but the case is nevertheless undoubtedly one of septic poisoning, taking its point of departure from the gangrenous changes in the cavity of the uterus.

The third fatal case of septicæmia was a multipara, twenty-four years of age. She was taken in labor on the evening of the 23d of January; the left shoulder presented, the head being upon the right side of the mother's pelvis. I was called to the case, but it was after the labor had lasted nearly twelve hours, and very serious injury resulted from the delay, which was in part caused by an unfortunate accident. The patient was etherized immediately upon my arrival, and in a brief time and without violence podalic version was performed, and a dead child delivered; the placenta passed off in the usual time, and neither before nor afterward was there any unusual discharge of blood. Visiting her the next morning I found that the nurse who had been directed to use the catheter, had failed to draw any water from the bladder, and introducing my finger into the vagina, I found quite

a large opening through the vesico-vaginal wall. I never dreamed, however, of the more serious mischief also resulting from the delay in delivery, which the post-mortem revealed. But not to anticipate, the patient's temperature twenty-four hours after labor, was $100\frac{1}{3}$, but the next morning it had fallen to $100\frac{1}{3}$, rising, however, that evening to 101 . Great irritability of the stomach began the second day after delivery, and continued with only slight occasional abatement; the third day she had a chill at 4 A. M., and the fourth day another chill at 8 A. M., her temperature then rising to 104 . She had great tenderness when pressure was made upon the uterus, and over the right broad ligament; the uterus was very little below the umbilicus, and the lochial discharge was very offensive; entire absence of milk secretion. She had occasional attacks of diarrhœa; her face was pinched, anxious, generally bathed in perspiration, and had a sort of leaden hue. The sixth and seventh days also a chill occurred, and on the eighth she died. The fourth and fifth days of her illness her temperature was only 99, but the sixth it rose to $102\frac{1}{3}$, and on the morning of the day of her death was a degree higher.

February 1, 1884. Maggie Dougherty, aged 26, white, autopsy 26 hours after death.

External appearance.—Considerable lividity and mottling of the skin of the dependent portions of the body, but not of the upper, it being blanched.

Thorax.—Pleural cavities normal. Pericardial cavity contains half an ounce of serous fluid. Pericardium normal.

Heart.—Some slight congestion of the small vessels at the root of the large cardiac vessels. Of normal size and normal external appearance, and of flabby consistence. The ventricles and auricles contain dark, clotted blood; no abnormality otherwise, except a small, somewhat tough fibrinous clot in the right ventricle.

Lungs.—Normal, except the lower lobes, which are much filled with hypostatic blood.

Abdomen.—Cavity contains a considerable amount of puriform fluid. Both the visceral and parietal peritonæum show general congestion, and some points are covered with lymph. In the iliac fossæ the adhesions of recent lymph are quite extensive. The purulent collection and lymph are quite marked in the pelvis.

Uterus.—Of flabby consistence, about six inches in length, four inches in breadth, and averaging an inch in thickness. On exposing the cavity, it is found that the mucous membrane and uterine wall at the cervix are extensively degenerated, of a dark gangrenous appearance, and on the left side there is a very extensive rupture, involving the whole length of cervix and lower portion of the body of the uterus.

Liver.—Pale, smooth surface, and flabby. Capsule of Glisson not abnormal, but the cut surface, notwithstanding its flabbiness, shows an increase of consistence. The finger is forced into it with some difficulty. Somewhat buff in color. The lobules are not distinctly marked. It weighs $2\frac{3}{4}$ pounds.

Spleen.—Pale in color, and weighs $4\frac{1}{2}$ ounces.

Capsule smooth ; pulp light-colored and only slightly softened.

Kidneys.—Nothing abnormal.

Cause of Death.—Acute puerperal peritonitis, probably of septicæmic origin.

E. O. SHAKESPEARE,

Pathologist.

Certainly this post-mortem greatly surprised me by the revelation of a rent in the uterus. Indeed, in thinking over the history of the case, knowing that an opening occurred soon after labor in the vesicovaginal wall, as a consequence of the long continued pressure, it seemed to me possible that the rupture of the uterus had a similar origin, and like it occurred after labor. In conversation with Dr. Shakespeare he admitted the possibility of this explanation. There had been no failure of uterine contractions, no severe, sudden suffering, no hæmorrhage, no indication of shock. Nevertheless rupture of the uterus may occur without any of these symptoms. Hervieux, *Maladies Puerperales*, remarks that in some cases the uterine rent is made silently—no pain, no complaint, no crisis; and if a post-mortem is made one is astonished to find a rupture has occurred. He further gives in illustration a case that occurred to Dubois, and one in his hospital service, under the care of Tarnier; in each of these patients a more extensive rupture was shown at the post-mortem than occurred in my patient, and yet there was not the least suspicion of it during life.

Admitting this to have been a rupture, and not the result of prolonged pressure with subsequent sloughing, should it be classed among the spontaneous, or the traumatic ruptures? I incline to the belief that it was traumatic, and that it was done during podalic version. Those who are familiar with Baudl's explanation of uterine rupture beginning in the neck, can readily understand how in this case of impossible labor the struggle between cervix and body had gone on until the wall of the latter becoming thicker and stronger, that of the former was thinner and weaker so that the additional strain made upon it, in even the gentle introduction of the hand, caused it to give way, or it might have given way by the sweeping of the head, or a foot now brought down, against that part which had been most injuriously pressed upon. Certainly I have learned the danger that may attend podalic version where some hours have passed with the shoulder wedged in the pelvic entrance. Baudl very well remarks that the practitioner is placed between Scylla and Charybdis in such a case—rupture is liable to occur at any minute from a violent contraction of the uterus, and it is liable to occur from his intervention, especially in performing version.

I shall not give in detail any of the seventeen cases of septicæmia in which recovery took place. In three of them no chill was observed at the beginning, or in the course of the disease, while in others not only the initial chill occurred, but repeated chills, the intervals being irregular, were noted during the illness. In most the milk secretion was arrested, in some only lessened. The lochial discharge was with one or two exceptions, offensive. The constant symptoms were fever, abdominal pain, and arrest of uterine invo-

lution—in some cases the uterus became notably enlarged at the beginning of the disease. The highest temperature observed was 106; one of the patients showing this evening elevation, the next morning had a temperature of only 100 $\frac{2}{5}$ —nevertheless it rose again in the evening to 102, the next evening to 103, and her illness continued for two weeks longer.

Another case of special interest was one in which the first elevation of temperature occurred the second day of puerperality immediately after an attack of epilepsy, a disease which she had suffered with for years, the attacks, however, occurring at long intervals.

In another patient in whom the eruption of measles appeared on the eleventh, and who was delivered on the twelfth of January, the septic poison seemed to first manifest itself on the sixteenth by symptoms very similar to those often observed in pernicious fever—copious perspiration, vomiting and purging, great prostration, cold extremities, pinched expression, and pulse exceedingly frequent and feeble.

Some of the patients had albuminuria, but as examinations were not made in all cases into this condition, I omit other reference to it.

The treatment was supporting, antipyretic and antiseptic. In carrying out the latter the rule was to give vaginal injections in all cases where the lochial discharge was offensive every four hours, and intra-uterine injections morning and evening, the material for injection being either a three per cent. solution of carbolic acid, or a solution of corrosive sublimate one part to 2,000 of water, or a mixture of equal quantities of these.

In conclusion, let me ask the members of the Section as to the prophylaxis and treatment of puerperal septicæmia, which their experience has proved the most useful.

MICROSCOPIC EXAMINATION OF THE DISCHARGES BY
DR. SHAKESPEARE.

My Dear Sir.—I regret much that you have not received an earlier response to your note requesting some statements of my examination of lochial discharges for the presence of bacteria. The examinations I have had the opportunity to make, although not extensive, appear in the main to confirm the opinion of Doleris as to the association of swarms of certain bacterial forms and the occurrence of fever.

As a rule, I have noticed both in those cases apparently progressing normally at the time of examination of the lochia, but which subsequently developed fever, and in those cases which, early after parturition and at the time of examination, were the subjects of febrile disturbance, that certain forms of bacteria were present in great numbers, viz.:

Swarms of micrococci in zöoglæcia masses; immense numbers of diplo-cocci; chaplets of micrococci in strings of from four to eight; and rods of a peculiar form.

Whether these bacteria have aught to do with the production of puerperal fever, or can be invariably relied upon as a sign of impending danger, my observations are as yet too limited to determine.

Yours truly, E. O. SHAKESPEARE.

DISCUSSION.

Dr. Seymour, of Troy, New York, referred to two cases bearing upon the subject of the paper, which were reported by him and printed in the April number of the *Obstetrical Journal* for the present year.

Dr. Robertson, of South Carolina.—Mr. Chairman: I would like to make a few remarks upon this subject. I have been practicing medicine for forty-four years amongst a population where you would suppose there would be septicæmia—in the negro cabins, where they have nothing but midwives. Such a thing as sepsis was never heard of until a short time ago I had a case, and I found a woman with a little fever, and I asked the midwife if she had practiced antiseptis, and she said no, that she had sent for "Auntie Sepsis," but she would not come. That is what she knew of antiseptis.

I have never found a case of puerperal fever in the negro population. If sepsis is such a horrible and dreadful bugbear, why should not we have it, when there is nothing to prevent it when we have nothing but ignorant midwives? and yet I have never seen a case of it among them. I have seen puerperal convulsions, but not one that I know of ever having had puerperal fever, or septicæmia. And where else would you expect to find it? If you read the account of these New York physicians, where it is necessary to wash the walls, inspect the curtains, and inject the women every three or four hours, you might find antiseptis there.

Gentlemen, I think there is a regular bacteriomania prevailing, and there must be something done to arrest it; or else I do not know what will become of the poor women if we have to have a nurse to go around and inject them every three or four hours, and wash the walls with bichloride of mercury and carbolic acid, and all those things. We will have to have some trained nurses.

Dr. Sutton, of Pennsylvania.—Mr. Chairman, this paper is so eloquent, so up to my own notions on the subject of septicæmic troubles after labor as well as after operations in the vagina, that I cannot pass it by without a word of commendation. I agree with Dr. Parvin that to say that puerperal septicæmia is autogenetic, is simply to acknowledge our ignorance. I believe that many a man and woman, going to attend a woman in confinement, carry her death warrant under their finger-nails. I believe that when a man has a case of puerperal septicæmia, he has not to look about him for causes that exist in the cellar or other parts of the house. But let him examine his own self, his hands and clothes, and all his surroundings, and see if he cannot trace the carrying of that poison to the woman. And again, if he has one case, let him stop until he is certain that he has purified himself. There is one precaution against puerperal septicæmia that every man and every woman can take, and that is making sure that his or her hands are perfectly clean before they are introduced into the vagina or uterus of a woman, to make sure that the nails be pared, the arms and hands should be washed with turpentine and subsequently with soap and water or some alkaline solution. I believe if this

precaution is taken and the bedding and other surroundings of the patient are clean, the chances are that the patient will escape.

Dr. Ross, of Pennsylvania.—Mr. Chairman: I simply rise to ask a question. In all cases that we see of puerperal diseases, we have it in a distinctly intermittent form. Now the question I want to ask is, are the diseases, or the parasites of the same kind? Is there a difference between the septicæmia of puerperal fever and any common septicæmia from other causes? I simply desire to ask the question.

Dr. Milner, of Chester, Pa., being called upon by Dr. Sutton.—Mr. Chairman: I remarked to Dr. Sutton that I thought I was to blame for not having taken proper precaution in some of my cases. Some of the cases of puerperal fever were due to our enemy along the river, but I think that some of the cases I have been to blame for. I did discover an old glove that I think had something to do with it.

Dr. Chancellor, of Virginia.—Mr. Chairman: I do not propose to speak of any experience I have had of puerperal septicæmia, but I am here, sir, as a learner. I may say that I have not had any large experience in the terribly fatal cases. I do not know whether it is from the great precaution that I use, as every physician ought to use and possibly does use; but I can just state this fact, which may carry with it some suggestion—that I never made a digital examination in the lying-in room without disinfecting my hands. As my old friend and valued preceptor, Dr. Charles Meigs, of Philadelphia, used to say, "No man should go to a lying-in patient without disinfecting his hands, or make an examination without having thoroughly washed and cleansed his hands, because the very last man or woman he might have shaken hands with might have infected his hands." It is upon that principle I have acted in the last thirty-five or forty years that I have been in general practice.

But I did not rise to speak of any practice of my own, for my experience has not been large; but to ask of Dr. Parvin, who has given us this able paper, to give us his experience in certain antiseptics. There are a great many of these antiseptics coming up now—"germicides," as I may call them—and I have the right to ask the doctor to answer one or two questions in regard to them—carbolic acid, the bi-chloride of mercury, turpentine (which has recently come up as a disinfectant), or the more recent, probably, new remedy of listerine. Will the author please favor the Section with his experience in regard to some of those remedies with which he is so familiar?

Dr. Parvin.—Mr. Chairman: I find that while I put questions the gentleman there (Dr. Chancellor) is putting questions to me, which is something that I did not quite expect. But I can say that, as to the use of listerine, I have never tried it. The disinfectants of which I have any practical knowledge—or the "germicides," I would rather say—are carbolic acid and corrosive sublimate.

I might say that as to the puerperal illness of septicæmia, I was induced to reject vaginal injections. I used them twice a day in several cases, and yet those very cases were just as liable to have septicæmia, if

not more so, than those in which the vaginal injection had not been made. I have seen within a few hours the temperature fall from 103 to 101 after a free injection of corrosive sublimate, and I have seen the offensive lochial discharge disappear; and I would rank as the most valuable treatment of septicæmia the use of germicides in the vagina or uterine cavity.

ON SUDDEN DEATH IN LABOR AND CHILDBED.

BY WILLIAM THOMPSON LUSK, M.D., OF NEW YORK CITY.

Read before the Obstetrical Section of the American Medical Association,
May, 1884.

On the first of January of the present year at six o'clock in the morning I received a summons to attend a case of confinement. The patient belonged to the clientèle of Dr. Bangs, but owing to the illness of one of his children with scarlatina, he had from conscientious motives, requested the family to call upon me in case the labor should occur before the recovery of his child should place him at liberty to resume his midwifery practice. The patient was a very beautiful young woman, a primipara, 23 years of age, to all appearances in the enjoyment of excellent health, and full of happiness at the prospect of becoming a mother. In the bright sunshine of the early morning there was nothing to suggest the tragedy with which the day closed. The examination made upon my arrival demonstrated the beginning of cervical dilatation, and a head presentation. The parts were, however, at that time excessively sensitive to the touch. The pains recurred at intervals of ten minutes. When I entered the room the patient was pacing the floor.

Noticing that she did not, as is usual, sit down when her pains seized her, I questioned her as to her reasons, and was told in reply that she was determined that no sound from her lips should betray her sufferings, and that she found it easier to support the pangs of labor when in motion than when at rest. I likewise learned that with the view of carrying out her resolution, labor having begun late in the previous afternoon, in the place of going to bed she had kept upon her feet throughout the entire night. To my repeated suggestions that she would tire herself out, she assured me that I need not worry, as she felt no apprehensions about herself, and indeed her cheerful spirits and bright color seemed abundantly to support her hopeful words. The labor, however, dragged along slowly. The head dilated the cervical canal without the formation of the bag of waters, and, though the head was low in the pelvic cavity, at eleven o'clock the dilatation of the os externum had made but slight progress. I then told my patient that I thought, by a slight manœuvre, I could shorten materially the duration of the labor. Owing to the sensitiveness of the genital canal, to which I have already referred, I gave her enough chloroform to dull sensation, but not enough to abolish consciousness. With two fingers I next lifted the head from the cervical walls

so as to allow the bag of waters to form in front of the child's head. As I had anticipated, dilatation speedily followed, and, in about half an hour, the head, freed from the cervix, rested on the perineal floor. At noon I suggested to my patient that she must be tired, and that as there was no longer any difficulty or danger from the use of forceps I would advise her to allow me to hasten the birth of the child. To this she energetically answered "that she wished the glory of having her baby herself;" and as in reality she seemed to be making fair progress I unfortunately acceded to her wishes.

From this time on the patient remained in bed. Between 1 and 2 P. M., on going to the bedside to make an examination, I noticed that the color had left her face. Although straining energetically, she manifested no signs of suffering. On asking her whether she was in pain, she replied in a dazed way, "I don't know; I suppose I am; I don't know whether I am or not." After hastily making preparations for possible post-partum hæmorrhage, I once more gave chloroform, applied the forceps, and without difficulty extracted a child weighing between seven and eight pounds. The child was pallid, and breathed feebly at first but soon cried lustily. Before the forceps were applied meconium appeared at the vulva. The uterus was like an empty sac, and the anticipated hæmorrhage was not long delayed after the removal of the placenta. A hot water vaginal douche quickly arrested the flow, but not until after a couple of pints of blood had been lost. Meantime the room had grown dark and, as the curtains were raised to enable me to see the face of my patient, it seemed as though the stamp of death was upon it. The extremities were cold, and at the wrist no pulse could be felt. Still consciousness was not lost as the patient responded to questions, and manifested slight pain when brandy was injected under the skin. The respirations were quiet and undisturbed. Under the continued use of restoratives the color returned to the face. The patient began to complain of thirst, and begged for a goblet of water in place of the teaspoonful of fluid administered to her at short intervals. She likewise begged to be allowed to turn upon her side. In spite of the extreme feebleness of the radial pulse, the condition of the patient at seven o'clock was such as to inspire me with the expectation of her recovery, so that, placing her in the hands of my friend, Dr. Anderton, I went down stairs to dinner. In my absence she suddenly turned in bed. For a moment the heart ceased to beat, and, though she rallied for a time, by 7:30 P. M. I was called hastily to her room, arriving just in time to witness the final breath.

In prefacing his remarks upon the class of cases to which the sad history I have related belongs, Winckel says, "He who has once seen a puerperal woman happy and joyous in the expectation of soon leaving her couch, and then directly afterward has found her a corpse, will be able to comprehend the truth of Hervieux's words: 'In the twinkling of an eye all the calculations of prudence are set at naught; the most untiring vigilance, the best established rules of hygiene, all the varied resources and the ingenious combinations of therapeutics are shattered against an

invisible rock.' ” And then Winckel adds: “The only thing which remains for the physician to do after such a depressing occurrence is to seek out the cause of the sudden death.”

But when the conscientious physician seeks for light concerning the cause of the tragedy in which he has played the part of a powerless spectator, he will find but scanty guidance in the few brief lines devoted to the subject in the systematic treatises upon midwifery. He will learn in later works that, apart from such rare accidents as cerebral apoplexy or heart rupture, or fatal endings from hæmorrhage, from eclampsia and acute septicæmia, the causes of sudden death are to be found in the entrance of air into the circulation and in pulmonary embolism; and to these, in older works, he will find the admission added that death may be due to exhaustion or shock; but in spite of the very copious clinical material scattered through journals and society reports, there will be but little information concerning the pathology, the symptoms, and the mechanical conditions which respectively belong to the various processes to which death is attributable. For convenience of reference, but with no pretense at originality, I have thought it might be profitable to arrange in orderly sequence such facts bearing upon the question as have come to my notice in the inquiries which my own case has rendered it obligatory upon me to institute.

THE ENTRANCE OF AIR INTO THE CIRCULATION.

The passage of air from the uterine cavity into the circulation is rendered possible by the presence of open sinuses, or of sinuses closed by soft, easily detached thrombi. These conditions are always present previous to delivery in the case of partial separation of the placenta, and in the puerperal state, especially in the latter where, owing to debility, or the undue prolongation of labor, the expulsion of the ovum has been followed by imperfect retraction.

Air may be forcibly driven into the uterus by means of the uterine or even the vaginal douche. For this reason the syphon syringe ought to be discarded from midwifery practice. It is never a safe instrument, and I have prohibited its employment in all the public institutions with which I have been connected. The objections to the continuous stream furnished by a vessel placed at a height above the patient, based upon the insufficient force of the current, are purely theoretical. It is not necessary that the nozzle of the syringe should be introduced directly into the uterine cavity for accidents to occur. When the vaginal douche was much in vogue as a means of inducing labor after the prescription of Kiwisch, not a few instances of sudden death were reported as the result of its employment. In a case reported by Wiener¹ in Spiegelberg's clinic, where the tube of the douche apparatus was free from air, collapse, from which, however, the patient recovered, resulted from the hydrostatic pressure forcing air previously introduced into the vagina up into the uterine cavity. If the method of Kiwisch is selected to induce labor,

the stream should at first be introduced with great gentleness.

Less familiar than these cases of forced air injection, are instances of the spontaneous entrance of air into the uterine sinuses. Every day gynecological experience teaches us the mechanism by which this phenomenon may be produced. In great part the modern advances in the treatment of the diseases of the genital canal result from the discovery we owe to Sims that, in certain body postures, the intra-abdominal pressure is reduced to such a degree that, provided the vaginal orifice be dilated by the speculum or the finger, air enters and distends the canal. The three positions which most favor this occurrence are, respectively, the knee-chest, the latero-prone and the lithotomy positions. In the non-puerperal conditions, owing to the closed canal of the cervix, the action is confined to the vagina. But in childbirth the sudden rupture of the membranes which have previously distended the vagina, or the rapid extraction of the child, may permit the ingress of air into the uterine cavity itself. Such an accident may not of necessity do harm, or the harm may be limited to the production of endometritis, but still there are recorded cases in which the occurrence has been followed by almost instant death.

In this category may be mentioned a very striking case reported by Kézmarysky,¹ of Budapest. The patient was 36 years of age, and in labor for the fourth time. An excessive amount of amniotic fluid was recognized. The patient entered the hospital at 10 A. M. At 3 P. M., as she lay upon her left side, the bag of waters was found protruding from the vulva. Spontaneous rupture occurred, and a gallon of water was discharged. Five minutes later the patient suddenly threw back her head, gasped a few times for air, the face became livid and respiration was arrested. In scarcely two minutes the clinical assistant, Dr. Liebmann, was at her side, but the pulse was extinct. An asphyxiated child was extracted with forceps, and the expulsion of the placenta followed during the tying of the cord. Meantime the heart had ceased to beat, and the woman was dead. At the post-mortem 20 hours afterward pale, reddish-brown blood, mingled with bubbles of air of large and small size were found in the veins of the uterus, in the vena cava inferior, in the left side of the heart, and especially at the orifice of the pulmonary artery. The lungs were pale, anæmic, and contained a small quantity of frothy serum. In the vena cava the blood was separated into distinct columns by intervening layers of air. Kézmarysky's explanation of the fatal issue is as follows: The patient lay upon her left side with the knees drawn up in very nearly the Sims position, with the vulva elevated above the concavity of the abdomen. As the membranes ruptured there was sudden diminution of the intra-abdominal pressure, so that the air passed through the open vulva between the collapsed membranes and the vagina to the uterus. The ensuing retraction of the uterus forced the head to the os externum, and caused partial placental sep-

¹Wiener. Zur Frage der Künstlichen Frühgeburt, bei Eugène Becken. Arch. für Gynæk. Vol. XII, p. 94.

¹Kézmarysky. Ueber Lufteintritt in die Blutbahnen durch den puerperalen Uterus. Arch. f. Gynæk., Vol. XIII, p. 200. To my indebtedness to this paper I herewith make my cordial acknowledgments.

aration. The next contraction caused the intra-uterine air to escape by the only channel that was possible, viz.: by the open mouths of the placental veins.

The aspiration force of the uterus in the knee-elbow position is thus illustrated by Hegar,¹ who, misled, he says, by the brochure of Ludwig, made some experiments with labor in that position. In one case delay in the expulsion of the trunk followed the birth of the child's head. Friction was employed upon the fundus, and then the body was drawn out by gentle traction made in the axilla. As soon as the child was born a stream of air rushed into the uterus with a gurgling sound. The patient was then placed upon her back, and the air, blood, and placenta were pressed out. The patient subsequently was attacked with endometritis and metro-peritonitis, from which, however, she recovered.

By way of warning I shall take the liberty of adding to these two cases the following, reported by Cordwint in the St. George's Hospital Reports (vol. vi):

At the patient's request she remained during labor in the standing position. Suddenly the child was precipitated to the ground, dragging the entire placenta with it. Immediately thereafter a gurgling sound was heard. The woman remained standing as before, and holding at the bed-post. Then she cried out: "I see nothing; I feel faint; put me to bed." Her request was carried out, but she died instantly. Air was found in the coronary artery of the stomach, the right side of the heart was slightly inflated, and air escaped from the punctured auricle. Here Kéz-marsky suggests that the sudden recession of the uterus after delivery exercised a suction force which drew the air directly into the uterus and into the uterine veins. With the body bent forward in the upright position Schatz has demonstrated the diminution of the intra-abdominal pressure.

These histories I present not as isolated instances, but as typical, and carrying with them the suggestions for the adoption of preventive measures.

The post-mortem examinations in these cases showed but little blood in the left side of the heart, frothy blood from the cut surfaces of the uterus, air in the uterine veins, the vena cava, the right side of the heart, and at the orifice of the pulmonary artery; the lungs were anæmic and contained much frothy serum; the brain was pale and infiltrated with serum. And corresponding to these conditions the hands were cold, the pulse scarcely perceptible, the face blue and livid, consciousness was lost, and the respiration was labored and jerky, with all the symptoms of intense air hunger.

In the case I have reported it is not possible in the absence of a post-mortem examination absolutely to exclude the entrance of air into the uterine vessels, for the vaginal douche was employed, and the excessive uterine relaxation might have conduced to the spontaneous aspiration of air, still such an event was improbable, for the douche was used with every known precaution, and the dorsal position was un-

favorable to the direct entrance of air into the genital passage. But the special reasons for discarding such an hypothesis were first the quiet, peaceful, and undisturbed respirations of the patient, and the fact that death from air in the veins is usually sudden. When life is prolonged for a few hours the dangerous symptoms as a rule subside, probably from absorption of the air.

ON THROMBOSIS AND EMBOLISM.

From this discussion I propose to exclude cases of phlegmasia dolens in which a detached portion of the thrombus in the femoral vein is suddenly carried to the right side of the heart and thence to the pulmonary artery, as this accident is one familiar to all practitioners, and occurs but rarely, if timely prophylactic measures are instituted. Death in such instances, though sudden, does not take place without warning, and lacks the element of unexpectedness which properly belongs to the class under immediate consideration. There are, however, two generally accepted forms which require closer study, viz.:

1. When the placenta is partially detached during labor, or the uterus after the birth of the child does not properly contract, sudden hæmorrhage followed by syncope or marked weakening of the heart's action may lead to the formation of large soft thrombi in the uterine sinuses, which by movement, by uterine action, or by the douche, may be set adrift and, carried by the vena cava to the left side of the heart and the pulmonary vessels, may cause extreme dyspnoea and death. That some of the reported cases of death from entrance of air into the circulation, where the diagnosis was not confirmed by a post-mortem examination, belong in this category, is inherently probable. I must, however, express my regrets that I have been unable to find a history which affords indubitable proof of such an occurrence.

2. It has been assumed, though not without question, that owing to the large proportion of fibrinoplastic and fibrinogenic substances in the blood during pregnancy and childbed, it is possible, when the heart's action is feeble, for spontaneous coagulation to take place in the pulmonary artery, and cause dyspnoea and death by obstruction of the pulmonary circulation. This theory, originally broached by Meigs, has been warmly supported by Playfair and Barker. Clinically, many striking facts have been adduced in support of this view. Playfair argues that when dyspnoea precedes phlegmasia dolens, the same causes which have led to thrombosis of the femoral vein had antecedently been at work in the formation of coagula in the pulmonary artery. But the post-mortem evidence of such a connexus is not conclusive. Dr. Mary Putnam Jacobi reported to the New York Pathological Society a death which occurred in a primipara five hours after childbirth. Two hours after the delivery was completed, the patient complained of præcordial oppression and dyspnoea. These symptoms continued to increase until the fatal termination. No lesions whatever to account for these symptoms were found at the autopsy. Her own opinion that the clots found in the two sides of the heart were formed subsequently to death,

¹Hegar. Sangphänomene am Unterleib. Arch. f. Gynæk., Vol. IV, p. 535.

was sustained by Dr. Janeway and other members of the Society who examined the specimen she presented. In a case reported by Dr. Playfair of sudden death occurring in a rheumatic patient, which he referred to thrombosis of the pulmonary artery, Drs. Wilks and Weber, of the London Pathological Society, reported upon the specimen as follows: "The characters of the clot are such as are not very rarely seen in cases of slow death, and there is nothing in its appearance to lead us to the belief that the clot was the cause of the death; in fact, judging simply from the specimen before us, we should have considered that it resulted merely from the diminution and gradual cessation of the heart's action." (Path. Trans., vol. xviii). Nor is it possible, when we recall the frequency with which thrombosis of the uterine veins precedes that of the veins of the thigh to be sure, in the absence of an autopsy, that the dyspnoea observed might not have been due to an embolus from a clot formed in a uterine vessel. Personally, I am far from willing to deny the possibility of Playfair's hypothesis. I only wish to state that so far as the evidence goes it lacks the positiveness of a scientific demonstration. Savage, in his reply to a paper on "Puerperal Thrombosis and Embolism," read by Playfair before the London Obstetrical Society (Trans., vol. xvi), while questioning the doctrine of primary thrombosis of the pulmonary artery, gives Virchow as his authority that "any of the few minor cardiac veins opening into the right auricle may be the seat of the primary thrombus, and give rise to a large secondary thrombus within the auricle," a fact which, if admitted, furnishes standing-ground for Playfair, and answers the objection that, excepting in the death agony, the force of the current in the pulmonary artery is such as to prevent spontaneous coagulation from taking place.

NERVE EXHAUSTION AND SHOCK.

Twenty years ago these two pathological states played a conspicuous part in the etiology of sudden death in childbirth. Now the fashion has changed. Such terms as "nervous apoplexy," or "idiopathic asphyxia," belong to an almost forgotten nomenclature. And yet none the less the necessity remains to account for a class of cases in which death takes place without recognizable organic lesions.

Instances of death attributed to heart-paralysis are to be found in the collections of McClintock¹ and Mordret², but to these objections have been made either that the post-mortem confirmation of the diagnosis was lacking, or that the examinations were wanting in the completeness necessary to shut out other possible causes of death. Baart de la Faille,³ however, has more recently collected thirteen cases of collapse in which the occurrence of embolism and the entrance of air could with every probability be excluded. Cases similar to my own, where the absence of all symptoms of pulmonary obstruction furnished certain evidence that the fatal ending was due neither to embolism nor to air, may be found scat-

tered through journal literature. As I write I find in the April number of the *American Practitioner* an account by Dr. O. T. Schultz in which an enfeebled patient was seized with deadly pallor and other signs of shock immediately after a precipitate labor occurring while the patient was at stool, the patient dying two hours later without dyspnoea.

Certainly in the absence of the visible lesions, or the characteristic symptoms of the conditions to which death in childbed is usually referred, we have the right to attribute the melancholy issue to the same causes which outside of childbed produce identical phenomena. It would be impossible to find in the annals of surgery a more striking example of the features of shock than those presented by my patient. The pinched features, the eyes sunken and surrounded by dark rings, the marble pallor of the skin, the hands and lips blue, the extremities cold, the sweat upon the brow, the thready, scarcely perceptible pulse, the shallow but not anxious breathing, with the closed sphincters, and with consciousness and sensibility preserved, present a complete picture of the torpid form of shock. As time passed by the erythritic symptoms followed; the face, with the exception of the mucous membranes, became reddened, beguiling me with false hopes; the eyes brightened, the patient became restless, bade her friends good-by in anticipation of death, and complained of constant thirst, while at the same time the pulse was too rapid to be counted, and the skin, in spite of artificial heat, never regained its normal temperature.

Modern pathological investigation refers the phenomena of shock to a reflex paralysis of the vasomotor, and especially of the splanchnic nerves, whereby the great mass of the blood is withdrawn from the surface, and collects in the large trunks of the cœliac, the mesenteric and the renal veins. Hence the skin becomes cold and is devoid of color, save at the points where a bluish hue is imparted by the stagnant blood still lingering in the veins; the muscles deprived of blood became enfeebled; and the empty vessels of the brain explain the sluggish intelligence, the nausea, the vomiting and the indifference of the patient; finally, during the diastole, the heart, pale and contracted, receives but little blood, and the radial pulse fades to nothingness, because a corresponding small amount of fluid is propelled during the systole into the arterial vessels.

From works on military surgery we learn that it is in the defeated army among homesick soldiers, at the close of a wearisome war after great exertions and deprivations, that shock is developed in its severest forms; that the finer the organization, the more readily the manifestations occur; that they are promoted by sudden losses of blood, and are in a special degree evoked by abdominal injuries.

It certainly would be singular if similar conditions in childbed were not followed by similar results. After prolonged labor, the woman has her nervous system depressed by pain, starvation, and deprivation of sleep. The sudden emptying of the uterus is followed by a recession of blood to the venous trunks of the abdomen. Hæmorrhage subsequent to parturition is followed by syncope, and the wonder is, not

¹McClintock. Dublin Med. Press, 1852.

²Mordret. Mem. Acad. Med., 1858.

³Baart de la Faille. I have only had access to the synopsis of these cases to be found in the Mon. Schr. f. Geb. Kunde. Vol. XXV, p. 318.

that the circulation should occasionally show the evidences of marked, and even fatal disturbance, but that the nervous system attacked from so many directions, should, as a rule, triumph over the adverse forces. In the old days of torture, shock often mercifully put an end to the victim's anguish. Women in childbirth are at times subjected to pain exceeding that of the rack and the thumb-screw. Now it is not sound pathology to ignore these facts, and to banish as unworthy of consideration a well established pathological condition, simply because in the days of ignorance the terms exhaustion and shock were indiscriminately employed to explain a multitude of cases, which, with our present enlightenment, we know are due to the entrance of air into the circulation and to pulmonary embolism. As the nervous organization of women loses in powers of resistance as the penalty of a higher civilization and of artificial refinement, it becomes imperatively necessary for the physician to guard her from the dangers of excessive and too prolonged suffering. Especially I would raise my voice in warning against the current opinion that the length of the first stage of labor before the rupture of the membranes is a matter of indifference, a teaching which I believe has cost the lives of many women; in a few, death resulting from shock; in more, the exhausted condition in which the woman is left after childbirth rendering her an easy prey to the perils of the puerperal state.

THE THERAPEUTIC USE OF MINERAL WATERS.

BY NORMAN BRIDGE, M.D.,

Professor of Hygiene and Adjunct Professor of the Practice of Medicine in Rush Medical College, Chicago.

It is always a question how much of the benefit experienced by invalids who visit springs and water cures is due to the water and how much to the change of air, scene, occupations, diversions and living. Doubtless both are important. That much is due to the change must be evident to any one who has observed the remarkable effects upon a chronic invalid of a vacation from effort and a journey from home. A few weeks spent out of the usual routine of cares and perhaps drudgery, in rest and amusement, will nearly always put new life into the chronic invalid not yet past recovery or improvement. But the water drunk and the baths taken are often, and may nearly always be, of great advantage to the sick. Invalids make all sorts of mistakes in the use of both, often drinking too much or too little water, and taking too many baths or too few, or at improper times and in the wrong way. But, with all their mistakes, they receive a balance of positive benefit whose value it is impossible to calculate. Moreover, they receive benefits that no one from a study of the chemical analysis of the waters would expect. Nor can the help derived always be explained by any known

effects of the chemical ingredients of the water in any doses or taken in any way. Artificial compounds made to imitate as nearly as possible the composition of the natural waters have frequently failed utterly to produce the same effect on the sick.

Mineral waters are therapeutic agents; they cannot all be used with benefit in the same way nor in a given state of system, and care and judgment are required in their use as in that of other therapeutic agents.

The different kinds of mineral waters. Waters may be classified as well as foods or drugs or clothes, but none of the classifications in vogue are entirely satisfactory. Waters in which the alkaline carbonates predominate are called *alkaline waters*. There is usually the greatest proportion of the carbonate or bicarbonate of sodium; in lesser quantities are the corresponding salts of potassium, calcium and magnesium. Other elements may enter which vary the therapeutic capabilities of the water, as sulphate of sodium and potassium, iron, etc. The milder waters of this class are diuretic in their effect, without irritating the kidneys or urinary passages. Of such springs are the Ems, Vichy, Apollinaris.

Saline waters, so-called, are mostly alkaline waters, but contain chloride of sodium in marked quantity. They affect the organism much as the pure alkaline waters do, only if the common salt is in large proportion, the waters are cathartic. The Saratoga springs—a dozen or more in number—are of this class, as are the Kissingen, the Selters and the springs of Manitou, Colorado.

Purgative waters contain the alkalies and the common salt in varying proportions, and in addition, Epsom or Glauber's salts or both, and in quantity sufficient to make them more or less cathartic. Of such are the Carlsbad in Bohemia, the Crab-Orchard in Kentucky, the Hunyadi-Janos in Hungary, and the Pagosa in Colorado.

Chalybeate waters contain, among many other ingredients of differing value, iron in tonic quantity. The Sweet Chalybeate Springs of Virginia, the Pyrmont of Germany, and the St. Moritz of Switzerland are examples.

Sulphur waters, many of them, resemble very closely waters of the other classes named, but they are distinctive in containing sulphur in the form of sulphuretted hydrogen, or sulphuret of sodium, calcium, potassium or magnesium. The Blue Lick Springs of Kentucky, and the Aix-les-Bains of France are good examples of this class.

Hot springs give forth water varying in temperature from 90 to 150° Fahr. Some of them contain minerals that make them valuable on that account, some are indifferent as to minerals and depend for their value entirely upon the heat, and are used chiefly or entirely in the form of the bath. The Carlsbad are mineralized and the Hot Springs of Arkansas are indifferent waters of this class.

The Calcic or Alkaline Calcic waters, so-called, are but slightly mineralized. The predominating element is some calcic salt, but they all contain more or less of the alkaline carbonates or bicarbonates and most of them some carbonic acid gas. They are nearly or quite tasteless, and their effect on the sys-

tem is in general that of an unirritating diuretic. The Contrexville, Leuk, Wildungen and Bagnères-de-Bigorre waters are old and the Waukesha waters new examples of this class.

Diseases likely to be benefited by mineral waters. Only a few of the many diseases that afflict mankind are susceptible of relief by the use of mineral waters. These are now fairly well understood, and although few, they make a list that is somewhat formidable. The following are among the more notable of them:

1. *Debility* and the digestive and assimilative disturbances attendant upon it. Victims of these conditions are numerous among men and women who work with brain or hands and who have cares. They are the drudges of all sorts who are ever improved by a vacation and whose indigestion and malassimilation always disappear upon an increase of vigor. Some of them are the *anæmic*, bloodless subjects of blood losses and wasting discharges of pus, and who lack recuperative ability; some are chlorotic.

2. The large class of diseases and disorders of the *digestive apparatus*, including: catarrh of the stomach, duodenum and bile ducts; formation of gall stones in the liver, bile ducts and gall bladder; catarrh of the intestines, with alternations of diarrhoea and constipation; constipation and hemorrhoids. From these conditions result perhaps every symptom ever ranged under the designation of dyspepsia.

3. Various *rheumatoid affections*. These are: gout (rare in this country); chronic rheumatism and rheumatoid arthritis or rheumatic gout; muscular rheumatism, and many cases of obstinate neuralgia, including some of sciatica.

4. *Syphilis*, not primary.

5. Certain diseases of the *skin*, such as eczema, psoriasis and pityriasis.

6. *Acute febrile diseases* in which there is a tendency to nephritis, albuminuria, and irritation of the urinary organs from deposits of solid matter from the urine, and from the concentration of this secretion incident to the fever state.

7. *Diabetes mellitus*—perhaps and probably.

8. *Disorders of the urinary apparatus*. Among these are inflammations of the kidneys (certain forms of Bright's disease), inflammation of the pelves of the kidneys, with or without gravel as a cause or a result, inflammation of the ureters and bladder—including catarrh of the bladder in all its multifarious shapes and degrees of severity.

The use of mineral waters in disease. Every chronic invalid who desires to get the best effect from the powers of the springs, should, if possible, visit them and drink the waters there. The change of life involved in such a visit will prove of great benefit, in addition to the good effect of the water.

The patient with *debility* from overwork or overworry, with some *indigestion and derangement of the bowels*, should have a radical change of diet. He should discard all condiments, new bread and pastry, and eat the most digestible and nourishing food, such as milk, stale bread with butter, eggs, oysters, tender meats, plain vegetables and fruits. He should eat slowly and without fluids to "wash down" his food,

and the quantity of the food should be restricted to what can be digested without discomfort.

In choosing his mineral drink he should take a mild alkaline water, either a plain alkaline, or one in which the saline or purgative elements slightly predominate. It must never be strongly alkaline nor strongly purgative, either from the chloride of sodium or the purgative salts.

If the conditions of the case and the character of the water will allow, he should take the water in rather large draughts, for the purpose of securing to some extent a diuretic effect, and to wash out the stomach. If in any case the stronger waters are used, particularly the laxative varieties, of course only a limited quantity can be drank. Yet a slight laxative effect is not objectionable, and is usually desirable.

When the bland waters are taken constipation sometimes occurs. This must be prevented in some way, and a very good way is to add to the morning draught the old-fashioned pinch of salt, or what is much better a pinch of some saline mixture which the physician may prescribe. Such a mixture would need to be varied according to the case, but it should always contain a major proportion of the sulphate of sodium. The patient will soon learn the dose of the mixture that is necessary for his case. No violent or prolonged purgative effect should be permitted.

Patients with *anæmia* and *chlorosis* should be advised to drink an alkaline iron water of only moderate strength, or a mild laxative alkaline water. Waters altogether too strong of iron are often taken by such patients. Chalybeate waters are liable and likely to aggravate any existing congestion of the liver or duodenum, and for this reason they are contraindicated in many cases of malarial anæmia, in which condition such congestions are common. All anæmic patients should have every aid of rest, recreation and change, with a most nourishing, digestible and full diet. Constipation and purgative effects are equally damaging to such cases.

Catarrh of the stomach of the usual form nearly always improves on the use of the alkaline, saline-alkaline or alkaline-purgative waters, with some rest of the organ. The amount of water proper to be taken is, to a certain extent, in inverse ratio to the concentration of the minerals. The bowels must be made to act rather freely, by the water unaided or by some mild laxative.

Catarrh of the duodenum and bile ducts improves on the use of the same class of waters, but a considerable admixture of sulphate of sodium (Glauber's salts) with the alkalies, is of advantage, particularly to the catarrh and congestion of the bile ducts and liver, the jaundice sometimes resulting and the tendency to the formation of gall stones. It is doubtless this salt that gives much of its value to the world-famous Carlsbad waters. If, in chronic cases of the last named disorders, the weaker alkaline waters are selected and anything like constipation should occur, benefit will be found in the addition of an artificial mixture of saline substances such as already suggested, with this difference, that the bicarbonate of sodium as well as the sulphate should enter quite largely into its com-

position. Chalybeate waters usually disagree with these patients, and should not be advised. Many cases of this class of ailments are caused by too much alcohol or some other stimulant, by over-eating or by some other abuse. Such cases are frequently called engorgement of the liver, and they seek the spas abroad and the springs at home in great numbers. A rigid adherence to a simple, unstimulating, and, unless there is debility, a rather low diet, must be insisted on with all such patients. This, with a prolonged use of the alkaline waters, will generally be followed by marked relief. Patients often feel so much improved after a short course of this treatment that they believe themselves to be well, and, returning to their old ways, are soon as bad off as ever. Nothing but patience in the regimen and prolonged use of the waters, or a frequent return to them, will give anything like permanency to the recovery. Many of these patients are plethoric, and can use waters much stronger in alkalies and purgative salts than the anæmic; for the latter the milder waters are preferable. The mistake is often made with the anæmic patient of trying, by violent purgation, to cure a congestion of some of the organs referred to, while the anæmia is growing worse. This is a serious mistake indeed, and it reminds one of a great French surgeon and his female patient with a bad skin disease. He gave her such powerful alteratives that, as the eruption grew less the patient did also, and finally died just as the eruption was disappearing, whereupon the surgeon triumphantly declared that "she died cured."

Jaundice, in the majority of cases, is due to catarrh or inflammation of the duodenum and bile ducts; hence, the relief of these possible conditions is the first thing to be thought of in connection with the treatment of icteroid troubles.

Catarrh of the intestines without constipation will experience more benefit from the mild alkaline or the alkaline-calcic waters than any other, unless there be also anæmia, in which case the element of iron as found in some of the mild chalybeate waters will be a good addition, provided it does not happen to cause constipation. A strong chalybeate water is likely to do this.

Obstinate constipation is benefited by the purgative waters taken regularly, a draught, large or small as required, daily before breakfast. In choosing water for this purpose, it is well to remember that the sulphate of sodium has a better effect on the intestinal mucous membrane than the salt of magnesium.

Hemorrhoids are relieved to a certain extent by anything that relieves or prevents constipation.

The chronic rheumatoid affections referred to are all susceptible of more or less relief by the free and prolonged use of the rather strong alkaline waters, particularly those that are laxative. In some cases, however, the milder waters seem to work better, but there is always benefit in a free action of the secretory organs, especially the skin, intestinal canal, liver and kidneys. Full function of the skin and kidneys may be maintained longer and more continuously by the milder alkaline waters than by any other. To do this rather large quantities must be drunk and they

may be taken continuously for an indefinite time. The body must be kept scrupulously warm at all times with woolen clothing, and wool or silk should be worn next the skin. Greater benefit than comes of drinking the water is derived from a long course of hot baths at the springs. It is not important that the water be mineralized; the indifferent thermal waters work quite as well as any. The product of the Hot Springs in Arkansas is an indifferent water, yet the resort is justly famous for this class of disorders. It is essential that the baths be taken regularly and for a number of weeks continuously. They must be of a uniform and high temperature and the air of the bath-rooms must be hot. It is next to an impossibility to attain all these conditions at the home of the patient, and they are rarely secured by a patient except at the springs. The bath treatment should always be directed as to all its details by a physician.

Syphilis, not primary, is benefited by hot air, hot climate, and hot baths, and the Arkansas resort has a great reputation in its treatment. Improvement occurs in most of the cases that resort to the baths faithfully, but most of the patients take large doses of the alterative medicines of mercury and iodine, while under the bath treatment, so that the results cannot all be attributed to the effects of the latter.

In using mineral waters for diseases of the *skin*, discrimination and care are necessary and be done under the advice of a physician. Eczema in certain forms, lichen, psoriasis and impetigo have been relieved by the waters. The sulphur and saline sulphur waters have seemed to do best, but if any catarrh of the stomach exists, which is not unfrequently the case, an alkaline water should be selected. Many cases of chronic skin disease have recovered at the springs, solely through the correction of some disorder of the internal excretory, or the assimilative organs, which had acted as a cause.

Mineral waters are generally supposed to be unadapted to *acute diseases*, or to do them positive harm. This view is irrational. Certain acute disorders receive the greatest benefit from laxatives, and a form of laxative medicine very grateful to many patients is such mineral waters as the Hunyadi, the Pillna, or the Friedrichshalle. To many fever patients the mild carbonated waters are extremely refreshing, and for the nausea and gastric irritability with which the sick are often annoyed, they frequently prove more soothing than anything else.

Such acute febrile diseases as are often attended by congestion of the kidneys and albuminuria may receive considerable benefit from the unirritating diuretic waters. They are grateful to the patient, cause probably an increased discharge of effete matter by the kidneys, dilute the urinary solids and render the passages more safe. The bland alkaline or calcic waters, with a touch of carbonic acid gas, will be found to agree best with such cases.

The water slightly carbonated is more grateful than the plain water, and the carbonic acid gas in small amount is oftentimes soothing to the stomach. Large doses of the gas are irritating. The charged waters as they come from the bottle are often too highly carbonated for a sensitive taste; they are too pun-

gent. When this is the case the water may be allowed to stand for a time exposed to the air to allow part of the gas to escape before using, or it may be briskly stirred with a spoon for half a minute. The patient will easily learn the proportion of gas that pleases him.

In *diabetes mellitus* the alkaline calcic waters may be taken freely, or the milder saline waters less freely, as a palliative. But the patient must subsist on the regulation anti-diabetic diet. Little hope of recovery need be entertained if ordinary diet is used.

Most of the *disorders of the urinary apparatus* are at beginning, and chiefly, irritation or inflammation of the mucous surfaces that are concerned in secreting the urine, in conveying it, in storing it for a time and finally in expelling it from the body. One of the first requirements in the proper management of such affections, is to put the disordered parts at rest and guard them from all irritating influences. Here rest of the parts is only to a very limited degree possible. Efforts must be mainly directed to relieving them from irritation. One of the first steps is to keep the skin uniformly warm, so that a large amount of blood may be retained in the surface of the body, and congestion of the deep organs be prevented. The general health should be maintained in a good condition, that the urine may be as nearly normal as possible. This principle is cardinal, since many of the diseases of the urinary organs are induced directly by the urinary aberrations of general ill health. Another thing to do, and that should never be omitted, is to decrease the irritation of the surfaces due to the urine, by diluting the solid matter thereof. Here is a means of some relief always within reach, and the wonder is, and the regret, that it is not always resorted to. Irritating substances in the urine, and substances irritating solely because they are in a concentrated state, may be made at once innocuous by the free dilution with water that a diuretic action produces. The employment of mineral water for ailments of the urinary apparatus, should be in this direction. Repeated and large draughts of the bland waters may be taken daily for a long time and with uniformly good results, particularly if the general health can be maintained, and the patient be under conditions of good hygiene. The waters adapted to such cases are the unirritating diuretic waters, the mild alkaline or alkaline calcic fulfilling this indication best.

In Bright's disease bodily exercise must be reduced to a low point for the purpose of lessening the labor of the kidneys. A restricted and very digestible diet should be taken, milk being one of the best foods. If the diet is restricted to this article and a large quantity be taken a diuretic action is induced not unlike that caused by the blander waters—the kidneys are, as has been said, washed out and their tubules are flushed. This is the purpose of the waters—to wash out, to flush the kidneys. Here hot baths are useful, but they must be used so as to increase the secretory action of the skin and keep it up to a high point of efficiency. The surface of the body must not be chilled; this is not enough—the possibility of chilling it must be prevented. Hence, hot

air and hot water, warm air and warm clothes must be the rule.

Owing to the great danger of disturbing injuriously the circulation in the kidneys in Bright's disease by a chill of the surface, it is unsafe for the patient to attempt to direct his baths himself. They should be taken under the direction, or better, under the observation of the physician.

How to drink mineral water. Do not drink it very cold unless it is a strong water and the dose is small. The milder waters must be taken in large doses (4 to 12 or more glasses daily) and should be drank cool, tepid or hot, never cold, as this might hurt the stomach and retard absorption. Many of the stronger waters, especially those that have an unpleasant taste, may be best drank hot, and, indeed, in the catarrhs of the upper abdominal portions of the digestive tube and in nearly all those conditions that go by the name of dyspepsia there is often great advantage in drinking the waters hot.

The water should in every case be taken slowly; several minutes should be given to each glass. With this precaution, several glasses may often be taken in succession without harm. The best time to drink is before a meal, especially before breakfast and supper. A meal must not immediately follow large draughts of water; half an hour at least should intervene. If any bad effect, like a sense of discomfort or fever should come on while using a water in large doses, reduce the daily quantum at once or stop it for a while altogether.

No discomfort at the stomach should be allowed to follow the taking of even moderate potions of the waters. If such should occur an effort must be made to learn the reason of it. Perhaps the water is taken too hot or too cold, too rapidly or in too large draughts, at the wrong time of day or in wrong relation to a meal. If the cause cannot be discovered and the difficulty corrected, the water is not adapted to the case and should be abandoned.

In this brief synopsis only a few of the more important facts and considerations regarding this interesting subject could be given; much has been omitted that might be said on the subject of baths, partly because much must be omitted and partly because the taking of baths, while often and best done at the springs, is nevertheless not so much a use of mineral water as it is a therapeutic use of hot water and air. Certainly the omission will not be taken as indicating any lack of appreciation of this valuable therapeutic measure.

CHOLERA---ITS DISASTROUS PAST AND ITS MORE HOPEFUL FUTURE.

BY H. RAYMOND ROGERS, M.D., DUNKIRK, N. Y.

The absolute failure in the past to read aright the clearly defined symptoms of this disease has left it, as found to-day, one of the most obscure and incomprehensible of all diseases. The wrong reading of symptoms is indicated by the fact that the rate of

mortality is virtually the same, whether nature alone is trusted for the cure, or whether the treatment is according to the best lights in medical science; viz.: 50 per cent. of those who are attacked.

Such being the fact, it is discreditable, not to say criminal, longer to entertain the theories or to employ the modes of treatment belonging to such a past. Our profession will be held to a rigid accountability by a world of growing intelligence. This disease will be studied by those outside of the profession who have faith in a better state of things as being possible.

The hope for better results clearly depends upon our breaking loose from old traditions, old theories, old systems, so as to be able to read the disease in the pure, simple light of its actual symptoms, and its well-known cadaveric autopsies. Then will the essential character of the disease be discovered, and at the same time its rational and successful treatment.

The fact that persons are attacked and die in the brief space of 20 or 30 minutes, proves that the fatal blow is expended upon the brain and nervous system. The malaise preceding the active stage of the disease, and the accompanying sense of prostration, add confirmation to this hypothesis. It is plain that the general nervous system is implicated, thus demonstrating that the disease is essentially a *neurosis*.

The rice-water discharges derived from the watery element of the blood constitute a true hæmorrhage. The brain and heart are thereby suddenly deprived of their natural stimulus. The rapid escape of a single element of the blood becomes disastrous, in the same manner as when the full blood is lost in the more ordinary forms of hæmorrhage. Such is the essence of the disease. But, owing to the failure to discriminate between the functions of the red corpuscles and the white discs, the two chief constituents of the blood, this philosophy has not been applied in its explanation. The vital force depends upon the red corpuscles, for through them chiefly is the oxygenation of the blood and consequent revitalization of the system. A small loss of this element is often speedily fatal. On the other hand, the serum or white element constituting the bulk of the blood apparently possesses less vital functions, and its abstraction becomes neither so quickly nor so seriously apparent. Enormous quantities are sometimes separated from the circulatory current without fatal consequence. The disregard of the true hæmorrhagic character of these discharges may account for the strange misconceptions that have heretofore prevailed.

The theory herein asserted, that cholera is essentially a *neurosis*—that its leading phenomenon is a true hæmorrhage, is incontrovertible, if any reference be made to actual conditions observed during or following an attack of the disease. Autopsy shows nothing which may not result from loss of the watery element of the blood. The so-called cholera microbe of Koch is now found *where cholera does not exist*, and, too, as Dr. Koch informs us, *in other epidemic diseases*. All diagnostic or therapeutic significance is removed from this microscopic object, as well as all scientific importance. The fact that these microbes have escaped the observation of such distinguished microscopists as Hayem, Thudicum, Macnamara, and Bruberger,

who number their autopsies by hundreds each, and a host of others of rare skill, whose investigations in this field were continued through long periods with infinitely better opportunities, shows them to be simply occasional concomitants of the disease, rather than its cause.

Assuming the correctness of the foregoing theories, the principle of treatment becomes unerringly determined, viz.: such treatment as is indicated in other forms of active hæmorrhage, with this important distinction—*i. e.*, the cholera hæmorrhage demands a vigorous watchfulness and attention, such as is rarely called for in its more common sanguineous forms.

It is essential to the healthy physiological action of the brain, that it be supplied with currents of blood normal in constitution and in full measure. The sudden disturbance in its equilibrium, in either of these respects, is capable of producing sudden and sometimes alarming or fatal effects. The pinched visage, sunken eye-balls, lusterless eyes, burning thirst, hoarse voice, washerwoman's hands, suppressed urine, cold extremities, and the voiceless yet speaking cadaver, all tell the story of emptied blood-vessels and a depleted brain. These conditions necessitate a speedy re-supply for the brain and heart. This can be accomplished only through the instrumentality of gravitation—*by position*. Let it therefore not be forgotten that the treatment of cholera resolves itself, in a measure, into a simple problem in mechanics—in hydraulics—upon the principle that water (or blood) tends to run down hill. This philosophy is emphasized in the fact that the loss of blood which, in the upright position, would quickly produce syncope or death, would scarcely be heeded in the horizontal position. *Position* thus becomes the fundamental consideration in the treatment of this disease—horizontal in mild cases, or inclined, with the head lowest, in grave attacks. We have reason to suppose that position alone would save a large proportion of the cases which otherwise would prove fatal. In severe attacks the inclination of the body should be strictly maintained until reaction becomes established. Murray tells us that "once sitting up in bed sometimes causes death in this disease." It should be well understood that no diarrhœa is harmless during a cholera epidemic. At such a time painless diarrhœa or vomiting are signals of danger. No attack, however mild, is free from the danger of suddenly and without warning passing into its gravest form. The obscurity incident to concealed hæmorrhage in this disease necessitates watchfulness, as death has at times been sudden, and the bowels found plugged with hardened fecal concretions and filled with rice-water secretions. The contents of the bowels being liquid, act upon the sphincter and by gravitation, and thus mechanically provoke catharsis; this necessitates the horizontal position.

Medication through the medium of the stomach cannot be relied upon in the treatment of cholera except in its earlier stages. At a period more advanced the physiological action of the mucous membrane becomes suspended, or reversed, and absorption no longer takes place. Hypodermic medication then becomes our surest reliance. Morphia, the king of

nerve-remedies, becomes our most efficient agency. While morphia in small quantities is of the highest value, yet, it cannot be too strongly impressed upon the mind that this drug has peculiar dangers when employed in the more advanced stages of the disease. Chloroform is of great value applied either by inhalation or internally. Opiates in any form are useful in guarded doses. Ice, *ad libitum*, or coldest water in small quantity, frequently repeated, also friction and external warmth, are *indispensable*.

As this disease is a neurosis and therefore mainly affects the general nervous system, any influence which is depressing to that system not only leaves it open to invasion, but actually invites attack, and often determines a fatal issue. Fear is the most potent nerve-depressor, and thus becomes its principal exciting cause and most fatal agency. In no other way is so wide-spread terror and depression generated and propagated as through the published press reports. The eagerness with which the public mind fastens upon anything which gives information as to the cholera, is phenomenal. The press cannot, therefore, too soon come to the full realization of the vast power which it exercises in determining the results of an epidemic, and the consequent necessity of caution in referring to the subject during its actual invasion.

National, State and local Boards of Health would promote the great cause which they represent by officially suggesting the value and importance of position as an element in the management of this disease, and by urging its early adoption in all cases of attack.

The foregoing theory of cholera and suggestions of treatment are simple—not the children of scientific imagination, nor are they due to the skillful construction of the theorist. They embody the results of a careful study of the disease both at home and abroad during the past 33 years, and an experience in its treatment in every epidemic since 1851, also a personal experience of its effects.

As a demonstration of the good effects in part due to the operation of this system, I may add that in all the cases in which it has been followed under my observation, 13 in number, the result has been favorable. The cases, although sporadic, were typical, and several of them were of the gravest character.

A concise description of a single case may be interesting and instructive.

Mr. A. was attacked by cholera in its gravest form. When first seen the pulse was only perceptible, and numbered 140. The prostration was extreme. His condition was such that morphia was inadmissible. The only hope in the case appeared to be in position. The body was inclined with the head lower than the feet—ice, warmth and frictions were employed and chloroform administered by inhalation for the relief of cramps. At the end of one hour the pulse had slightly increased in firmness, thus warranting the application of $\frac{1}{6}$ of a grain of morphia hypodermically. This was repeated at long intervals. The result, recovery. This case was the first in which I recognized the vital necessity of a position inclined, with the head the lowest, as an element in the treatment of

this disease. It is reasonable to suppose that life in this instance depended upon the adoption of this expedient.

We offer the preceding philosophy of this disease as one capable of explaining its phenomena in a clear and rational manner, and as meeting the indications for treatment by a method at once simple, rational, and consistent.

Its crucial test may be found only in the results of treatment when applied under all conditions and circumstances of the disease. The problem, therefore, remains for future solution.

MEDICAL PROGRESS.

MATERIA MEDICA AND THERAPEUTICS.

THE PASTE TREATMENT OF INFLAMMATORY SKIN DISEASES, ESPECIALLY ECZEMA.—Dr. P. G. Unna, (*Monatshefte für Praktische Dermatologie*; Edinburgh *Med. Jour.*) finding the greasiness and expense of ointments to be strong objections to their use—found that he could use a kaoline paste to advantage, and soon found that lead, starch, dextrin and gum pastes, might replace the kaoline paste. A good paste should be quickly and easily spread as a thin layer on the skin, and should spontaneously form in a short time a dry, firmly adherent coating.

Kaoline pastes.—Pure kaoline, with vaseline or glycerine in equal parts, with oils such as olive, almond, linseed in the proportion of 2 to 1, will produce a good paste. With more linseed oil a liniment is produced. This spread on extensive surfaces leaves a quickly drying residuum. When other ingredients, such as acetate of lead or oxide of zinc, are used, the kaoline and oil or glycerine are first to be mixed, and then the lead or zinc added, as the kaoline and the mineral are otherwise apt to form an insoluble cement. A suitable paste for eczema is this:

R Kaolini puri.

Ol. lini (v. glycerini).....āā 30-0

Zinci oxidi.....

Liq. plumbi subacet.....āā 20-0

Instead of white kaoline, the yellow or red is occasionally preferable for pastes for the face. The kaoline pastes are not merely suitable for the treatment of all kinds of eczemas, erythemata, and intertrigines, but are also suited as vehicles for strongly oxidizing, reducing or caustic remedies.

Lead pastes.—Boil a quantity of litharge with double the quantity of vinegar till the vinegar has evaporated, and the litharge has been transformed into a moderately damp paste. Should the paste become dry in time, it can be heated up with a fresh quantity of vinegar. This paste possesses considerable exsiccative power.

R Lithargyri subt. pulv.....50-0

Aceti.....80-0

Boil to the consistency of paste and add

Ol. lini (v. glycerini, v. ol. olivæ)..10-0

Starch pastes.—Here the property of drying must be imparted by the addition of some tempering material, as oxide of zinc, sulphur, etc. The following forms a good starch paste for eczema:

R Zinci oxid.	50-0
Acid salicylici.	2-0
Amyli oryzæ.	15-0
Glycerini.	15-0
Aq. distill.	75-0

Mixed directly and all heated at once to 140-0.

Starch paste for acne:

R Sulphuris precip.	40-0
Calcis carbonat.	2-0
Zinci oxid.	20-0
Amyli oryzæ.	15-0
Glycerini.	20-0
Aq. distill.	75-1

M. boil to.....120-0

Dextrin pastes.—It is recommended to use the official pulverized dextrin.

For eczema:

R Zinci oxid.	40-0
Dextrini.	20-0
Aq. distill.	āā 20-0
Glycerini.	40-0
Sulphuris sublim. (v. natri sulpho. ichthyolici).	2-0

M. boil to a paste.

For freckles:

R Zinci oxid.	10-0
Bismuth oxychloridi.	2-0
Hyd. perchloridi.	0-2—0-5
Dextrini.	10-0
Aq. distill.	āā 10-0
Glycerini.	15-0

M. boil to paste.

If hard, a few drops of hot water renders the paste easily spread.

Gum pastes.—For eczema when chronic in children:

R Zinci oxid.	40-0
Hyd. oxid rub.	2-0
Mucilag. acaciæ.	20-0
Glycerini.	āā 20-0
R Cretæ preparat.	
Sulphuris sublim.	āā 2-0
Picis liquid.	8-0
Amyli.	20-0
Mucilag. acaciæ.	
Glycerini.	āā 15-0

For scabies:

R Zinci oxid.	40-0
Bals. Peru.	20-0
Mucilag. acaciæ.	
Glycerini.	āā 30-0

In chapped nipples:

R Sacchari albi.	
Zinci oxid.	
Mucilaginis acaciæ.	
Glycerini.	āā 5-0

The gum pastes suit well as excipients for chrysarobin and pyrogallie acid. They cannot be employed

as vehicles for acids, since these destroy their adhesiveness. Oily substances can be incorporated with them.

Endeavors to find such pastes, which can be kept ready prepared in bulk, have not so far been crowned with success. The addition of glycerine and oil does not hinder them from drying up in time, and the better the paste, that is, the more rapidly it dries when applied to the skin, the more quickly it perishes when kept. But by these pastes a commonly felt defect in our medication is filled up and a suitable method of employing various active drugs is presented, as for example: *Lead* can be best employed as acetate in the simple lead paste or in combination with the dextrin paste; with both all other preparations of lead mix well, as the carbonate, the oleate, and the iodide. *Oxide of zinc* appears as a subordinate ingredient in the kaolin and lead pastes, as a principal element in the starch, dextrin, and gum pastes. *Sulphur* suits the starch, dextrin, and gum pastes, is less compatible with the kaolin, and not at all with the lead paste. The preparations of *ichthyol* suit for all except the gum paste. *Tar* suits better for the starch, dextrin, and gum than for the kaolin and lead pastes. *Naphthol*, *carbolic acid*, *chloral hydrate*, and *camphor* can be incorporated with all the pastes. *Salicylic acid* mixes well with all the pastes, unless with the gum paste, in large proportions. *Iodine* and *iodoform* suit for the lead, kaolin, and gum pastes, not for the starch and dextrin. *Corrosive sublimate*, *calomel*, *red and white precipitate*, can be incorporated with all the pastes. *Chrysarobin* and *pyrogallie acid* suit best the kaolin and gum pastes. Animal, vegetable, and mineral fats and soaps can be mixed in small quantities with the pastes without injuring their properties, but not in large amounts.

PINE BATHS.—*The Midland Medical Miscellany* tells us of the practice at some of the watering-places of Germany of using pine baths as highly beneficial in kidney diseases and for delicate children. The bath is prepared by simply pouring into the water about half a tumblerful of an extract made from the fresh needles of the pine. This extract is dark in color and closely resembles molasses in consistency, and when poured into the bath gives the water a muddy appearance with a slight foam on the surface. The repugnance one feels to enter into such a muddy looking fluid, is dispelled as soon as the delightful aroma which arises from the bath is inhaled. Although there may be some doubt whether pine baths act upon the system in any other manner than as a tonic, still, as an adjunct to the daily bath, infusion of the pine extract induces a most agreeable sensation. It gives the skin a deliciously soft and silky feeling, and the effect upon the nerves is quieting. The extract when properly bottled and securely corked, will not deteriorate for a long time, and the cost for gathering the pine needles and extracting their tarry substance is not very great.

It has long been recognized that the atmosphere of pine forests has an invigorating and beneficial effect upon people with weak constitutions and suffering from pulmonary disorders. A very simple prescrip-

tion of the physician is that the patient should spend several hours a day walking or riding through the pine wood.

To this we would add that the amusement of ladies and children at such places, of stuffing pillow cases and sofa cushions with these pine needles, and particularly with the strippings of the spruce, should be encouraged as taking them out of doors into the very midst of the pines, with healthy exercise, and saturating them with the aromatic principle of the trees. The pillows and cushions are reasonably soft and retain the aroma for a long time, to the pleasure and possible benefit of both the invalid and the healthy.

ON THE ACTION OF CARBOLIC ACID, ATROPIA, AND CONVALLARIA ON THE HEART OF THE TERRAPIN AND FROG.—Dr. H. G. Beyer, U. S. N., has been conducting a series of experiments on this subject, the results of which are given in the Proceedings of the Naval Medical Society. His experiments on carbolic acid show: 1st, that carbolic acid, in small as well as large doses, acts as a depressant on the heart from first to last, reducing its rate, its work done, and the blood pressure; 2nd, that the heart, as long as it is supplied with good oxygenated blood, will, up to a certain degree, show what almost amounts to an immunity from the poisonous effects of the drug; 3rd, that any effects produced by carbolic acid other than depressant are due to other causes, probably to primary stimulation of the respiratory centre in the medulla oblongata.

His experiments on atropia show: 1st, that after the heart has been carbolized, atropia increases its rate, and also its work; 2nd, it shows a more rapid recovery takes place after carbolization under atropinized blood than under normal blood. He believes with H. C. Wood that atropia must have a very powerful stimulant action upon the intra-cardiac accelerator centres.

His experiments with convallaria majalis were mainly with the glucoside convallamarin and showed: 1. Increase of heart-rate. 2. Slight increase in work done. 3. A raising of intracardiac and aortic pressure. 4. Both auricles and ventricles arrested in systole when medium doses were used. 5. Large doses arrested the heart at once. 6. It produced its results most probably by its direct action on the muscular substance of the heart. 7. Has a decided cumulative action, acting much slower than digitalis, and is much more persistent after the heart is once under its influence. He deduces from these results that convallaria is counter-indicated in advanced cases of cardiac disease, in which the muscular structure of the heart has undergone degeneration. Convallamarin should be used in preference to any other preparation. Not more than one full medicinal dose should be given daily on account of the cumulative action of the drug.

INJECTIONS OF CITRATE OF IRON IN CHLOROANÆMIA.—*El Siglo Medico* recently published the description of an interesting case of chloroanæmia cured by hypodermic injections of citrate of iron. The patient had presented symptoms of chloroanæmia since

1879, and had become excessively reduced in weight. It was determined to give dilute hydrochloric acid in gtt. viij doses, and at the same time hypodermatic injections of citrate of iron in the proportion of grs. xxx to f3 v of water; m. xv to be injected in different parts of the body every day. After forty injections the morbid phenomena disappeared, and the patient had gained over twenty pounds.—*Midland Med. Miscellany*.

MEDICINE.

RELATION BETWEEN AFFECTIONS OF THE EYE AND LESIONS OF THE TEETH.—The *Recueil d'Ophthalmologie* (*Jour. de Med.*) gives a résumé of a work by Prof. Power relative to this question, which has been but little studied. These relations are various in their character, and act either upon the muscular fibre, upon the cornea, or upon the optic nerve, the retina and the intra-ocular tissues.

One of the most common affections produced by dental diseases is the weakening, or even the loss, of the power of accommodation of the eye. This influence seems to be more marked in young subjects than in those that are older.

These reflex phenomena may also act especially upon the fibres of the iris. Desmarres cites the case of a patient who was cured of a mydriasis by the extraction of a carious molar tooth. Exophthalmos with glaucomatous phenomena has also been noted in connection with carious teeth, and has disappeared after their extraction. Von Graefe has given a case of blepharospasm which was produced in the same way.

The influence of carious teeth is also very often shown upon the conjunctiva and the cornea. Phlyctenular ophthalmia is very often associated with these alterations. Almost exclusively confined to children, it is relieved readily, but careful attention must be paid to the diet of the little patient, and sugars and acid fruits must be interdicted, because these substances, by depositing upon the carious teeth products susceptible of fermentation, produce inflammatory affections which propagate themselves along the nerve and become the cause of conjunctival inflammation. By this statement it is not the intention to deny that there is a phlyctenular ophthalmia of a different etiology, but this cause is a very common one.

Power cites an interesting case of corneal lesion: An abscess of the cornea occurred in a young girl accompanied by anæsthesia extending over the whole of the region supplied by the ophthalmic branch. No treatment was beneficial until the patient decided to have several carious teeth extracted which had given her much pain. From that time on there was a marked and progressive improvement.

The same action is demonstrated in the fundus of the eye by an observation of Lawrence in a case of complete cecity of one eye in a patient suffering from a carious molar. This (the molar) was extracted, and a foreign body found at its extremity, a little piece of wood, which had traversed the centre of the tooth through its carious portion and had re-

mained implanted there. The pain ceased at once, and the same evening the eye commenced to be again sensible to light. On the ninth day the patient was cured, after a cecity of 13 months.

If the irritation of the fifth pair produced in consequence of dental decay is persistent, it is perfectly possible that it should give rise to serious and permanent visual affections. The glaucoma, which is due to alteration in the nutrition of the eye, may frequently have its origin in a lesion of the dental nerves. In conclusion, Power lays down as a law that in all cases of commencing glaucoma, in myosis or mydriasis without apparent cause, in the sudden paralysis of one of the muscles of the eye, or in amaurosis not of cerebral origin, in phlyctenular conjunctiva, or in persistent ulcerations of the cornea, as well as in paralyses of accommodation, particularly in children, a careful and minute examination of the teeth must be made at the beginning, and any lesions found there must be properly attended to, for very often by so doing the affections of the eye will be relieved.

SURGERY.

MASSAGE IN STRICTURE OF THE URETHRA.—*The Midland Medical Miscellany* gives us an extract from the *Centralblatt für Chirurgie* of Dr. Géza v. Antal's experience with this treatment in a number of cases.

The difficulty of passing a sound in stricture of the urethra following gonorrhœa depends, in the majority of cases, not so much upon the simple narrowing of the urethra itself as upon proliferation of the connective tissue in the surrounding parts. This hyperplasia of the connective tissue occurs in irregular patches about the urethra in such a way as to render the canal tortuous, thus increasing the difficulty of passing an instrument to the bladder. Dr. v. Antal succeeded in inducing absorption of this hyperplasia by massage. The duration of each sitting was from eight to ten minutes, and the massage was repeated daily.

Massage of the pendulous portion of the urethra presents no difficulties, but that of the membranous and prostatic portion is possible only through the rectum. Internal massage by means of the repeated introduction and withdrawal of a sound, as recommended by Bardinet, does not commend itself to the author. It is only possible in those cases in which the stricture is already permeable, while v. Antal's method is of especial value precisely in those cases in which the urethra will not admit of the passage of a bougie. Further than this, internal massage acts only upon the thin layer of tissue immediately surrounding the urethra, while the external method causes the entire hyperplasia to disappear. The author thinks that in many cases massage will be used in preference to urethrotomy.

ECHINOCOCCUS OF THE SPLEEN.—Prof. Mosler (*Deutsche Med. Wochenschrift*) has studied 56 cases of this disease with the following conclusions:

1. Sex seems to give no predisposition toward echinococcus of the spleen.
2. The affection is most usual between the ages of 20 and 30 years.
3. As regards symptomatology, the signs of the tumor may be so slight as to give no symptom during life. In other cases the first symptom is an intense pain after some exertion, or after labor, showing inflammation of the echinococcus cyst.
4. The diagnosis rests mainly on the physical signs, and is difficult. These tumors differ from other tumors of the spleen in their fluctuation.
5. The prognosis of solitary echinococcus of the spleen is certainly more favorable.
6. Internal treatment amounts to nothing. The sac must be opened by means of scissors, and Volkmann's method for suppurating echinococcus of the spleen followed.—*Midland Med. Miscellany*.

OBSTETRICS AND GYNÆCOLOGY.

CHRONIC HEART DISEASE AND PREGNANCY.—This is the subject of an inaugural dissertation by G. Wesner, of St. Gall, who gives the following résumé, after a careful review of the literature of the subject:

1. There is no specific physiological hypertrophy of pregnancy. The heart of the pregnant woman only obeys the general law that the mass of the cardiac muscle increases with that of the body.
2. Other grounds for believing in a physiological hypertrophy are faulty, and cannot be brought into pathological relation.
3. The conditional hypertrophy of the heart, of pregnancy, caused by increased body-weight, is so slight that it can only be considered as a danger in very severe heart trouble.
4. The causes of the unfavorable influence of pregnancy on heart trouble, lie not so much in the increased cardiac activity, on account of the pregnancy, or the pressure suddenly removed by labor, and the high position of the diaphragm, as in the physical and physical fatigue of labor, which reacts on the heart.
5. But, as statistics show, these are endured in by far the greater number of cases, without especial damage. It seldom occurs that severe heart trouble is specifically due to pregnancy, but it more usually happens that we have to do with very severe heart disease as a secondary complication.
6. As malignant endocarditis occurs especially in the course of old heart diseases, so it also seems to occur after labor, as septic poisoning.
7. The prognosis is considerably better for both mother and child, if it exists from the beginning.
8. The treatment is symptomatic, not the performance of premature delivery, but hastening labor if necessary.—(*Centralbl. für Gynäk.*; *Midland Med. Miscellany*).

THE
Journal of the American Medical Association.

PUBLISHED WEEKLY.

THE EDITOR of this JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information, should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE..... \$5.00.
SINGLE COPIES..... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 65 RANDOLPH STREET,
CHICAGO, ILLINOIS.

SATURDAY, OCTOBER 18, 1884.

THE DIAGNOSIS OF GASTRIC CANCER.—The difficulty of diagnosing cancer of the stomach was set forth in a paper by Dujardin-Beaumetz at a meeting of the Société Médicale de Hopitaux the 25th of last July. The importance of differentiating this affection from gastric ulcer, gastric dilatation and chronic gastritis, with reference to prognosis and treatment, becomes apparent when we consider the relative frequency with which the stomach is the seat of cancer.

DaCosta states: (Medical Diagnosis, fourth edition, page 442) Cancer is found more frequently in the stomach than in any other organ except the uterus. Of 9,118 cases of cancer which occurred in Paris from 1837 to 1840, 2,303 were in the stomach.

According to the report of Dujardin-Beaumetz's paper, for which we are indebted to the New York *Medical Record* of October 4, there is no sign nor symptom which renders carcinoma of the stomach easy of recognition. There is no symptom that is pathognomonic of carcinoma of the stomach. At the bedside we are "usually unable to determine the precise nature of any internal tumor," and though "histology has given us a very complete list of the various forms of cancer," we are not capable of clinically distinguishing them with corresponding nicety. Cancer generally presents itself after the age of 40, and is more frequent in males than in females. But so also is gastric dilatation. As to the duration of the disease, it is said not to exceed three years. This the author pronounces incorrect, as he has observed one case in which, in all probability, it did not run its course short of 12 years. He knew of other in-

stances where it had existed for periods longer than three years. Pain cannot be relied on, since it is not invariably present. "Painful oedema" of the extremities, which Trousseau considered as characteristic of cancer, may attend dilatation of the stomach. The coffee-grounds appearance of the *ejecta* is not trustworthy, since it is sometimes observed in gastric ulcer. Other dyspeptic symptoms are equally delusive by reason of their occurrence in chronic gastritis and dilatation. Even the presence of a tumor may be deceptive. According to the author, dilatation of this organ may exist together with thickening of the walls. Moreover, Quesnel's assertion, that the conjunction of cachexia, with a disorder of the stomach, is always proof of the affection being cancerous, is denied by Dujardin-Beaumetz. He has determined the amount of urea daily eliminated by patients suffering from cancer of the stomach, and found Romelare's statements correct in the main, though not without exception. M. Romelare declares that in gastric cancer the amount of urea excreted ranges between 120 and 150 grains in the 24 hours, whereas in ulcer it never falls below 225 grains, but varies from that up to 500 grains. Dujardin-Beaumetz found 45 grains to be the daily average of urea in one patient, and hence concluded the disorder of the stomach in this case was cancerous. The necropsy, however, showed it to have been "an hydatid cyst." The author also denies the utility of distending the stomach with gas, as do the German clinicians. On the whole, the distinguished author leaves the matter of the differential diagnosis of gastric cancer very much in the dark.

In many instances this must certainly be the case with the most of us, but, in the hands of a Mikulicz, the gastroscope appears to do much toward illuminating the obscurity. This instrument is so difficult of manipulation, that it is not likely ever to become a part of the physician's paraphernalia. In Billroth's clinic, however, it is relied on as a valuable means of diagnosis. The Americans have a reputation as skillful manipulators, and it is to be hoped they will not neglect to cultivate the ability to utilize the gastroscope.

Though this instrument be so difficult of employment, there is another which is not so, and may often yield valuable results. We mean the microscope. Though fragments of cancerous tissue are not always to be found in the *ejecta*, their presence or absence is to be determined by microscopic inspection alone. Their absence would not disprove the existence of the suspected lesion, but, on the other hand, their detection would settle the question beyond a doubt.

Again, in hospital practice distension of the stomach, either with gas or liquids, is certainly advisable, since, Dujardin-Beaumetz to the contrary notwithstanding, it is often of great practical service. Else, why its employment at Vienna, Berlin, Munich, and elsewhere?

CORRECTIONS AND ADDITIONS.—For several months past we have endeavored to have all leading papers put in type in time to have the first corrected galley proof sent to the authors for their own correction and return before the sheets were finally put through the press. In the meantime the same proof is carefully revised here in close comparison with the manuscript.

In two or three instances it has happened that the author's proof has not reached us until a few hours after the printing was completed. Such was the case with the valuable paper of Dr. T. R. Varick in the JOURNAL for the 4th inst. And in consequence our readers are requested to make the following corrections: On page 373, in 41st line from the top of the left hand column strike out the word "femoris;" and in the 45th line of the same column for "extensors of the thigh," substitute "extensors of the leg." On page 376, in 44th line from the top of the right hand column, insert the following: "In private practice I report three cases, all successful, viz.:" At the bottom of the same column what is said of the temperature, pulse, etc., should have constituted a part of the marginal "Note" in reference to the two operations since the paper was written.

The report of discussions in the Section of Obstetrics and Diseases of Women at the last annual meeting of the Association, was not only more full than from any other Section, but was also written out in plain type-writing, indicating that the Secretary had given a commendable degree of attention to the duties of his office. Nevertheless some mistakes were made, one of which consisted in giving the name of "Dr. Holman of Boston," several times in the discussion on the paper of Dr. R. S. Sutton, of Pittsburgh, published in the JOURNAL of the Association for September 20, 1884, when the name should have been Dr. John Homans, of Boston. Dr. Homans, in a letter bearing date the 6th inst., asking for a correction of his name, gives incidentally the interesting fact that he has "just had a run of 38 successful ovariectomies."

CHOLERA IN EUROPE.—During the last two weeks the cholera epidemic in France has been rapidly subsiding, the total deaths from that disease upon Oct. 7 in the whole country only reaching eight.

From Italy we have the report under date of Oct. 12 of only 239 fresh cases and 137 deaths in all the infected districts, and of these 115 fresh cases and 31 deaths occurred at Naples.

From Spain we have notice that at Madrid, Oct. 12, the *Official Gazette* announces the cholera epidemic ended, and that the bulletins will no longer appear.

We are thus relieved, for the time, of apprehension as to the immediate appearance of cholera in this country. Judging from past experiences, it is more than probable that it will reach this country during the coming year. We are thus forewarned and have ample time to do all that our present knowledge of sanitary science can suggest for the mitigation and control of this terrible scourge. The present is a time most fit for all who have the interests of the people at heart to bestir themselves for the securing of all needed sanitary legislation.

It seems to us that the time is at hand when the combined wisdom of our ablest medical men and jurists as well, should formulate a *code* of sanitary laws worthy of the age and of the nation—a code in which the interests of municipalities, the rights of States and the supremacy of the nation should be so wisely recognized that its provisions should secure universal approval—and as the law of the land an universal enforcement.

CHICAGO COLLEGE OF PHARMACY.—This excellent institution, which was organized in 1859, celebrated its twenty-fifth anniversary on Monday evening, Oct. 13, by the opening and dedication of its new college building.

The new edifice is at 465 State street, and has been designed and constructed throughout for the purposes of a College of Pharmacy, under the direction of those who are thoroughly conversant with the needs of such an institution. This college is now in all respects one of the best educational institutions of its kind in this or any other country.

DRS. F. C. HOTZ AND A. P. GILMORE VINDICATED.—Some time since a Mr. A. B. Lee brought suit for malpractice against these parties, who are members of the Surgical Staff of the Illinois Eye and Ear Infirmary of this city. Dr. Hotz was dismissed at the commencement of the trial, and the jury found a verdict of *not* guilty in regard to Dr. Gilmore. The whole charge was without adequate foundation.

NEW YORK STATE MEDICAL ASSOCIATION.—The regular annual meeting of this important organization will be held in Murray Hill Hotel, New York City, commencing on the 18th of November, 1884, and continuing four days. We are informed that the Association now numbers more than 300 members, and the coming meeting will undoubtedly be one of much interest and profit.

INTERNATIONAL COLLECTIVE INVESTIGATION.

WE ask the careful attention of all our readers to the following statement relating to the international collective investigation of disease proposed at the International Medical Congress at Copenhagen:

The general meeting of the International Medical Congress, held at Copenhagen on August 14, 1884, upon propositions made by Sir James Paget, Professor Ewald, of Berlin, Professor Bouchard, of Paris, and Dr. Billings, of Washington, passed the following resolutions:

1. That an International Committee be formed for the collective investigation of disease, in connection with the work of the International Medical Congress.

2. That the following gentlemen do represent their respective countries thereon:

As representatives of Denmark—Professor Trier, of Copenhagen; Professor C. Lange, of Copenhagen.

As representative of Scandinavia—Dr. E. Bull, of Christiania.

As representative of Russia—Dr. Rauchfuss, of St. Petersburg.

As representatives of Germany—Professor Ewald, of Berlin; Professor Bernhardt, of Berlin.

As representatives of Austria-Hungary—Professor Schnitzler, of Vienna; Professor Pribram, of Prague.

To whom was added by co-optation—Professor Koranyi, of Buda-Pest.

As representative of Switzerland—Professor Despine, of Geneva.

As representatives of France—Professor Bouchard, of Paris; Dr. Lépine, of Lyons.

As representatives of Great Britain and Ireland—Sir William W. Gull, Bart.; Professor Humphry, of Cambridge; Dr. Mahomed, of London.

As representative of British India—Sir Joseph Fayrer, K.C.S.I.

As representatives of the United States—Professor Jacobi, of New York; Prof N. S. Davis, of Chicago.

As representative of South America—Dr. Gutiérrez-Ponce, of Paris.

As Secretary-General—Dr. Isambard Owen, of London.

Representatives of other countries to be hereafter appointed.

In accordance with the following resolution of the first meeting of the above committee, held at Copenhagen on the following day, viz.:

“That the Secretary be instructed to prepare a statement as to the objects of the committee, for translation and publication in the journals of the various countries represented;”

I beg leave to submit the following statement to the members of the medical profession of America.

ISAMBARD OWEN, Secretary-General.

5 Hertford street, Mayfair, London.

The main objects which the committee seeks to attain through the collective investigation of disease are to widen the basis of medical science, to gather and store the mass of information that at present goes to waste, to verify or correct existing opinions, to discover laws where now only irregularity is perceived,

to amplify our knowledge of rare affections, and to ascertain such points as the geographical distribution of diseases and their modifications in different districts. It will be its endeavor to place clearly before the whole profession the limits and defects of existing knowledge, as well as to stimulate observation, and to give it a definite direction. It will be a not unimportant incidental result of its work should it tend, as is hoped, to the better training of the members of the profession in habits of scientific and practical observation, and in systematic methods of recording the facts which they observe.

The age in which we live has seen enormous advances in the sciences on which the fabric of medicine rests, such as chemistry and other branches of physics, physiology, and pathology. Each of these has taken giant strides. It must be admitted, however, that purely medical knowledge has scarcely made proportionate progress. It cannot be expected that it should do so, as it deals with the aberrations of the most complex of organisms, is of all sciences the most difficult, and demands the greatest patience and the largest accumulation of data.

Hitherto the advancement of medical science has been brought about mainly by individual effort. The value of such work in the past we in no way under-rate, nor do we desire to lessen the amount of it in the future; but in medical science there is much that defies interpretation from individual experience, and many problems so far-reaching in an ever-widening field, with elements so manifold, that no single man, however gifted and long-lived, can hope to bring the whole within his range. The need, therefore, in medicine, of that combination and concentration of individual work which is adopted in many other branches of science and in commerce, and to which increasing facilities of intercommunication have given so much impulse and so much strength, cannot be questioned. Indeed, it may be said that, resting on individual research alone, medical knowledge can be advanced but slowly and with difficulty. Future progress to any great extent must be the work, not of units acting disconnectedly, but of the collected force of many acting as one. For many to act as one, organization is needed; that organization it is the purpose of our committee to supply.

Disease is many-sided; and we wish to include in our organization those who see it from every side. All, therefore, whether hospital physicians, family and school attendants, specialists, medical officers of the Army and Navy, and of workhouses and asylums, will be asked to contribute their quota of observation to the common fund.

In England and in Germany organizations for this purpose already exist, through which good work has been accomplished; and a volume entitled the *Collective Investigation Record*, containing tabulated returns, with reports upon them and other matter, is published annually by the British Medical Association. France and Austria are alive to the importance of the new method. In Scandinavia and in the United States the foundations of associations have been laid. Denmark, Russia, and Switzerland are setting their hands to the task. To unite these sev-

eral associations by an international organization for the study of various problems, and to induce the formation of similar combinations elsewhere, is felt to be a work peculiarly befitting an International Congress. Our committee is enjoined by the Congress at Copenhagen to endeavor to carry out this work, and, in compliance with that injunction, it invites the co-operation of all who have at heart the promotion of medical science and practice.

The following is the proposed method: A subject having been selected, a person or persons of acknowledged authority will be asked to write a memorandum, in the form of a short essay, upon it. The memorandum will succinctly give the present state of our knowledge. It will also point out the directions in which further research may best be made; and, with this view, will suggest a few simple and definite questions upon the subject selected. The questions will relate to matters of fact, to be elicited by observation of cases, rather than to matters of opinion.

The contemplated organization will, it is hoped, in time enable the committee to ask and collect answers to these questions from the profession at large wherever scientific medicine is studied or practiced. It will be a further duty to examine, arrange, tabulate, and deduce results from the mass of observations thus collected, due credit being given to each contributor for the information he has furnished; and reports on the results of the several investigators will be laid before the International Congress at its next meeting at Washington.

SOCIETY PROCEEDINGS.

AMERICAN GYNÆCOLOGICAL SOCIETY.

[Continued from No. 15.]

Ninth Annual meeting, held at the Palmer House, Chicago, September 30 and October 1 and 2, 1884.

Dr. Baker had a fatal case where a post-mortem examination showed a tubal pregnancy of six weeks. The sac was not ruptured, but blood, which came from a ruptured vessel at the end of the Fallopian tube, was found in the abdomen. It would have been a good case for operation.

A Case of Tubal Pregnancy with Rupture of the Sac, by Dr. R. B. Maury, of Memphis. The patient was the mother of five children. Five months after the birth of the last child she had an operation for lacerated perinæum. Later she had an obstinate bronchial catarrh and her menses stopped for five months. Still later her menses stopped again, and on account of nausea and other symptoms she suspected pregnancy. In the last of December she had abdominal pains and cramps and some hæmorrhage. Dec. 30 she had an attack of great pain and syncope. Her pulse was one hundred and fifty, and her temperature subnormal. There were symptoms of an intra-peritoneal hematocoele and a tumor was found to the right of the uterus. After the patient had recovered from the shock the tumor was again found and

the uterus was enlarged. The diagnosis of pregnancy with rupture of the sac was made. For four days there was severe peritonitis. On the sixth day a slight attack of pneumonia began. February 15 the tumor was still felt in Douglas' pouch. There was no hæmorrhage nor discharge.

In regard to etiology the only statement that the writer would make was that the husband had a stricture.

In regard to the treatment of these cases, Playfair advises laparotomy and ligation of the cord. Lusk, writing later, says that no one has ventured to practice this. Of the thirty-five cases of Tait in only one did he operate at the time of rupture, and that was fatal. The writer's conclusion is that laparotomy should be postponed till after recovery from shock.

In the afternoon session of Wednesday there was presented, The Limits of Vaginal Hysterectomy for Cancer, by Dr. Paul F. Mundé, of New York.

At the last meeting of the Society Dr. A. Reeves Jackson, of Chicago, read a paper strongly condemning the operation for removal of the uterus in cases of cancer. Most of the speakers who commented on the paper agreed with him, so that the impression had gone forth, not only in this country, but in Europe, that the American Gynæcological Society had passed its judgment in condemnation of the operation. If the judgment concerned only Freund's operation of hysterectomy by abdominal incision, Dr. Mundé would agree with it. The statistics are fatally against that operation. He thinks that most of the speakers last year had in mind that operation. The history of vaginal hysterectomy has been much better, and its future is much more promising.

Before considering the conclusions of Dr. Jackson in detail, Dr. Mundé gave an account of two cases of his own, not as a confirmation of his views, for the results were not good, but rather as an addition to the record. In the first case there was epithelioma of the cervix, which had been first noticed six months before. The uterus was enlarged to six or seven ounces. The patient was out of bed in twelve days after the operation, and in six weeks the wound was closed. A microscopical examination of a section of the mucosa was made by Heitzmann, and an infiltration of the tissue with small cells led him to predict a probable recurrence of the disease within two years. In fact it did recur in the cicatrix nine months after the operation. The second case was operated on Nov. 9, 1883. The uterus weighed three and one-half ounces. The epithelioma had extended to the vaginal vault. The hæmorrhage during the operation was great, and the patient died forty-eight hours later from shock.

The writer next considered the conclusions of Dr. Jackson which were three. First, the diagnosis cannot be made sufficiently early. Second, when the diagnosis is made there is no hope for a cure. Third, the operation is very dangerous to life.

The failure of an early diagnosis is due to the fact that the patient does not go early enough to the gynæcologist. The microscope will tell if the infiltration has begun. The laity should be impressed with such

fear of a purulent discharge that every woman would seek advice upon the appearance of the first symptoms. Out of eight hundred and twelve cases of cancer Schroeder found thirty-four suitable for operation. Ohlhausen had thirty-two. Out of one hundred and sixty cases of his own Dr. Mundé has operated but twice, and neither of those cases does he now consider suitable for operation.

The operation is of such recent origin that the facts bearing on the cure or recurrence of the disease are meagre. Of the eighty-two cases that have lived more than two years after the operation, in forty-eight there has been a recurrence of the disease in from two months to two and one-half years. Thirty-two, or thirty-nine and two-tenths per cent., are well after two years. This showing is better than that for any other cancers. It is twice as good as the record of Billroth's cancer operations. Yet when the disease returns the palliative results may be important. If it produce a temporary freedom from the disease, if it diminish pain, its value is not to be overlooked. Of course if the parametrium is involved palliative measures, as curetting, partial excision, cauterizing, etc., should be employed.

In considering its danger the writer compared its mortality with that of other cancer operations. Billroth has operated for mammary cancer one hundred and seventy times, with thirty-four deaths, or twenty per cent; for lingual cancer forty-two times with eighteen deaths, or forty-five per cent.; for rectal cancer nine times with five deaths or fifty-three per cent. Rosé (Marburg) has had a mortality, for mammary cancer of twenty-six and three-tenths per cent., for rectal cancer of fifty-three per cent., for lingual cancer of eleven per cent. Schroeder had one hundred and five high vaginal amputations with thirteen deaths, or twelve and three-tenths per cent. In his (Freund's) operations sixty-two per cent. died. In thirteen cases of supra-vaginal amputation by laparotomy thirty per cent. died. All cases of vaginal hysterectomy that have been reported number two hundred and fifty-six. Of these sixty-two, or twenty-four and six-tenths per cent. have died. The *Philadelphia Medical News* for Sept. 19, 1883, gave one hundred and sixty-seven operations as having been performed at that time. Of these there were fifty-two deaths, or about thirty-one per cent. Thus it is seen that with the increase in the number of operations, with increase of technique, with a more careful selection of cases, there is a decrease in the mortality.

The present status of the operation may be given in an answer to two questions: 1. Can vaginal hysterectomy for uterine cancer be performed without so great a loss of life as to render it unjustifiable? 2. Can we hope to secure by it complete immunity from a return of the disease? The first question can be answered in the affirmative. No answer can be given to the second question till the operation is older.

The following conclusions state the conditions and indications for the operation: 1. Limitation of the cancerous degeneration to the uterus and absolute freedom from disease of the parametrium. (Of course the disease must extend above the level of the vaginal

vault and be beyond simple amputation or excision). If the finger in the vagina or rectum detect the slightest infiltration of glands, lymphatic vessels or cellular tissue, or the microscope reveal doubtful cell formation in sections of mucous membrane removed from the vaginal vault, complete extirpation should be abandoned. 2. Cancer of the cervix extending up the cervical canal to a height the precise limit of which is doubtful, thereby rendering the probability of complete removal of the disease by high supra-vaginal amputation and cautery extremely doubtful. 3. Cancer or sarcoma of the body of the uterus. (Schroeder's method of intraperitoneal amputation of the corpus uteri might be substituted. There have been seven operations with two deaths. No recurrence within two and one-half to five years in four cases. The fifth could not be traced). 4. Perfect freedom of motion of the uterus, so that it can easily be drawn down to the vulva by traction on the cervix and can be moved in any direction. This condition is absolutely indispensable. 5. A capacious vagina, permitting ready exposure of the cervix and vaginal vault and easy manipulation of ligatures and instruments. Section of the perinaeum should be admitted only when a narrow vagina is the sole obstacle to a surgical operation. 6. A sufficiently vigorous condition of the general system, such as absence of other serious organic disease of other organs, so as to permit the patient to stand the shock which, however, is as a rule much less than the gravity of the operation would lead one to expect. Cachexia, if present, will probably denote such progress of the local disease as to contraindicate the operation.

In the spirited discussion which followed, Dr. Mundé replied to questions as to what was meant by recoveries in the mortality statistics that he did not know the time of death in each case, nor did he consider it important. All the deaths that were due to the operation were included in the mortality list, whether the patient died on the table or several days later.

Dr. Jackson stated that every therapeutic measure, surgical or medical, must be judged by certain underlying principles. Every surgical measure must relieve suffering or prolong life. If cancer returns it brings with it the same pain. Hence, unless the operation cures it does not relieve suffering. Over two hundred years of life have been lost by the operation. This statement is based upon statistics which show that the average length of life after discovery of a cancer of the cervix is eighteen months, and after discovery of cancer of the body it is two and one half years. The other factor in the computation is the mortality, which a year ago was 28 per cent.

The microscope can detect cancer, but it cannot tell how far it has extended, for the extension is not always by the involvement of contiguous tissues. What is meant by a successful operation? If the disease reappears it was not a success. Recurrence is not a proper term; the disease continues. The operation then is only a partial removal.

Dr. Van de Warker reminded the Society of the old opposition to ovariectomy, and thought that this operation should not yet be judged. He thought

that the cases should be divided into two classes: first, menstruating women; second, women who have passed the climacteric. In the first class he suspected that the dangers of an operation were greater.

Dr. Engelmann held that we are justified in testing the operation.

Dr. Palmer thought that the mortality would probably be reduced to ten per cent. He thought that the operation should be limited to sarcomata starting in the uterus on account of the impossibility of determining, in cases of carcinoma, whether the pelvic glands are involved or not.

Dr. Baker has operated six times, and in only one case has there been recurrence. The rest are healthy.

Dr. Scott thought that the camp was divided between the young fellows and the old fellows. He gave the history of a case which seemed favorable for operation. The uterus was small and perfectly mobile. The operation was not difficult. There was no hæmorrhage. The patient made a good recovery and fattened. But in seven months later the disease returned, and in two months more she died.

Dr. Reamy said that this operation had no analogy to ovariectomy, and any comparison was irrelevant. An ovarian cyst never returned. He spoke of a case where a patient was living three years after the discovery of a cancer, no operation having been performed. Also of another case where a patient lived four and one-half years. He thought it important to collect more of these cases. The statistics of the operation have improved, but the statistics of recurrence have not improved. He held that if the cancer is confined to the cervix, amputation should be performed. If the cancer extends to the body, the diagnosis of the extent of infiltration cannot be made, and no operation is justifiable.

Dr. Fenger, of Chicago, thought that there was theoretical reason for the operation where amputation was not sufficient, and he believed that the operation would go on until it justified itself.

In the evening a business meeting was held, with closed doors. The following offices were elected for next year: President, W. T. Howard, of Baltimore; Vice-Presidents, W. L. Richardson, of Boston, and Paul F. Mundé, of New York; Secretary, Frank P. Foster, of New York; Treasurer, Matthew D. Mann, of Buffalo; other members of the Council, J. T. Johnson, of Washington; A. Reeves Jackson, of Chicago; H. P. C. Wilson, of Baltimore; Eli Van de Warker, of Syracuse. The limit of membership was increased to 100. It was decided to hold the next meeting of the Society in Washington, on the third Tuesday of September, 1885.

The first paper presented at the morning session of the third day was the President's address. The Present Aspect of the Puerperal Diseases, by Dr. Albert H. Smith, of Philadelphia. He spoke first of the brilliant career of gynæcology, especially in the field of abdominal surgery, and of the promise for the future. He also alluded to the charge that with the rise of the specialty there had been a decrease in the feeling of modesty and a lowering of the moral tone of women, and showed how it should be disproven

by care for the cultivation of a pure literature and classroom teaching.

The President then stated the different theories of purperal fever held by the essentialists, represented in this country by Barker, and the infectionists, represented by Thomas. The latter class he divided into the followers of Semelweis, who believe that puerperal fever, like any surgical fever, results from the absorption of decomposing matter either heterogenetic or autogenetic, and the disciples of Pasteur who hold that microbes are the cause of the disease. He gave his reasons at length for differing from the essentialist theory and also from the microbe theory, holding with Billroth that microbes are present in the disease, but it is not shown that they have any causative relation to it. He thought the latter theory did harm in ascribing undue importance to the microscopic character of the lochia, and also because of the discouragement concerning treatment that must attend its acceptance by the young doctor.

In regard to treatment, he emphasized the importance of clean hands and irrigation of the vagina and uterus when necessary. For a uterine douche he used a sublimate solution, one in a thousand, at a temperature of 115° F. He closed by describing his method of washing the uterus. A hole is made in the end of a rectal bougie of the Davidson syringe and an English catheter is carried through the bougie till its end is outside the perforation. The solution is introduced through the catheter while the bougie allows the return of the liquid.

Dr. Edward Warren Sawyer, of Chicago, then read a paper entitled Some Remarks on the Occipito-Posterior Position in Vertex Labors; with an Analysis of Thirty-eight Cases.

The writer has had thirty-eight cases in three hundred and forty-nine labors, or about one in five. In three the occiput was to the left and in thirty-five to the right. Twenty-six cases were in primiparæ. This fact suggests, concerning the etiology of the condition, that the unyielding abdominal walls of the primipara do not conform well to the back of the fetus and force it into the hollow of the spinal column. Dr. Sawyer thinks that the occiput does not rotate forward as often as is generally taught. The rotation occurred in only two of his cases. In many of the cases there were imperative indications for interference before the vertex reached the floor of the pelvis, but had he waited he did not believe that rotation would have occurred. He would never leave the fetus stationary more than two hours on account of danger to the soft parts of the mother. As soon as a positive diagnosis is made, which can be accomplished by introducing the hand in front of the face, he would endeavor to rotate the head by combined external and internal manipulation with the hands. When it became necessary to deliver the child by forceps he called attention to the importance of keeping the head flexed and making traction in the right direction. For this purpose he recommended his modification of Simpson's forceps, which consisted in giving the instrument a continuous posterior curve.

Dr. Richardson believed that the head would rotate when it reached the pelvic floor if it were kept prop-

erly flexed. Improper use of the forceps was generally the reason why it was sometimes caught in the middle strait partly extended. The proper treatment in such case was to introduce the forceps and produce flexion. For this purpose he often used the forceps reversed.

Dr. Reamy thought that rotation would generally occur, but he agreed with Dr. Sawyer in the statement that interference is best to diminish suffering and to lessen danger to both mother and child. The time for interference is when dilatation is sufficient. The forceps should be thoroughly applied, and the head pushed up as far as possible and rotated. The dorsal position of the patient is best.

Drs. Johnson, Howard and Englemann made remarks.

President Smith said that nothing was known concerning the etiology of the position. In regard to interference, if the diagnosis is made before the head is engaged, place the patient in the knee-elbow position and introduce the hand and gently rotate. Never attempt to rotate after engagement of the head. The best way is to put on the forceps and move the head on its biparietal axis to complete flexion. Then reapply the forceps and make traction, leaving nature to rotate, or the whole may be left to nature after flexion is completed.

At the afternoon session the President-elect, Dr. Howard, was introduced. The thanks of the Society were then given Dr. Smith.

Dr. Geo. J. Englemann, of St. Louis, next read a paper on A Rare and Fatal Form of Sepsis without Symptoms.

This dangerous and little recognized form of sepsis is characterized, negatively, by a more or less complete absence of fever, pain and the other symptoms of septicaemia. Intuition rather than skill seems necessary for its diagnosis. It may be acute or chronic, heterogenetic or autogenetic. Where the prognosis seems good and the symptoms least the danger is greatest. It disproves Barker's statement when he says that the intensity of the symptoms shows the amount of poison absorbed and the danger. Several typical cases are given to illustrate this characterization and prove the fatality of the disease.

Dr. Richardson had had five or six cases which confirmed the writer's statements. He had noticed a slight diarrhoea in all of his cases. But the most remarkable fact was the peculiar mental condition of the patient, who seemed to herself to be doing nicely till the last. The paper was further discussed by Drs. Meyers, Reamy and Johnson.

After the reading of the following papers by title the Society adjourned:

The Physiognomy of the Vulva as a Sequence of Anal Disease, and the Cause or Sustaining Cause of Uterine Disease, by Dr. Isaac E. Taylor, of New York.

The Early History of the Treatment of Vesico-Vaginal Fistula in the United States, and the Statistics of the Several Modes of Operating, by Dr. Nathan Bozeman, of New York.

Periodical Symptoms in Uterine Disease, by Dr. George J. Englemann, of St. Louis.

Contributions to the Topographical and Sectional Anatomy of the Female Pelvis, by Dr. David Berry Hart, of Edinburgh.

Fibro-Myomata and Fibro-Cystic Myomata of the Uterus—their Diagnosis, Prognosis, Pathology and Treatment; with Cases and Specimens, by Dr. R. Stansbury Sutton, of Pittsburgh.

On the Ring of Baudl, by Dr. William T. Lusk, of New York.

FOREIGN CORRESPONDENCE.

PARIS LETTER.

PARIS, September 24, 1884.

The value of blood-letting in the treatment of apoplexy was lately discussed at the Therapeutic Society of Paris, when most of the members condemned the practice as a mere routine measure. Even the non-professional public are so imbued with the idea that bleeding is indispensable in this case, that a certain amount of pressure is put on the medical attendants to open a vein, and should the case prove fatal without the operation being performed, the unfortunate physician is sure to be blamed. Dr. Dujardin-Beaumez does not approve of blood-letting in the condition usually termed apoplexy, which has no definite signification. Apoplexy may result from the rupture of a miliary aneurism, or from cerebral anæmia, whether produced mechanically or otherwise. In either case the drawing of blood would not only be useless, but positively dangerous, as it would tend to weaken the patient unnecessarily, and fulfil no useful indication. Even in cerebral inflammation nothing is to be gained by it. The only case in which the orator thought blood-letting might prove useful was congestion of the brain, in which case it is employed to prevent an attack of apoplexy, but the diagnosis of such a condition is not always an easy matter. Whenever, however, the patient is affected with hemiplegia, and this lasts for any time, even twenty-four hours, one may with certainty conclude that it was not caused by cerebral congestion, but by hæmorrhage or anæmia. We shall therefore have to resort to other measures, such as revulsives, which are as efficacious, but less dangerous than blood-letting.

The question as to whether a tuberculous patient suffering from fistula in ano may be operated on for the cure of the latter has often been mooted in the profession, and Dr. Jannel has again brought the subject before the Surgical Society of Paris. After a discussion pro and con, Professor Verneuil concluded that from his experience he thought it advisable that the operation, if necessary, should be performed as early as possible; for the longer it is put off the greater the risk to the patient, and to the success of the operation which will relieve him of an infirmity which, if left to itself or treated by palliatives, can but aggravate his general condition.

M. Ritter lately brought to the notice of the Pharmaceutical Society of Paris the vesicant properties of chloral, which may be utilized in certain cases

where it would be unsafe to employ the ordinary blisters made of cantharides. Spread on sticking plaster, which is slightly heated and applied to the skin, powdered chloral produces in a very short time and without great pain the same effect as a Spanish fly blister, which is produced about six hours after its application. In this form the chloral possesses the sedative and analgesic properties which may be utilized in the treatment of neuralgic and rheumatic pains.

M. Mairet has communicated a work to the Academy of Sciences on the biological relations between phosphoric acid on the one hand, and general nutrition and the nutrition of muscle on the other, and after a series of observations he summed up his conclusions as follows:

1. With reference to muscular work, when the intensity of the latter surpasses the richness of the food, it increases the elimination by the urine of the nitrogen and phosphoric acid combined with alkalies.
2. The muscles employ phosphoric acid to produce work; the phosphoric acid which is found in excess in the urine under the influence of muscular work is the phosphoric acid of the wasted tissues.
3. The elimination of phosphoric acid is connected with the nutrition and function of the muscles; muscular work marks its action on the phosphoric acid eliminated by the urine in increasing the amount of alkaline phosphates.

At a subsequent meeting M. Mairet brought to the notice of the Academy the modifications which intellectual work produces on the elimination of phosphoric acid, and the relations that exist between this acid and the nutrition of the nervous system. In this paper the author makes out, 1, that phosphoric acid is intimately connected with the nutrition and the function of the brain. In its functions the brain absorbs the phosphoric acid combined with the alkalies and sets free the phosphoric acid of the earthy salts. 2, that intellectual work retards the general nutrition. 3, that intellectual work modifies the elimination of phosphoric acid by the urine, it diminishes the phosphoric acid combined with the alkalies and increases the phosphoric acid of the earthy salts.

It is curious to note that while there is a growing tendency in the profession towards specialism, specialists show a tendency to extend their views in a more general way. At a clinical lecture at the Hotel-Dieu, Professor Panas endeavored to impress on his hearers the necessity of medical men to have a greater scope in their professional education so as to be able to deal with all cases that may be submitted to their care without always having recourse to specialists.

This advice is all the more valuable as it comes from a gentleman who, though a general surgeon, has adopted ophthalmology as a specialty without prejudice to his other attainments as surgeon and physicians. As an ophthalmologist, however, he felt bound to dwell upon the importance of this branch of medicine and surgery, as it is too often depreciated, and those who occupy themselves specially with the diseases of the eye are generally looked down

upon and are even at times ranked among quacks. Those who act thus, he added, forget that the immortal discovery of Helmholtz has rendered ophthalmology the surest, and the best known branch of medicine; they forget also that, thanks to the ophthalmoscope, one can study the phenomena of the circulation, a thing which can not be done directly with the eye in any other part. Moreover, the eye is found to be the seat in which may be reflected general or constitutional affections.

Hence Professor Panas concludes that a regular ophthalmologist, far from confining his knowledge to the eye, ought to be an encyclopedist. It is an opinion also widely spread in the profession that ophthalmology constitutes only an insignificant part of medicine, and he has often heard it repeated that one or two months suffice to learn the science of ophthalmology, and it is against this idea that Professor Panas directs his efforts. In concluding his lecture, the learned professor expressed himself to the following effect: "Scarcely a day passes without my being required to give my advice whether in a prognostic or diagnostic point of view, on general affections in patients sent from the different hospitals or by general practitioners. This fact will serve to show the necessity of studying ophthalmology, which is daily increasing in importance, and the ophthalmoscopic examination of patients is as necessary as that by auscultation or percussion, or the analysis of the urine. The ophthalmoscope not only helps the physician in his diagnosis of a general malady, but it often leads him to the discovery of a morbid condition that would otherwise have escaped his attention."

In a very interesting article reproduced in the "*Journal d'Oculistique*" of Paris, on the influence of hot entire baths and hot footbaths on the ocular circulation, the author, Dr. Kacavurov, states that he had performed experiments on 15 subjects, 12 of whom had sound eyes. The temperature of the water of the bath was 104° F.; the duration of the immersion of the body was 15 minutes. In the majority of the cases, the optic papillæ were pale; the arteries of the retina were diminished in calibre; the veins of this membrane were slightly distended; the intra-ocular pressure was diminished. The author attributed these phenomena to the weakening of the action of the heart and to the lowering of the blood pressure. He however concludes that the preceding effects are too weak and too uncertain to induce practitioners to introduce whole baths into ocular therapeutics. As for footbaths, the author thought that they had a very different effect from what they are generally supposed to have. In the 15 subjects on whom the experiments were performed the pediluvia produced no paleness of the optic papillæ, nor a diminution of the calibre of the arteries, nor any lowering of the intra-ocular pressure. In the greater number of the cases, there were on the contrary evident phenomena of congestion of the eye which lasted about ten minutes after the footbath. A. B.

BOOK REVIEWS.

HEALTH AND HOW TO PROMOTE IT, FROM INFANCY TO ADVANCED AGE. By RICHARD MCSHERRY, M.D. Second edition. D. Appleton & Co., New York: 1884. Cloth; 185 pages.

As stated in the preface, the author directs "attention principally, almost entirely, to personal matters under individual control; that is, to what each individual may do for himself."

The style is simple and pleasing, and not at all technical. The fault of the work grows from the fact of its unscientific nature, and from its compilation from various, often conflicting writers. This may be illustrated by the remarks on alcohol. He says it is "a stimulant in small doses, a narcotic in large doses." This is true only of certain individuals, or of certain functions of the body. The normal effect of alcohol on the healthy individual is probably always narcotic. At another page this fact is made evident by a reference to Mr. Bryant, who is quoted as saying: "I am a natural temperance man, finding myself rather confused than exhilarated by wine." And again, in a quotation from Dr. Edes: "It may be doubted whether such a condition as true stimulation by alcohol exists for the perfectly healthy man in a normal condition. The early phenomena, if carefully observed, are better explained as the beginning of intoxication."

The book is worthy of a place in popular medical literature, for its perusal will benefit and enlighten the average citizen respecting many things of which he is often grossly ignorant.

MISCELLANEOUS.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM OCTOBER 4, 1884, TO OCTOBER 10, 1884.

Clements, B. A., Major and Surgeon, in addition to present duties, to take charge of the office of the Medical Director of the Dept. during the temporary absence of that officer. (Par. 1, S. O. 195, D. of Mo., Sept. 29, 1884.)

Happersett, John C. G., Major and Surgeon, will be relieved from duty in Dept. of the East and ordered for duty at Willet's Point, New York.

Woodruff, Ezra, Captain and Assistant-Surgeon, granted leave of absence for 4 months. (S. O. 235, A. G. O., Oct. 7, 1884.)

Cronkhite, Henry M., Captain and Assistant-Surgeon, assigned to duty as Post Surgeon, Fort Reno, Ind. T. (S. O. 197, D. of Mo., Oct. 2, 1884.)

Crampton, L. W., Captain and Assistant-Surgeon, granted leave of absence for 1 month and 10 days. (S. O. 60, Hdqr's Div. of Atlantic, Oct. 2, 1884.)

Powell, J. L., Captain and Assistant-Surgeon, granted leave of absence for 1 month, on surgeon's certificate of disability.

Spencer, Wm. G., Captain and Assistant-Surgeon, granted leave of absence for 1 month. (S. O. 204, Hdqr's Dept. East, Oct. 8, 1884.)

McCreery, Geo., First Lieutenant and Assistant-Surgeon, assigned to duty at Fort Meade, D. T. (S. O. 115, Hdqr's Dept. of Dak., Oct. 6, 1884.)

Taylor, A. W., First Lieutenant and Assistant-Surgeon, assigned

to duty at Fort Omaha, Neb. (Par. 3, S. O. 87, Hdqr's Dept. Platte, Oct. 3, 1884.)

Black, C. S., First Lieutenant and Assistant-Surgeon, granted leave of absence for 15 days, to take effect this date. (Par. 3, S. O. 131, Hdqr's D. of Tex., Sept. 29, 1884.)

OFFICIAL LIST OF CHANGES IN MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING OCTOBER 11, 1884.

Lippincott, G. C., Passed Assistant-Surgeon, granted sick leave Oct. 4, 1884.

Whiting, Robert, Passed Assistant-Surgeon, to the Naval Hospital, New York, Oct. 6, 1884.

Brown, S. A., Passed Assistant-Surgeon, resignation accepted, Oct. 7, 1884.

Brush, George R., Surgeon, detached from the Vandalia, and placed on waiting orders, Oct. 8, 1884.

Craig, Thos. C., Passed Assistant-Surgeon, detached from the Vandalia, and placed on waiting orders, Oct. 8, 1884.

Ayers, Jos. G., leave of absence for 1 month, Oct. 10, 1884.

Oberly, A. S., Surgeon, to the Naval Hospital, Portsmouth, N. H., Oct. 10, 1884.

Cleborne, C. J., Medical Inspector, detached from duty at Portsmouth, N. H., and placed on waiting orders, Oct. 10, 1884.

Steele, Jno. W., Passed Assistant-Surgeon, detached from the Brooklyn, and placed on waiting orders, Oct. 10, 1884.

Boyd, Jno. C., Passed Assistant-Surgeon, to duty at Navy Yard, Washington, D. C., Oct. 10, 1884.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE, JULY 1, 1884, TO SEPTEMBER 30, 1884.

Bailhache, P. H., Surgeon, to proceed to Delaware Breakwater Quarantine Station as inspector, September 10, 1884; to investigate reported pollution of Potomac River water supply, September 20, 1884.

Miller, T. W., Surgeon, granted leave of absence for fourteen days, July 10, 1884; detailed as president Board of Examiners, September 2, 1884.

Wyman, Walter, Surgeon, detailed as member of Board of Examiners, September 2, 1884.

Long, W. H., Surgeon, granted leave of absence for twenty days July 30, 1884.

Purviance, George, Surgeon, detailed as recorder Board of Examiners, September 2, 1884.

Stoner, G. W., Passed Assistant Surgeon, to proceed to Lewes, Del. (Delaware Breakwater), as inspector, July 25, 1884; to act as quarantine officer at Delaware Breakwater, July 31, 1884.

Fisher, J. C., Passed Assistant-Surgeon, granted leave of absence for thirty days, August 23, 1884.

Goldsborough, C. B., Passed Assistant-Surgeon, granted leave of absence for thirty days, July 12, 1884; leave of absence extended thirty days on surgeon's certificate of disability, August 11, 1884; leave of absence extended thirty days, without pay, September 11, 1884.

Heath, W. H., Passed Assistant-Surgeon; granted leave of absence for thirty days, September 8, 1884.

Guitéras, John, Passed Assistant-Surgeon, granted leave of absence for thirty days, September 24, 1884.

Banks, C. E., Passed Assistant-Surgeon, granted leave of absence for thirty days, August 27, 1884.

Bennett, P. H., Assistant-Surgeon, to proceed to Buffalo, New York, for temporary duty, September 19, 1884.

Glennan, A. H., Assistant-Surgeon, to proceed to Mobile, Alabama, for temporary duty, July 7, 1884.

RESIGNATION.

Fisher, J. C., Passed Assistant-Surgeon, resignation accepted by the Secretary of the Treasury, to take effect September 30, 1884, August 21, 1884.

THE CONSIDERATION OF SOME POINTS CONNECTED WITH PROTRACTED LABOR.

BY WM. H. TAYLOR, M.D., CINCINNATI, OHIO.

Read in Section of Obstetrics and Diseases of Women of the American Medical Association, May, 1884.

The character of the audience before whom I have the honor to appear in response to the polite invitation of our esteemed President, forbids that I should enter into any consideration of the ordinary phenomena of a protracted labor, and equally inappropriate would it be to discuss the more generally adopted methods of treatment.

The second and third stages of labor have of recent years claimed much attention from obstetric writers, so that we are warranted in saying that the principles of their management are well established, and hence need no discussion at this time.

Such exclusion limits me to the study of detention from some causes acting during the earlier processes of parturition, and it is to such conditions that I ask your attention. In addition to my own convictions of the importance of this subject, my justification for bringing such a topic before you is found in no small degree in the opinion of Prof. J. E. Taylor recently expressed in these words: "The mind of the profession has dwelt most generally, in instrumental deliveries, on the state or condition of the os uteri,—its thinness or thickness, its rigidity or its oedematous condition, its hardness or its tenseness. The profession has, as I believe, not considered the great difference relating to each of these points as the guide to the use of the forceps either in natural or complex labors," and in the assertion of a late German writer, that "the recent progress in midwifery is not characterized by the production of remarkable new instruments, but chiefly in rendering more simple and definite our principles of action, in greater accuracy of diagnosis and clearer indications for active interference."

From such opinions is deduced the proposition that there are various conditions of the parts which are the result of varying causes, and with due regard for cause and effect demand different methods of treatment. Accepting this proposition as true, it

forms the basis of my remarks, and I desire to be understood as excluding from consideration all marked deformities and all great irregularities of position of the foetus.

Until recently, almost universally our scope of active interference in labor has been after dilatation of the os, or even engagement of the head, the patient being allowed to suffer for hours with the consolation, that "when the womb was opened she would progress faster." That we are growing out of such expectant treatment you all know, and just here we are met with the antique admonition that "meddlesome midwifery is bad." But with the increased knowledge of the present day, is it not true conservatism to *avert* danger and difficulties by economizing our patient's powers, by not allowing pain to continue unmitigated for hours? Is it not more perfectly fulfilling the purpose of our professional attendance, promptly to respond to the first intimations of evil and not wait to be driven to a last resort? And to an early recognition of the existence of untoward conditions our studies in the near future must be directed; and of prime importance is the proposition that the *lapse of time* alone must not be made a criterion by which to determine the effects of the labor. A point which I think of much importance—though to many only conventional—is the datum which distinguishes between the first and second stages of labor. An examination of more than twenty of the more recent systematic works on obstetrics shows that all but three make "full dilatation of the os," the termination of the first stage. Prolongation of labor before rupture of the membranes is much less likely to have ill effects than equal protraction after their rupture, and doubtless the majority would estimate the evil effects of pressure on the maternal tissues or the jeopardizing of the child from uterine contraction from the time the membranes rupture, and therefore the indications for operative interference would be based largely upon the lapse of time after such rupture. In the well-known discussion on "Forceps and their Alternatives" in the London Obstetrical Society, a great diversity of opinion prevailed as to whether or not a prolonged first stage is injurious, some high authorities assuming the negative, and others of equal eminence asserting that sometimes it is. A careful study of this discussion will show that the first class referred to cases before rupture of the membranes, the latter spoke of cases where the membranes had been ruptured.

¹Taylor, Gynecological Transactions, vol. iv, 253.

²Lumpe, Archiv f. Gynäkologie, Vol. XXI-I, 42.

¹Obstetrical Transactions, vol. xxi.

In a proposed operation the degree of dilatation of the os is a matter of far less consideration than formerly, whereas rupture of the membranes can never be an insignificant fact in the course of the labor. I submit, therefore, that a more definite period could be fixed, and a far better guide for action would be established if rupture of the membranes were made the boundary between the first and second stage. Now, while I believe that the dangers to mother and child resulting from pressure, and also of sepsis, almost exclusively supervene after rupture of the membranes, yet there are other evil influences which manifest themselves during the first stage, and which urge us to active interference.

All recognize the depressing influence of severe pain, whatever its source, consequently inducing the dangers of exhaustion; and further, as suggested by Lusk,¹ possibly the inhibitory influence of the uterine nerves of cerebro-spinal origin may cause the suspension of uterine action, thereby prolonging the labor. With such view, the existence of unduly severe or prolonged pain during the first stage demands our aid.

But it is especially to conditions manifest in the lower segment of the uterus that I would call attention. I use the expression "lower segment of the uterus" purposely, for the all but universal reference to the condition of the os as indicative of the general state, or as determining the propriety of a certain line of treatment, is, as I believe, to say the least, often telling but part of the truth, and sometimes even leading to positive error. Further, in cases where the structure of the uterus is injured by pressure, if, unfortunately, we have opportunity for thorough examination, we not rarely find serious lesions far above the os. It is necessary, therefore, to consider the condition of the cervix and body, also.

During the last week or two of gestation oedema of the lower portion of the uterus develops, by which the cervix is prepared for dilatation, and, as every practitioner knows, the cervix may be dilated for days before the active labor begins; but the obliteration of the canal is the result only of uterine contractions, being effected normally by the projection of the fluid wedge into the lax cervix and the pressure of the presenting part, but normal condition of the parts and proper relation of the forces do not always obtain. A commonly asserted cause of delay is a "rigid os." That such a condition exists *per se*, I doubt. The os uteri yields to the pressure exerted by the bag of membranes propelled by the uterine contractions, and the tissues are concurrently prepared for dilatation, and I believe that efficient uterine contraction will be accompanied by proper changes of the tissues of the cervix and os. Delay in labor is attributed to a resisting os, which really is due to inefficient uterine action, and I believe the constantly practiced dilatation of the os by digital distension is more efficient by inducing uterine contraction, than by direct local action.

And now just a reversed condition may obtain,² the os more or less dilated, but such a state of rigidity that however strong and active the uterine contrac-

tions may be, and however forcibly expulsive the efforts of the patient, the rigidity, the result of some local irritation, *e. g.* laceration, or premature rupture of the membranes, prevents the progress of the labor for an indefinite time, the size of the os, "is no criterion of the progress the labor has made; the os may be small, and yet the cervix may be thinned and attenuated, and the patient in extreme danger."

Passing beyond the cervix we encounter a multiplicity of impediments to delivery, which, because of the inaccessibility of the parts when the os is imperfectly dilated, are difficult of appreciation.

All are familiar with the symptoms of excess of liquor amnii, but rarely do we see notice of the effects of too little fluid. Skene says: "A tense condition of the membranes may prevent bulging down to form a 'bag of waters,' in such cases the membranes appear to the touch as if stretched across the os uteri, but do not engage in it, or what is not unfrequently the case, the head lies close down over the os (I should say cervix), so as to prevent the liquor amnii from forcing the membranes into the os, in such cases the liquor amnii is usually scanty." As further indication of paucity of fluid, I should add a small inelastic uterine tumor, and the resonance of the intestine reaching close to the solid portion of the uterine mass. Where such small amount of fluid exists we may have the evil results of pressure, with intensity almost equal to those after rupture of the membranes.

As our cities become larger, and poverty and anti-hygienic influences are increased and intensified, we shall undoubtedly find malformations of the pelvis more common, and consequently, especially in our urban population, may we look for retarded labor from this cause, and I am satisfied of the correctness of P. Müller's assertion, "that a great many irregularities in parturition which formerly were attributed to other causes are dependent on some form of contraction of the pelvis." We may not be able to measure the diminution accurately, but it is well-known that conditions develop during labor which suggest improper relations between the head and the pelvis. (The membranes may dilate the cervix to some degree, and then further expansion cease, notwithstanding active uterine effort continues, meanwhile the head remains above the brim, or but imperfectly engaged in it, under these circumstances we may safely assert the existence of an abnormal condition, most probably a slight contraction of the brim, and as is so often the case, if a malposition of the head be found, our suspicion is well nigh confirmed). The question of treatment of labor delayed before rupture of the membranes is the one which at present demands much attention, the management of the second and third stages have been well determined, but the treatment of the first has received comparatively little attention. Where the head follows the amniotic sac as it dilates the cervix, but progress is slow with intolerance of pain by the patient, the use of ether to slight anæsthetic effect will hasten relaxation, or it may be expedient to give a large dose of

opium to stay all action for a time. Where pains continue, "but the os does not expand, or the head does not adapt itself properly to the os, or the pains be ineffectual or active and strong with no advance, the membranes ruptured or unruptured," the os uteri from some cause or other is expanded to a limited extent, I believe dilatation of the os by Barnes' dilators, or better, Skene's, because they may be used earlier, to be followed by the forceps, as advocated by Prof. Taylor, is the proper treatment. I am satisfied that much misapprehension exists as to the immediate purpose of applying the forceps thus early. The object is not delivery of the child, but to bring the head into the cervix to accomplish its dilatation, by doing which, of course the cause of detention, be it what it may, is overcome. Now this being the purpose makes the operation different from, and far simpler, than complete delivery from the superior strait, an operation which all will agree is always serious and not to be lightly undertaken. Among the obstacles to delivery I have mentioned slight contraction of the brim, and with recognition of that condition we are plunged into a dilemma. Given a moderate contraction of the conjugate at the brim, a head not engaged, uterine action having continued for some time, the membranes unruptured, what shall we do? Shall we wait? The condition of the head may help us to an answer. If the fontanelles are small, if ossification of the bones is firm, if but slight overlapping of the parietal bones, we shall gain nothing by delay, the head may appear to lengthen by development of a caput succedaneum, or if any real advance takes place it will be so slow that it will be more than counterbalanced by the evil results of pressure and pain; if a compressible head be found we may hope for good results from waiting.

If we deem it inexpedient to trust to natural efforts, what then? With forceps at the brim there is always danger, and while undoubtedly it is the operation, if the head be fixed, yet the opinion is very general that it is not the operation with the head movable above the brim, but that version is the method for delivery. I do not propose to discuss this question, for the exhaustive essay of Goodell needs no supplement from me; but I venture to suggest that it be resorted to far earlier than is usually advised. Version is divested of all its dangers and much of its difficulty, if performed before the membranes rupture, and before the woman is exhausted by long continued suffering and anxiety. And to the child we have the dangers of a breech delivery, which are less than unaided delivery through a pelvis contracted to so slight a degree that unaided delivery is possible, and it has the advantage of the delivery of the after-coming head in such conditions.

Of the class of cases to which Johnson, of Dublin,¹ refers as constituting the most frequent cause for his operation, viz.: "Early rupture of the membranes, with escape of the liquor amnii before dilatation of the os, thereby allowing the foetal head to press injuriously on the soft parts of the mother," I think we can only concur in his practice of early use

of the forceps. But I give to the Association the very recent suggestions of Fritsch,² viz.: that long continued pressure of the uterus without liquor amnii is dangerous to the mother, and probably will result in the death of the child. The co-existence of these evils are his justification for early craniotomy in such cases, a suggestion which will meet with little approbation in this country till we are assured that the child no longer has claims on our protection.

NEOPLASM OF THE LACHRYMAL GLAND.

BY PETER D. KEYSER, A.M., M.D.,

Professor of Ophthalmology Medico-Chirurgical College, and Surgeon
Will's Eye Hospital, Philadelphia.

Read in the Section of Ophthalmology, Otology and Laryngology of American Medical Association, May, 1884.

Neoplasms of the lachrymal gland are of very rare occurrence, and great care is necessary in the examination of the same to be certain of the origin of the morbid growth. But whether it originates in the gland proper, or begins its existence in the neighboring tissues and passes into the gland by the natural process of contact and extension, can only be determined after the extirpation and by microscopical examination. The character of the tumor can only be ascertained by the same manner of examination.

The following two cases illustrate the two processes of origin as above mentioned, *i. e.*, that in the gland proper, and that external and affecting the gland secondarily.

The first case, Lydia Mayberry, aet., 55, came to me in May, 1877, with a lump, as she called it, growing from under the brow. The examination revealed a tumor of a flat almond shape fully $1\frac{1}{2}$ inches long lying over the eyeball and protruding from under the brow. The eyeball was also protruding somewhat and pushed downward and inward, with its movements upward and outward restricted. This state of affairs, by her history, had been going on for several years, and without the least pain.

The tumor had a firm but elastic consistency, and the end of my finger could be carefully pushed in above and below it; and by its movement, feeling and position it could be diagnosed as the lachrymal gland very much increased in size. Pressure on the growth as well as on the eyeball caused some pain. Nothing abnormal was to be seen on nor in the eyeball. V. $20/xx$.

Extirpation of the morbid growth was the only remedy to be recommended, and to which consenting, she was the following day etherized, and after an incision of about an inch in length was made along the outer edge of the brow through the skin and underlying tissue to the tumor, it was clearly seen by its characteristic appearances to be of glandular construction. By careful dissection the whole of the enlarged gland was removed, and found to be $1\frac{1}{2}$ inches

long by the same in depth, and twice the normal thickness.

The wound healed readily, but ptosis remained with some contraction of the tissue of the eyelid over the eyeball in the region of the wound.

The extirpated tumor was hardened and by microscopical examination was found to be an adenoid growth of the gland, the degenerative process springing from the centre while the outer or peripheral part appeared comparatively free from the alveolar cells, but containing large inflammatory cells.

I saw the patient two years ago and there had been no return of the morbid growth; the lid remaining as above described after the operation.

The second case, Frederick Koetzle, aged 47, a well-built and nourished German, came to my clinic in the Will's Eye Hospital, December, 1880, to have a swelling of the right upper lid examined, which he first noticed in October previously, and which had increased so that the eye could not now be opened as wide as the other.

The general appearance of the eye was one of puffiness of the upper lid, with a feeling as if the lachrymal gland was enlarged and protruding slightly from under the orbital ridge. On opening the lid very widely, with the ball rolled downward, a fullness was seen projecting from the outer and upper fold of the conjunctiva. The pupil was slightly contracted. Vision $\frac{20}{xx}$. There was no pain of any account. At times a feeling of fullness only.

February 7, 1881, he complains of a rapid increase of the neoplasm, which now comes well out from under the supra-orbital arch, and is felt as a hard mass extending well over the eye-ball toward the inner canthus, and also down around the outer canthus. It does not have a glandular feeling, but that of a solid, firm mass, with the exception of one place of indentation or separation directly over the eyeball, near the centre of the ridge. Vision reduced to $\frac{20}{xl}$. Ophthalmoscopic examination shows choroidal congestion only.

Local applications and inward treatment were tried faithfully, without any beneficial effect. By May following the morbid growth had increased so as to press the eye ball downward and inward, and there is an impossibility to raise the upper lid.

By careful palpation a hard substance could be felt extending all along the upper part of the orbit above the eye, and as far back as the finger could be pushed. There was some dull aching pain now accompanying it.

Extirpation being the only chance for relief, he was admitted into the hospital May 21, on which day the whole of the tumor was carefully removed without an anæsthetic, as it was found inexpedient to use any on account of heart trouble.

Examination of the part removed showed the lachrymal gland was entire, but much enlarged with new growths extending from either side; that toward the nasal side fully twice as large as the gland, and of a firm, solid consistency. A continuous fibrous capsule appeared to hold the whole together.

My friend Dr. Carl Seiler was kind enough to make a microscopical examination for me. After harden-

ing, a thin section throughout the tumor was made, which shows at one extremity an aggregation of small granular, round cells, held together by a delicate stroma, while the other shows the normal structure of the gland slightly infiltrated by inflammatory cells. There are no alveolar cells to be seen in the gland. The whole growth is surrounded by a capsule of clear, fibrous tissue.

The wound from the operation healed readily without suppuration, and the eye looked well for some time. But after awhile a secondary growth appeared and grew so rapidly that by October of the same year there was a tumor lying in the same place, but nearly twice the size of the former.

This was again removed Oct. 22, 1881, and a section prepared for the microscope shows no glandular structure, but small granular round cells throughout, and is not surrounded by a capsule. The tumors therefore must be considered as round-celled sarcomata, and originating external to the gland, but appears under its external lining capsule.

June 2, 1883, the patient returned to my clinic after an absence of 18 months to show me that there was another return of the morbid growth taking place on the outer side of the eye, covering the globe almost up to the edge of the cornea. It is a hard, smooth, roundish tumor, apparently under the conjunctiva but not attached to the sclerotica. There is no actual pain attending it, only a dull feeling in bad weather. All the other parts surrounding the eye appear to be in good condition, except the inability to raise the lid. Vision reduced to $\frac{6}{24}$. D. ($\frac{20}{lxx}$), while that in the L. E. is $\frac{6}{9}$. D. ($\frac{20}{xxx}$). The man is in good health and attends to his work every day.

The etiology and character of morbid growths of the lachrymal gland and its surrounding tissues is not different from those occurring in other glandular and muscular parts of the body. So seldom do injuries of this part take place that really there can be no cause ascribed to or suspected for the diseased growth.

When the neoplasm is confined entirely to the gland and does not extend into the neighboring tissue, the careful extirpation of the tumor or gland is really a permanent cure, no return of the growth taking place, as in the first case described. But when the origin is either external to the gland, or when in the gland and exuding therefrom into the surrounding tissue, a return is more or less likely to occur, as in the second case mentioned.

In the study of the literature of tumors of the lachrymal gland we find different forms of morbid growths described by the several writers, such as

hypertrophy, adenoma, adenoid, colloid, sarcoma, myxoma, fungus, encephaloid, scirrhous, etc., but Prof. Becker claims that the adenoid form is the only one, and covers the first eight forms. (*See Graefe and Saemish, Handbuch der Augenheilkunde, pt. VII.*) I think he is not far from correct, for in an adenoid growth of the gland we have more or less some of the characteristics of at least five or six of the several forms above mentioned. As in my first case there was hypertrophy, alveolar cells, myxomatous cells, that is cavities filled with a gelatinous mass, etc. In cases of sarcoma, fungus, encephaloid, etc., I think the origin is in the tissues external, and by proliferation extends into the gland (as in my second case), and may have been described as a primary instead of a secondary affection of the gland.

Many attempts at reducing these tumors by absorption with external and internal remedies have been made, but without success. Free and complete extirpation is the only thing to be done, and the earlier it is accomplished the better, and the greater likelihood of a permanent cure. Care must be taken to know thoroughly the anatomy of the part and eyeball, so that in the operation no injury will be caused to the globe, the optic nerve or ocular muscles.

EPISTAXIS.

BY D. N. RANKIN, A.M., M.D., ALLEGHENY CITY, PA.,

ASSOCIATE PHYSICIAN TO (NOSE, THROAT AND CHEST DEPARTMENT) PITTSBURGH DISPENSARY.

Read in Section of Ophthalmology, Otology and Laryngology of the American Medical Association, May, 1884.

It is the duty of the specialist to provide remedies for the various diseases to which the organs in his specialty are liable, and be prepared for their accidental emergencies.

Of all the hæmorrhages which the rhinoscopist and laryngologist are called upon to relieve, epistaxis or nose-bleed is by far the most common. I propose in this paper to limit myself to its consideration.

We learn from Galen that the word hæmorrhage was limited by Hippocrates to flux of blood from the nostrils, and he has been followed in this restrained use of the term by Sauvages, and most of the nosologists of that time. It was Vogel who first pointed out the inconvenience of this limitation, and exchanged hæmorrhagia for epistaxis, thus liberating the former term to express flux of blood generally.

When we reflect on the structure of the schneiderian membrane, there being a considerable net-work of blood-vessels, which traverse it in every direction, and are covered with a layer of tessellated epithelium, which is also provided with a nearly continuous layer of branched mucous glands, the ducts of which open upon its surface, it is not surprising that its occurrence is so frequent.

Persons of all ages, sexes, constitutions and temperaments are liable to be attacked with this form of hæmorrhage.

As in all hæmorrhages, two opposite pathological conditions of the blood-vessels are observed in epistaxis; the one, an hyperæmic or entonic condition, in which the extreme vessels are ruptured by the determination of a greater quantity of blood than ordinary to the vessels of the head, as in whooping-cough, tumors of the neck, cardiac hypertrophy, etc.

Persons of a sanguine and plethoric habit, especially the young, owing to the state of the balance of the system peculiar to that age. When it occurs later in life, it may be considered as a mark of venous plethora of the vessels of the head; it may also be observed in certain febrile diseases, and frequently aids greatly in forming an intelligent diagnosis. Males, as a rule, are more liable to epistaxis than females, doubtless owing to their habits and greater exposure to the vicissitudes of weather, but many females have a vicarious periodical nose-bleed, caused by the suppression of the menstrual discharge, which has been welcomed as a salutary effort of nature to relieve or bring a hyperæmic condition of the brain, lungs, liver, etc., to a favorable issue.

Great heat, violent exertion, either mental or physical, as coughing, sneezing, singing or reading aloud for any length of time, external violence, suppressed discharges, particular postures of the body, and various conditions of the atmosphere, have a powerful effect on the expansive quality of the blood. It frequently happens that passing from a cold to a heated room will produce it, and this feature is also exemplified in the coal or iron miner making a rapid transition from a rare to a denser atmosphere.

It is a well-known fact, that in the ascent of high mountains, a flow of blood from the nose, ears and lungs, as well as other alarming symptoms, has been an early physical consequence. We have numerous examples of this in the reports of travellers who have ascended points at extreme elevation.

Mechanical hyperæmia, excitation of the olfactory nerves, has been known to have induced epistaxis, an example of which has been recorded by Bruyerin, in which it was induced by smelling an apple. Another instance is given in which the odor of a rose appeared to be the exciting cause. Vascular polypi as a cause of nose-bleed must not be overlooked.

Morgagni has handed down to us the record of an extraordinary phase of this disease, when alluding to epistaxis appearing in an epidemic form, he states that in the year 1200, there was a great mortality of men in the space of twenty-four hours in Tuscany and Romandiola by a flux of blood from the nose.

Epistaxis assumes various forms; sometimes it appears as an habitual nose-bleed; again in an hereditary form in some families, of which numerous instances have recently been given, and which is now very properly considered a form of hæmophilia. Many theories have been proposed to account for its appearance, but an hereditary disposition appears the best established cause. Dr. J. Wickham Legg, in his treatise on Hæmophilia in 1872, refers to a disease superficially described in the writings of Albucasis, an Arabic author, who lived at Cordova in the eleventh or twelfth century. Until the year 1784, when Fordyce rediscovered the disease, no special mention

of it was made in either the Greek, Latin, or Arabic writings.

From that time to the present 650 cases have been reported. In almost all the reported cases, a rheumatic diathesis appears to accompany them. Some authors attribute it to an hereditary predisposition, while others ascribe the disease to intermarriage of relatives; among the most prominent authors who advocate the hereditary theory are Schonlein, Nasse, Wachsmuth, and Grandilier. Babington, in the London *Lancet*, thus described a remarkable case of this latter kind: A woman who had suffered from habitual nose-bleed, had six female children, three of whom also suffered from epistaxis, one of these also had six children, of whom the two female ones were affected in the same way. The older of these last two had a son living who was similarly troubled. The sister of the woman first mentioned likewise has a daughter living who is subject to violent nose-bleed. Here the presence of severe epistaxis is demonstrated down to the fifth generation, Babington himself having witnessed it in the mother, daughter and grandchild. In the latter, the attacks were so severe that the tampon had to be used every time. In the passive or atonic epistaxis an anæmic condition appears; the blood-vessels lose their elasticity, and are incapable of propelling their contents; their walls become relaxed; and red blood insinuates itself through the exhalants. In the extreme states of vital depression which occasionally follow the active stages of fever, especially those of a putrescent tendency, as malignant small-pox, typhus and scarlet fever, purpura hæmorrhagica and scurvy, this form of epistaxis is a very grave symptom. As to the pathology of this disease, modern research has failed to discover characteristic anatomical conditions to account for it. Blagden calls attention to the thinness and transparency of the arteries. Some writers have observed a congenital malformation of the heart; others a fatty degeneration of that organ. A great many plausible theories have been advanced to account for this peculiarly interesting form of hæmorrhage, none of which thus far are entirely satisfactory. We might suppose that the blood itself would be found to be changed in quality; that its fibrin would be found wanting, but all observers agree that the blood clots firmly and quickly, and upon careful analysis, fail to discover any unnatural condition of this fluid.

Instances are recorded of the loss of almost incredible quantities of blood. Bartholin mentions a case of forty-eight pounds, Rhodius another of eighteen pounds lost within thirty-six hours. Good, in his study of medicine, reports a case where the patient lost seventy-five pounds in ten days, the same author reports another case, in which the quantity is not given, owing to the difficulty in taking an account of it, but which continued without cessation for six weeks.

The principal hæmorrhages with which nose-bleed may be confounded, are those of the naso-pharynx, œsophagus, stomach, larynx, bronchi, lungs, and tympanic cavity via the Eustachian tubes, but a careful observer will find very little difficulty in deciding whence the blood comes. It is usually confined to

one nostril, but its occurrence from both nostrils is by no means uncommon.

The best plan of treatment to be pursued will next occupy our attention. Reliance must not be placed entirely on local or general treatment; the latter should be a combination of medical and hygienic; it may be divided into therapeutic (including local and general), and operative. Unfortunately few cases of nose-bleed are brought to our attention in time for early interference, and serious mischief is often effected before the time of observation. On account of the inaccessibility of the bleeding points, until a comparatively recent period, its treatment has been very superficial and often-times difficult, but with the rhinoscope a new avenue has been opened, and wonderful indeed have been the results of this instrument, as a means of localizing this disease, which previously had often-times been full of obscurity, and as often mere guess work. The advantages of the rhinoscope, however, would have been very limited had it not been for the ingenuity of other eminent rhinoscopists, who have devised such useful instruments for making therapeutical and electrical applications to this region.

With the rhinoscope alone, we would have learned only of the existence of a lesion of structure, without the means of curing it. This is really progress, progress based upon truthful and reliable investigations.

I am aware that as to novelty of views, or etiology of this disease, your attention cannot be claimed, but only from the intrinsic importance of the subject, do I wish to interest you. We must all admit, that our efforts to check this form of hæmorrhage with the usual astringents locally and generally, have been far from satisfactory. I do not wish to be understood that the astringents should all be expunged from the list of therapeutics in this disease, as there are some very valuable ones, that it would be impossible to get along without. Of these I would mention ergot in its various forms, to be used locally, generally, and hypodermically. It has a peculiar and decided power in contracting the involuntary muscular fibre; causes divided arteries to contract, acts upon the smaller arteries and capillaries, and has been proven a valuable arrester of hæmorrhages in many affections. In passive epistaxis I have successfully used bougies composed of ergotin three grains, ext. belladonna one-third of a grain and cocoa butter q. s. Solution of sub-sulphate of iron, used both locally and generally, I have found very effective as an hæmostatic in a great many cases of this kind of hæmorrhage. In my hands the salicylate of zinc, nitrate of silver, glycerole of tannic acid, chromic acid, and tannate of iron have proven to be very active local astringents. Hot water at a temperature ranging from 100° to 110° as a remedy, has long been extensively used by the profession, but not until recently have its hæmostatic qualities been known. As a means of compression, the great success with which the sponge and seatangle tents have been used in uterine diseases suggested to my mind that they could be well utilized in epistaxis. I therefore some two years ago, commenced their use, and have no hesitation in saying they have

answered my most sanguine expectations. My plan of using them is the following: When a case of nose-bleed is presented, I first dip the tent into glycerole of tannic acid; introduce it into the bleeding nostril, and let it remain for twenty-four hours at least. In vinegar, as a local astringent, we perhaps have more of the styptic qualities, especially for the relief of active epistaxis, than are to be found in any of the other astringents.

Packing the nostrils with hæmostatic cotton, by means of Bellocq's canula is often deemed necessary. When the source of the hæmorrhage can be discovered, the galvano-cautery is certainly a great addition to our armamentarium. In order, therefore, to illustrate the plan of treatment which I have found most successful in the treatment of epistaxis, I will briefly enumerate several cases culled from my notebook.

CASE 1. On June 30, 1881, I was summoned to visit Miss M. J. for the relief of nose-bleed, when I learned the history of her case from her mother. She stated her daughter was nearly 15 years old; that about a year ago she had suffered from severe attacks of headache, fullness of head and flushed face; previous to that time sickness was a thing unknown to her. This condition continued for some months, until in walking abroad in a very warm day her nose commenced bleeding profusely, and continued to do so every day for some ten days. Becoming weak, the family became alarmed, and called in the family physician for advice. He directed to have her kept quiet, and prescribed the usual remedies, and very judiciously stated to the mother that it was a vicarious hæmorrhage; that as soon as her menstrual flow was established the hæmorrhage of the nose would cease, and gave her some directions to encourage the appearance of the menses. Notwithstanding, the epistaxis continued very profusely every day, generally in the evening, and her condition became alarming. It was at this time her case was brought to my attention. Upon my arrival I found my patient to be an extremely nervous creature, presenting an exceedingly exsanguine appearance, with blood of a pale red coming drop by drop from the left nostril; her pulse was feeble, and extremities cool. I concluded there was no time to be lost; brandy and ergot were liberally administered, and a douche was improvised for the occasion, and vinegar passed through it into the bleeding nostril, the exit being from the right nostril. By the time four ounces of this fluid had been used, the hæmorrhage ceased. It being late in the evening, it was deemed most prudent to pack the bleeding nostril; I used cotton saturated with vinegar, by means of Bellocq's canula. From the heroic manner in which the doses of brandy and ergot were administered, her stomach became rebellious; I therefore, as a substitute, gave her hypodermically 12 drops Squibb's fld. ext. ergot every three hours. At the end of twenty-four hours the packing was removed, and, to my agreeable surprise, there was no return of the hæmorrhage. The hypodermic injections of ergot were continued for forty-eight hours; then ergotin 2 grs., strychnia $\frac{1}{40}$ gr. and iron

were prescribed, and their use continued for one month, when her menses made their appearance, and her nose-bleed gave her no further trouble.

CASE 2. W. R. This patient was a gentleman, aged 40, of a wiry constitution and nervous temperament; by occupation a railroad contractor, and necessarily exposed to all kinds of weather. He had suffered from severe attacks of rheumatism. He presented himself at my office September 7, 1882, with the following history: He stated that he had been on duty constantly, superintending the construction of a railroad in Western Pennsylvania during the intensely hot weather in July of that year; he experienced some very unpleasant symptoms, as ringing of the ears, vertigo, etc. Early in August bleeding from the left nostril commenced. At first he supposed it was an effort of nature to relieve the unpleasant head symptoms; but it being of daily occurrence, symptoms of exhaustion came on, so that he was almost unable to walk; and this daily recurrence of bleeding continued until he presented himself at my office. By careful examination of the affected nostril by reflected light, I discovered a small blood spot at the middle third of the inferior turbinated bone. I at once applied the galvano-cautery to the spot, by laying the electrode on cold, and then allowing it to become of a cherry red; but one application of the cautery was sufficient to arrest the bleeding. When examined the next day, a scab was found at the bleeding point. He was placed upon ergotin, quinine and iron. With no return of hæmorrhage, he made a rapid recovery to his usual good health.

CASE 3. G. P., æt. 32, a coal miner by occupation, came under my observation Aug. 12, 1882. He informed me that nose-bleed is a disease peculiar to his family, as far back as the third generation some members of the family being afflicted with it. In his own case, it assumed no regular daily occurrence, but when it did occur, the hæmorrhage was so excessive as to produce alarming exhaustion. It was in this exhausted condition that I found him, with the blood flowing copiously from the left nostril. As it was impossible to clear the nostril sufficiently of blood to get a good view, and to discover the bleeding point by reflected light, I concluded to place a sponge tent, in the hope of checking this exhausting hæmorrhage by making equable pressure upon the weakened vessels. I therefore dipped a small-sized sponge tent into glycerole of tannic acid, and introduced it into the nostril to its full extent, retaining it by a string run through the loop which is attached to the tent, and passing it around the head, and gave him twenty drops fld. ext. ergot every four hours. The effect was most satisfactory, the tent was allowed to remain 48 hours; when removed it had swollen to almost twice its original size. The ergot was continued for one week, then he was put upon quinine, strychnia and iron for six months, with no return of the trouble. It is to be presumed that no return of the hæmorrhage has occurred, as I have not heard from him since. My object in this paper is accomplished, if I have adduced anything, that will aid in relieving this often-times trying and persistent hæmorrhage.

THE RECOGNITION OF GLAUCOMA BY THE GENERAL PRACTITIONER.

EDWARD JACKSON, M.D., OF PHILADELPHIA.

In his address, upon assuming the Presidency of the Ophthalmological Society of the United Kingdom of Great Britain and Ireland, in October of last year, Jonathan Hutchinson said: "There is no one present who has not been pained over and over again by having to treat cases of glaucoma which were brought to him too late. In spite of all that has been done by specialists, and in spite of the fame which iridectomy cures have obtained, it is still the fact that a large proportion of the cases of acute glaucoma are unrecognized during the first fortnight by those under whose observation the patients come."

Dr. Chisolm, chairman of the Section on Ophthalmology, in his address before the American Medical Association, May, 1884, says: "Very seldom does a specialist see a case of glaucoma diagnosed as such by the family physician."

Doubtless this truth is felt by everyone specially engaged in ophthalmic practice; and to all who understand the importance of this malady, its constant tendency to an unfavorable termination, and the efficiency of certain well-known measures for checking its disastrous course, such common inability to recognize it must seem a very serious matter.

True, glaucoma is not one of the most common affections, yet it is common enough to cause a good deal of blindness and a very considerable aggregate of suffering. The cases mentioned below all came to me within nine months of a comparatively small practice, and in the community from which they were drawn there are probably fifty cases of glaucoma to one of stone in the bladder, an affection about which most practitioners would be more loath to confess equal ignorance.

In view of these facts, since the mass of medical literature is but the restatement of previously published truth, few matters would seem more worthy of space and attention than the well-known symptoms, which should always cause the physician to recognize, or, at least suspect the presence of glaucoma. To promote the desirable familiarity with these symptoms, the following notes of cases, stripped of any account of ophthalmoscopic appearances, and other matters not suited to the present purpose, are offered.

CASE I. J. McC., aged 54 years, subject to dyspepsia and chronic rheumatism, is rather anæmic and poorly nourished. Sixteen months ago she found she could not see perfectly with her left eye. From that time it grew worse, not steadily but by frequent slight increments of the dimness, with congestion of the eye and pain in and around it. During the periods between these attacks there was little or no pain, while vision remained unchanged or improved slightly. At first the dimness only affected objects that lay away from the centre of the field of vision in certain directions. Then the dimness, and later the blindness, spread until they involved everything before her. Four months later, the right eye began

to go in the same way, and has continued to fail, though rather more slowly than the left. Now (when I first saw her, April, 1883) she can with the left perceive light at a little below the centre of the field of vision; in all other directions the blindness is complete. In the right vision $V. = \frac{1}{24}$, and there is very marked contraction of the field of vision. The pupils are large for a person of her age, and the iris very close to the cornea, making a shallow anterior chamber. Emerging back of the ciliary region, and passing backward over the sclerotic, are several unusually large and tortuous veins. The cornea, aqueous and lens are perfectly clear. On comparison, I found her eyes somewhat more resisting to pressure than her husband's, which were apparently normal. The note made was $+T_1$, for each eye. From the above history and symptoms I inferred that Mrs. McC. was suffering from glaucoma, and the ophthalmoscopic examination quickly confirmed the diagnosis. She allowed me to make an iridectomy in the right eye, and five months later her vision, with correcting glasses, was $\frac{1}{6}$. It remained unchanged September, 1884, or perhaps very slightly better.

The left eye, untreated, has changed but little, except that all power of perceiving light has been lost.

This patient's trouble was of sixteen months' standing, and during pretty much all that time she had been "doctoring for her eyes." There had been constitutional treatment and local treatment; the latter including extensive blistering of the temple and side of the face, and the use of belladonna, the mydriatic action of which is in this disease liable to be attended with the most disastrous results. The neighboring physicians had been furnishing her with advice as to a malady which they did not understand. They had been engaged in what Dr. Williams appropriately styles "shot-gun" practice.

CASE II. Mr. McL., aged 75 years, was in fair general health, when, in the summer of 1882, the left eye became very painful and its vision impaired. It was "better and worse by spells," but on the whole, grew worse, so that in nine months it became completely blind. During the summer of 1883 the right eye became affected. At first vision was impaired, later pain came on which was at times terribly severe, preventing rest and "making him 'go out of his head' almost." "It felt as though the eye were being pulled out of its socket." When I saw him, January, 1884, the left eye had for many months been "dead;" that is, he "could wipe things off the eyeball without feeling it." I found also that the sensibility of the right cornea was much blunted. The left eye was absolutely blind, and in the right there was bare perception of a bright light within six or eight degrees of the centre of the field of vision. Both corneas were hazy, but there was no marked opacity of either lens. The touch showed that the left eye was very much harder than normal, while the right resisted the pressure put upon it by the finger tips just as though it had been a ball of wood or stone; or, as expressed by the customary formula, the condition was $R. +T_1$, $L. +T_2$.

Dr. C., with whom I saw this case, had not made

a diagnosis. The physicians under whose care he had previously been had told Mr. McL. that he was suffering from cataract; and having waited some weeks in blindness, he was anxious for an operation. Of course he had to be told that no operation could restore his sight, that his blindness was beyond all help; and the only comfort that could be offered was that having gone through months of suffering that might at any time have been relieved, that all sight being gone by a progressive loss that might at any time have been checked, the eyes might henceforth remain painless and be no more a source of active trouble. To thus destroy the one hope of an old man is no pleasant duty, nor is there pleasure in reflecting on how different it would have been if the case had been seen earlier. It is the simplest of the applications of the ophthalmoscope which determines whether cataract be present or not; but even without it, such a mistaken diagnosis should in this case not have been made; for the uncomplicated advance of cataract is as painless as the whitening of the hair.

CASE III. E. G. W., aged 67 years, somewhat anæmic and not very well nourished. August 22, 1883, after noticing for an hour or so that "things looked yellow and shiny," she was attacked with very severe pain in and about the left eye. Under warm opiate fomentations the pain left her in four or five hours, and the next day her vision seemed about as before. In October she had two similar attacks. November 21 she had a fourth attack, after which the pain grew less, but was not entirely relieved until on the 23d the fifth and worst attack began. There was now great impairment of vision, which, with the pain, continued with varying intensity but without intermission. The pain was intense, preventing sleep, and being but partially relieved by opiates, and there was associated with it anorexia, nausea and vomiting. On December 5, the twelfth night of the attack, I saw her with Dr. M. The anterior chamber was extremely shallow, if not entirely obliterated; the pupil dilated and immobile (no mydriatic had been used); the cornea was slightly hazy, the lens more markedly hazy (the lens of the other eye was equally so). There was dread of light, excessive lachrymation, and great pericorneal and conjunctival hyperæmia. She could barely count fingers at eighteen inches; but the field of vision, roughly taken by moving a small lamp-flame from place to place, seemed normal.

The pain was referred to the left eye, brow, temple and cheek, and the left side of the nose. When least severe it seemed mainly confined to the eye, when most severe it spread over the larger area. The tension of the eyeball was noted as $+T_3$. Eserine was used in this eye with slight benefit, but as soon as the patient assented, December 9, I made an iridectomy which gave complete relief. Five days later the right eye was attacked even more severely than the left had been, the pain being terrible, and vision in a few hours reduced to counting fingers at one foot; but again iridectomy gave complete relief.

In June, 1884, she was quite well, with vision in the right = $\frac{1}{18}$, left = $\frac{1}{12}$, in spite of a very noticeable nuclear opacity of each lens.

This case may seem plain enough when thus set down, but the history of earlier attacks, though clear and definite when obtained, was only elicited by inquiry. At first no complaint was made as to impairment of vision, and in the earlier stages the ocular hyperæmia and hyperæsthesia were not so marked as they became later. Dr. M. had been called to a patient suffering from headache, nausea and vomiting, and as Hutchinson says: "Practitioners of the most scrupulous care, of wide general information and the most conscientious regard for their patients' good, are yet very commonly misled by the acute congestion and severe constitutional symptoms which often attend the early stages of this disease." They must be so misled unless the possibility of these symptoms arising from this cause be constantly borne in mind, so that when the symptoms are discovered the idea of glaucoma as their possible explanation will occur as promptly as the idea of indigestion or of migraine.

CASE IV. Mary M., aged 55 years. Her right eye received a blow from a stick in November, 1881, and after that she had repeated attacks of "cold" in the eye; that is, attacks of pain, photophobia and conjunctival hyperæmia. With each attack the pain was severe and the sight got dimmer. Various "eye-waters" were used, without benefit, and the only relief afforded by three physicians consulted during the eighteen months was by the administration of anodynes, which lessened the pain but did not cure it. This pain was described by herself and by those about her, as terrible, and when I first saw her, in May, 1883, she was anæmic, even cachectic, and her facial expression indicative of great suffering. At that time the right eye had but the faintest perception of light at the centre of the field of vision. The lens was opaque, the pupil widely dilated and the iris degenerated. Pain was constantly present, referred to the whole area supplied by the ophthalmic division of the right trigeminus nerve, and during exacerbations still severe. Tension $+T_3$. The other eye was normal. I advised enucleation. She refused at first to submit to it, but, after seeking other counsel, she consented, and obtained relief.

In this case it seems that glaucoma was a result of the injury; perhaps by damage causing opacity with swelling of the lens. At any rate the case may illustrate the fact that glaucoma is one way, and not an uncommon way, in which eyes are lost after injury. Occurring so it involves only the injured eye, and may come on at any age, while, on the other hand, primary glaucoma, as the foregoing cases illustrate, is wont to affect the two eyes successively, and is very rare before middle life.

If, then, a patient have an eye injured either by accident or previous disease, or have reached or passed middle life, glaucoma should be thought of when one or more of the following symptoms are discovered:

Failure of sight, which, except early in an acute attack, will be greatest in some peripheral portion of the field of vision and may for a time be entirely confined to such portion. This may from time to time seem checked or even give way to temporary

improvement, but in the long run it is progressive to complete blindness.

Pain not proportioned to the failure of sight, but rather to the suddenness of the attack, varying in intensity from none, or that which occasions no complaint, to that which persons of great fortitude cannot endure in silence. It is usually centered in the eye, but when severe, may also be referred to neighboring parts, and its origin may be masked by the accompanying prostration, vertigo, nausea, or vomiting.

Anæsthesia of the cornea, not often mentioned by the patient, but to be discovered by touching it with a bit of thread.

A dilated pupil with the iris pressed forward close to the cornea; and it is to be remembered, that in the aged, a pupil the diameter of which is one-fourth that of the cornea may be markedly dilated, while in a young person one that is over half the diameter of the cornea may be normal. The dilated pupil reacts sluggishly or not at all to changes of light.

Symptoms of inflammation, as photophobia, excessive lachrymation, conjunctival hyperæmia, or conjunctival discharge and haziness of the cornea. The last is due to great and sudden rise of tension, yet it might be taken as conclusive evidence of keratitis. Indeed this whole group of symptoms may, if properly understood, suggest the diagnosis by the attention they attract to the eye; but, on the other hand, they may prevent a correct diagnosis by suggesting to the uninformed medical attendant that a simple, visible inflammation is the whole trouble, thus stopping further search for the *fons et origo mali*.

Increased tension is the essence of glaucoma, and the physical evidence of it obtained by the finger tips is pathognomonic. But the accomplished ophthalmic surgeon does not always feel sure that his finger tips will positively inform him as to the slightest change that may in time prove serious; and though the increase may one day be marked, on another it may be quite absent. So that while the finding of increased tension establishes the diagnosis, the failure to find it does not negative the idea of glaucoma.

REPORT OF A PECULIAR CASE OF MALFORMATION OF THE JAWS, AND THE TREATMENT.

BY W. W. ALLPORT, M.D., CHICAGO, ILL.

Read to the Section of Dental and Oral Surgery of the American Med. Association, May, 1884.

MR. CHAIRMAN AND GENTLEMEN.--The plaster casts I exhibit to you are models of a case that I have recently had under treatment. It had excited considerable interest and discussion among some of the surgeons and dentists of the patient's native State, but no definite treatment had been decided upon.

On taking up his residence in Chicago, the dentists

at his home in New Hampshire advised that he put himself into my hands for such treatment as might be thought best, and the case is, I think, of sufficient interest to warrant me in presenting it to the Section.

Mr. F. L. S—, aged 25 years, consulted me June 22, 1884, for a malformed condition of both maxillary arches. The young gentleman is a graduate of Harvard College, and a civil engineer by profession.

The malformation was such as to make it impossible to properly masticate his food, and his personal appearance, especially when eating, was very unsightly and a source of great mortification.

The trouble was largely due to a lack of development of the upper jaw, consequent upon a failure in the formation and development of the temporary and permanent teeth. Just how many temporary teeth were erupted I am unable to say, but from the best information gained, it is evident he did not have the full complement.

When the examination was made there were only seven teeth in the superior jaw, two temporary cuspids, two permanent central incisors, and three molars, the first and second upon the right side, and the second upon the left, all being somewhat imperfect in form, and these are the only permanent teeth that have made their appearance in this jaw. In the lower jaw the six anterior temporary teeth were still in position, though much worn away on the cutting edges (see cut No. 2), and the second temporary molar on the left side, and both temporary molars on the right side, each considerably decayed. The permanent teeth were the first bicuspid on the left side, and the first molar on either side.

The angle of the lower jaw was less acute than normal, causing the jaw to protrude to a slight extent, but would have caused no marked deformity had the superior jaw been properly developed.

Cut No. 1.

Cut No. 1 represents a front view of the case (taken from plaster casts) with the jaws closed to the full extent.

Cut No. 2.

Cut No. 2 represents a side view of the same models, which shows the extent of the recession of the upper jaw, and the protrusion of the lower; also that the occlusion was such that when the jaws were closed "the bite" was so short as to produce a most unsightly appearance of the face.

To lengthen the bite permanently, gold crowns were fitted over the only superior molar of the left side, and the anterior of the two molars on the right side, and so shaped as to cover in their occlusion about one-third of the grinding surface of the permanent molars in the lower jaw. By this process the bite was lengthened three-fourths of an inch, as evidenced by cuts No. 3 and No. 4, which placed the

Cut No. 3.

jaws in a normal position. After the jaws were thus thrown apart, the four front teeth were extracted, a gold plate was fitted to the mouth, and secured by heavy clasps around the gold crowns, and then mounted with artificial teeth secured to the plate by rubber attachments as represented in cut No. 3. Cut No. 4 is taken from a photograph of the gentleman after the operation was completed.

Cut No. 4.

It is a matter of regret that a photograph was not taken with the mouth closed before the jaws were permanently thrown apart by the gold crowns, that the great change in the expression might be seen and contrasted with cut No. 4. But this can readily be imagined.

MEDICAL PROGRESS.

MATERIA MEDICA AND THERAPEUTICS.

A NEW MODE OF OBTAINING RAPIDLY THE CONSTITUTIONAL EFFECTS OF MERCURY.—M. Petithan (*Archives Médicales Belges*), has an article entitled, "Iodure Intus, Mercure Extra," in which he gives the benefits resulting from doses of iodide of potassium given by the mouth and followed in a few minutes with hypodermic injections of the salts of mercury—as producing in a short but variable time, a quite abundant salivation, a metallic or acid taste, sometimes nausea, and a lowering of the pulse and temperature followed by a reaction. He was led to this use of the drugs by noting a curious case of mercurial intoxication resulting from the internal use of an iodide simultaneously with the external use of a mercurial ointment.

He uses for his hypodermic injections a solution of corrosive sublimate, and also the peptonate. The results have been the same in both cases, but a little deferred in the case of the peptonate, in which it was also more painful. In six cases of syphilis the relief

seemed to be hastened—the infinitely small quantity used, and the rapidity of the reaction were both marked features in this new mode of application.

OBSTETRICS AND GYNÆCOLOGY.

SPONDYLOLISTHESIS.—A recent number of the *Archiv. für Gynäkologie* contains a valuable and interesting paper by Dr. A. Swedelin, of St. Petersburg, on a case of labor with spondylolisthesis. He begins (*Medical Times*) by expressing the opinion that this deformity is not so rare as was at one time supposed. In his case the patient was healthy until the age of 17, when she fell backwards in such a manner that the edge of a table caught her in the lower part of the back. Soon after the fall she suffered from pain in that region which, in spite of treatment, continued severely for half a year; and in the course of this time a backward inclination of the trunk was acquired, the patient feeling as if without this inclination she would fall forwards. About a year after the fall she noticed greater prominence of the iliac crests, and protuberance of the lower belly. She was married at 25, and soon became pregnant. At about four months' pregnancy she consulted her medical man who found retroversion of the gravid uterus. He twice reduced the displacement, but it each time returned, and at four and a half months' pregnancy she miscarried. In her second pregnancy retroversion again occurred at the beginning of the fourth month, and this time was successfully corrected by a Hodge's pessary. The presence of pelvic deformity having been ascertained, labor was induced at the thirty-sixth week, and terminated successfully, the child, a male, as big as one at full term, being born without assistance. The mother recovered well and was afterwards carefully examined and measured. There were no deformities elsewhere than in the pelvis. The patient stood upright with the knees slightly bent, complete extension of them being painful to her. The gait at first glance presented nothing peculiar, but when carefully watched was seen to be of the "rope dancer type," one foot being put down almost exactly in front of the other, and the heel of one foot occasionally striking the other as it passed it. The figure of the patient presented the peculiarities pointed out by Neugebauer as characteristic of spondylolisthesis. "Shortness of stature, especially diminution in the trunk, and therefore apparently disproportionate length of leg; a deep lumbo-dorsal hollow in the spine, sinking of the thorax into the false pelvis; wider separation than normal of the hip bones as compared with the trochanters; the presence in the lateral contour of the trunk of an angle above the iliac crests; width of the hips above owing to greater separation of the innominate bones; but smallness of the buttocks, each being bounded by a deep lateral hollow; projection backwards of the upper part of the sacrum, and of the posterior superior iliac spines." The sinking downwards of the thorax leads to the formation of a very marked cutaneous fold, running parallel to the lower ribs, which Neugebauer calls the

thoraco-pelvic fold. Dr. Swedelin's case was further complicated by slight scoliosis. The sacrum was also bent, so that its third spine was unusually prominent. This our author attributes to the pressure of the body-weight in sitting. Neugebauer's description of spondylolisthetic subjects, as seen in profile, also applied exactly to Dr. Swedelin's case: "characteristic saddle-shape of the loins, shortening of the trunk, coincidence of increased lumbar lordosis with diminished pelvic inclination, flattened buttocks, pendulous belly, abnormal visibility from the side of the mons veneris, apparent uprightness of trunk." On palpation the muscles of the lumbar spine could be felt as thick rolls on each side, and between them the last dorsal and upper two lumbar vertebral spines could be felt indistinctly, and the third and fourth lumbar spines not at all; the fifth lumbar spine could be very plainly felt above the base of the sacrum.

The upper eleven dorsal spines were easily made out. The pelvis externally looked very large, the ilia well developed, the crests almost horizontal, the spines strongly projecting. The symphysis pubis was high, and the pubic arch narrow. The base of the sacrum was apparently displaced backwards. Above it the last lumbar spine was felt, and in a line with it two other long projections, one on each side, evidently the inferior articular processes of the last lumbar vertebra.

By abdominal examination the spine could be so easily palpated in the interval left by the separation of the recti that the inter-vertebral substance could be distinguished from the bodies of the vertebræ. It was made out with certainty that the outline of the projecting vertebral mass was not gradually lost in the structures attached to it at the sides, but was sharply defined, leaving an angular hollow on each side. Internal examination gave at first no indication of narrowing of the pelvis; and the finger pressed up as usual toward the sacral promontory, would fail to detect any. But when the finger was passed up in the axis of the pelvic inlet, then it encountered the displaced lumbar vertebra, sharply projecting, not merging into lateral masses at the side; below it an angular hollow, bounded by the surface of the last lumbar vertebra and the upper part of the sacrum. Both the true and the diagonal conjugate diameters were shortened, the diagonal measuring 10 centimetres, the true, or rather apparently true, conjugate $7\frac{1}{2}$ centimetres, and the transverse diameter of the outlet was only 7.5 centimetres. There was, therefore, no doubt that the case was one of spondylolisthesis, produced in the way Neugebauer has described, viz.: by fracture of the inter-articular part of the vertebral ring." Dr. Swedelin gives complete measurements. He then considers the obstetric management of these cases; and has collected and examined from this point of view every case of labor with spondylolisthesis that he could find. The first point of interest in his own case, clinically, is the occurrence of retroversion in each pregnancy, which the author attributes to increased pelvic inclination, bringing the intra-abdominal pressure to bear on the anterior surface of the organ, aided by the deformity which prevented the

uterus from righting itself. The course of labor in these cases has been before studied, and on the basis of the recorded cases, by Schwing and by Perroulaz; but Swedelin has been able to collect a larger number of cases than either of these authors. He draws the following conclusions as to the course and management of labor in the spondylolisthetic pelvis. (1.) Slight degrees of narrowness of the pelvis by olisthesis, in which the conjugate pseudo-vera (that is, the measurement between the internal surface of the symphysis and the anterior surface of the olisthetic vertebra) exceeds 9 centimetres ($3\frac{1}{2}$ inches), do not as a rule cause any hindrance to the parturient process; (2.) Moderate contractions, conjugata pseudo-vera of $7\frac{1}{2}$ –9 centimetres (3 – $3\frac{1}{2}$ inches), permit labor at term without very great difficulty; (3.) Higher degrees, 6.5–7.5 centimetres ($2\frac{1}{2}$ –3 inches), cause labor to be attended with great danger to the child, but the prognosis for the mother is favorable; (4.) Extreme contraction of conjugata pseudo-vera when it is under 6.5 centimetres ($2\frac{1}{2}$ inches), will not allow the head to pass without diminution in its size; (5.) In multiparæ the prognosis of an approaching labor is worse in proportion to the difficulty of the preceding one. From these propositions Dr. Swedelin deduces the following therapeutical rules: (1.) With a conjugate pseudo-vera under 7 centimetres premature labor should be induced in the 32nd week; (2.) With a pseudo-conjugate of between 7 and 8 centimetres it should be induced in the 36th week; (3.) When the dimension mentioned is between 8 and 9 centimetres, pregnancy may be allowed to go to term, but if the patient be feeble, or unfavorably circumstanced, it is better to induce labor in the 36th week; (4.) With a conjugate pseudo-vera over 9 centimetres there is no reason for inducing labor; (5.) If the patient has been allowed to go her full time, and the pseudo-conjugate is between 6 and 7 centimetres, then the case must be treated according to its individual features, either by craniotomy and cranioclastism, or by Cæsarean section; (6.) With a conjugata pseudo-vera below 6 centimetres, Cæsarean section is indicated. Appended to the paper is a valuable bibliographical list of the literature of the subject.

A NEW MEANS OF DIAGNOSIS OF PREGNANCY IN ITS EARLIER MONTHS.—Prof Hegar, of Fribourg, (*Prager Med. Wochenschrift, Annales de Gynécologie*) recognizes a peculiar softening, suppleness and thinning of the inferior segment of the uterus, that is to say, the portion immediately superior to the insertion of the sacro-uterine ligaments, as a constant and positive sign of pregnancy. It can be easily recognized not only when the uterus is resisting, as ordinarily, but when it is elastic and soft. Even then it is possible, by depressing the inferior portion of the uterus, to distinguish the superior portions and the rigid neck. The softness of the part is such as to cause the question whether the neck be not simply in contact with a pelvic or abdominal tumor. He knows of no pathological condition of the uterus which could give this symptom, hydrometritis and hæmatometritis become in this way easy of diagnosis.

The cause of this remarkable sign is from the fact that the inferior segment of the uterus becomes the thinnest, softest, and most elastic portion. It results, consequently, that in practicing the rectal touch with abdominal palpation, it is possible to feel this portion between the fingers with the characteristics which it presents. It is evident, however, that the absence of this sign is by no means an evidence of the absence of pregnancy, which may exist without producing these modifications in so marked a degree.

MEDICINE.

REGULATORY ALBUMINURIA.—Rosenbach (*Zeitschr. f. Klin. Med., Edinburgh Clin. Jour.*) defines regulatory albuminuria as an albuminuria in which the quantity and quality of the urine are normal (except in containing albumen), and there are present no products of inflammation, such as tube-casts or blood-corpuscles. In such cases the kidneys are for the time functioning more than they normally do, and the albuminuria arises from anomalies of the blood or of tissue-change, and not from any disease of the kidneys themselves. It is to be remembered that in these cases the blood may be either absolutely or relatively richer in albumen than is normally the case. In the first of these cases the blood holds absolutely more albumen in solution than normal, and this may be due to a great absorption of albuminates from the food, to the transfusion of blood, or to peptonuria and the absorption of large pus collections. In the second case, the blood contains relatively more albumen than normal—relatively, that is, to its power of combining albumen—and this arises from increased loss of water through the skin or intestine, from diminished supply of water to the system, or from diminished functioning power in the white blood-corpuscles. In both these cases the excretory organs strive to reduce the albuminous concentration of the blood to the normal level, and hence the regulatory albuminuria.

Rosenbach holds that the only characteristics of nephritis in its strictest sense are white (and the so-called “fatty”) blood-corpuscles, and the tube-casts which are formed out of these corpuscles. He holds the hyaline corpuscles only as an indication of the presence of albumen, since, as is well known, they often occur when there can be no question of renal lesion. The red blood-corpuscles are only indications that the process possesses considerable acuteness.

A NEW FORM OF PEPTONURIA.—Maixner (*Zeitschr. f. Klin. Med., Edin. Clin. Jour.*) as far back as 1879 pointed out that in most cases of peptonuria the presence of peptone in the urine was dependent upon the simultaneous presence of large collections of pus in the body. It was afterwards shown by Hofmeister that the peptone which is present in pus is united to the formed elements (pus corpuscles), and only appears in the urine when these break up. Von Jaksch still more recently pointed out that a second form of peptonuria existed, which was occasioned by the breaking up of the lymphatic elements of the blood.

This theory rested upon the investigation of some cases of scorbutus, in which, coincidentally with the appearance of peptone in the urine, it was observed that the white blood corpuscles were undergoing disintegration, while there was no other cause for the presence of peptonuria. This second form of peptonuria was described as "hæmatogenic," in contradistinction to the first or "pyogenic" form.

Still more recent investigations have led Maixner in this article to conclude that there exists a third form of peptonuria, which completely differs in its mode of origin from the hæmatogenic, as well as from the pyogenic form, and which is not dependent upon the breaking up of leucocytes, whether in pus or in the blood-stream, but which is brought about solely by an abnormal passage of peptone from the digestive tract into the blood-stream.

In the course of former observations Maixner found a case of gastric carcinoma and one of typhoid fever in which peptones were found in the urine. Neither during the life of these patients nor on post-mortem examination was Maixner able to find any cause for this condition which harmonized with the theory as then held. Since that time he has much extended his observations in such cases, and he embodies the results in the present paper. The method he employed for the detection of peptone in the urine was that of Hofmeister. The clinical material consisted of twelve cases of carcinoma of the stomach and several of typhoid fever, in all of which there existed distinct peptonuria.

In considering the cause of peptonuria in these cases, Maixner commences by stating the three following possibilities:

(1.) It was possible, though unlikely, that the carcinoma of itself formed peptone, which being absorbed by the blood, came to elimination through the kidneys.

(2.) The disintegration of the tumor might have set free peptone, which would then appear in the urine.

(3.) The peptone which was formed in the stomach might, owing to the disease of the mucous membrane, pass unchanged into the blood, and from hence find its way into the urine.

The first of these suppositions was untenable, for peptone has not hitherto been found in such tumors; nor does the peptonuria increase along with the growth of the tumor mass. Nor is it at all probable that the peptone was derived from the breaking up of the tumor, and Maixner adduces weighty reasons against that view.

There remains, therefore, only the third possibility, viz.: that the peptonuria results from the absorption of peptone from the stomach. All physiological facts point to this, that when the gastric mucous membrane is destroyed or is diseased, it is robbed of its assimilating function, and so when a portion is affected by the tumor growth a part of the peptone escapes the assimilating process, and passing unchanged through the diseased mucous membrane, it appears in the urine. In a similar manner is to be explained the occurrence of peptonuria in cases of enteric fever.

Maixner applies to this third form of peptonuria the name "enterogenic," and he believes that it will be found to occur in diseased conditions of the intestinal mucous membrane other than those in which he has detected its presence, such as gastric ulcer, dysentery, etc.

SURGERY.

SURGICAL USES OF COLLODION.—Mr. Sampson Gamgee writes (*Birmingham Med. Review*, Glasgow *Med. Jour.*): Collodion is one of those therapeutic agents of which the value to the surgeon is admitted, without being adequately appreciated or utilized. Composed of ether, gun-cotton and spirit, collodion is a powerful anti-putrescent; and by ready evaporation and contraction it exercises the dual antiphlogistic power of refrigeration and compression. In acute orchitis I know no plan so simple, rapid, and satisfactory as coating the cord and scrotum with layers of collodion by the aid of a camel's hair brush previously dipped into it. The sensation is momentarily sharp, the shrinkage rapid, and so is the subsidence of the inflammatory process—facts pointed out some 30 years ago by Bonnafont, but much doubted and almost forgotten. To swollen parts which cannot well be bandaged, collodion is especially applicable for the compression attending its contraction. I was lately consulted in the case of a good-looking boy considerably disfigured by a red and swollen nose, which became very pale and visibly contracted just after I painted it with successive layers of collodion. I repeated the application three times in the succeeding fortnight, with the effect of producing shrinkage of the organ to its natural size and color. When the nasal bones are fractured, a very effective mould for keeping them immovable, after adjusting them with the fingers, may be thus made: Place over the nose a thin layer of absorbent cotton soaked in collodion; as it dries another layer of cotton and collodion, taking care that the application extends sufficiently on each side to give buttress-like support. The patient compares the feeling to the application of a firm bandage on the nose, and the bones consolidate effectively under the shield, which may be renewed as it cracks and peels off.

Other cuts than recent ones do well under collodion. A horse-breaker sought my advice for a grazed wound inflicted by a carriage step on the front of his right shin 10 days previously. He had applied water-dressing continuously. The surface of the sore had suppurated, and its edges for some distance round were red and tender. I raised the foot to empty the limb of blood, dried the surface of the sore with absorbent tissue, then brushed it over with collodion, and applied a smoothly compressing bandage over one of my pads. The part was easy at once, and with two more dressings at intervals of four days, cicatrization was perfect, the patient having continued his business of riding and driving without losing an hour.

SATURDAY, OCTOBER 25, 1884.

THE COMMUNICABILITY OF TUBERCULOSIS.—So long as this universal scourge of humanity has been the object of clinical study, it has been regarded as contagious; and this not merely by the people, but also by the profoundest minds of the medical profession.

Aristotle is reported to have so considered it, and Morgagni is said to have entertained such fear of its contagion, that he would not perform an autopsy on any one who died of the disease. For ages, the opinions of the profession were based upon clinical observation. At length, however, with advance in pathological knowledge, seekers after truth grew distrustful of mere clinical observation, and this method, with its liability to error, became subjected to the test of another.

Various of the lower animals were inoculated with tuberculous tissues; and though this procedure was likewise liable to error, it was thought to afford the best prospect of ultimately solving the problem. Klencke, whose researches have been largely forgotten, was the first to initiate this method, in 1843. The attention of the medical world was not seriously engaged, however, until M. Villemin published the results of his experiments some twenty years later. Then in rapid succession followed investigations by other pathologists, chief among whom were Cohnheim and Salmonsén. Reports were conflicting, and for years the question was an open one. Recent experiments, however, made by Robert Koch and his co-workers, and detailed by him in "The Reports of the Imperial Board of Health, Second Volume, Edited by Dr. Struck, Director; Berlin, Hirschwald. 1881, appear to have settled the dispute. An abstract of

this paper may be found in *The Lancet* of March 15, 1884.

To quote from this abstract: * * * "He describes at length the infection experiments—first, those made by inoculation with tuberculous tissues; and, secondly, those made with pure cultures of the bacillus. These latter include inoculation of the anterior chamber of the eye, of the peritoneal cavity, intravenous injection, and experiments by inhalation. We know the results of this research, and how upon it the doctrine of *contagium vivum* in tuberculosis has been based." Now, if the disease may be contracted by inoculation, why may it not in human beings be contracted from intimate relationship with tuberculous patients? With a view to investigating this latter contingency, a commission was some time ago appointed by the "Société Médicale des Hôpitaux" of Paris, and on the eleventh of last July, M. Vallin read before the society a report in behalf of the Commission, (see "*Gazette Hebdom.*," July 25, 1884, and the *American Journal of the Medical Sciences*, for October, 1884, an abstract of his report, under the title "Transmissibility and Prophylaxis of Tuberculosis.") The first part of his paper reviewed experiments and observations made with reference to determining these points, and incidentally mentioned that Cohnheim, who formerly denied the contagiousness of phthisis, is now arrayed on the affirmative side of the question, in consequence of having seen animals in his own laboratory which had never been inoculated, contract tuberculosis from too intimate proximity to diseased companions. In short, after having recounted the history of the subject up to the present, M. Vallin passed to a consideration of the prophylaxis of tuberculosis. His points are as follows:

A phthisical patient should occupy a bed, and, if possible, his apartment, alone. Two arguments may be employed to effect this end: the danger to the healthy person of contamination, and the importance to the invalid of fresh air, unfouled by the breath of another. Children in particular should not be allowed to share the bed or room of a consumptive. The danger is enhanced if they are recovering from measles, bronchitis, or any other pulmonary affection that is attended with abrasion of the epithelial lining of the air passages. Ulceration of the buccal, pharyngeal and laryngeal membranes, due to phthisis, appear to be specially prone to disseminate the disease—a fact so generally recognized by experimenters, that inoculations are now made directly into the peritoneal cavity. Verneuil's statements, that tuberculosis of the genital organs is particularly liable to propagation, though not yet proven, are probably cor-

rect. Hence, consumptives should be restricted in their sexual relations. For this and other reasons a tuberculous woman, or one predisposed to the disease, should be dissuaded from marrying, especially from nursing her offspring. In this respect the views of the Commission accord with those of the best obstetricians, who regard pregnancy and the *puerperium* as likely to favor the development and progress of destructive processes in the lungs. (See Playfair, Lusk, Spiegelberg, Schroeder, etc.). It is a mooted point whether or no the milk of a phthisical mother can infect her nursling; but this seems improbable unless the mammary gland be the seat of disease. However, M. Vallin suggests that great precaution be exercised in the consumption of milk and flesh of tuberculous animals, and that they be not admitted as articles of food before having been thoroughly cooked. The real prophylaxis of phthisis consists in the disinfection of the *sputa*. For this purpose are recommended solutions of chloride of zinc, 3jss to the pint of water and glycerine, of chloride of lime, thymic, nitric and carbolic acids, or sulphate of copper. The fresh *sputa* are particularly resisting to the action of disinfectants, being unaffected by a solution of the bichloride of mercury of the strength of one part to two hundred. The experiments of Schill and Fischer, detailed in the *Medical News*, Sept. 19, 1880, prove that the *sputum* of tuberculosis retains its virulence from three to seven months. As dried *sputa* are particularly dangerous, as particles floating in the atmosphere, it is highly important that the apartments and clothing of consumptives be thoroughly disinfected. *Fomites* should be treated with steam at 212° F., and until so treated, scrupulously protected from the air within closed vessels. Rooms where phthisical patients have died or resided long, should be fumigated with burning flowers of sulphur, 3viiss to the cubic yard of space. Barracks, hospital wards, health resorts, etc., should from time to time, at least once a year, be likewise disinfected. When a patient leaves his apartment by day, it should be thoroughly aired and heated. If ventilation be properly conducted, there need be no danger to the inmate, and by night this is very necessary in order to avoid confined air. Patients should not be allowed to expectorate into handkerchiefs and the like, or on to the floor, but into receptacles filled with wet sand or sawdust, or, still better, with disinfectant solutions. In conclusion, the report stated that while the communicability of phthisis from one person to another is not proven, it is so probable as to render strict prophylaxis an imperative duty.

The foregoing fair statement of the present status

of the investigations concerning the communicability and prophylaxis of tuberculosis, naturally leads to the inquiry how it has happened that a strictly contagious disease, with abundant infectious sputa, has existed for centuries in every civilized nation on the globe, with perfect freedom of intercourse both in families and communities, without having long since infected and destroyed the whole human race?

And how is it that physicians examine minutely tuberculous patients and their sputa almost daily for years without the slightest harm? Or why is it that both physicians and nurses in daily attendance on hospital wards constantly occupied by tuberculous patients, show no greater ratio of attacks of the disease than those who never enter such wards?

AMERICAN PUBLIC HEALTH ASSOCIATION.—The twelfth annual meeting of this important national organization convened in Liederkranz Hall, St. Louis, on the morning of the 14th inst. The meeting was called to order at 10 o'clock A. M. by the President, Dr. Albert L. Gihon, Medical Director of the United States Navy.

Dr. Spiegelhalter, Chairman of the local Committee of Arrangements, welcomed the members and announced an extended list of invitations and entertainments. Eighty-one members were reported present, representing 21 States, the District of Columbia, Canada, the Medical Corps of the U. S. Army and Navy, and the Marine Hospital Service. A strictly business meeting was first held, during which reports were submitted by the Treasurer, by a committee on the incorporation of the Association, and by the Secretary on the election of new members.

A list of sixty-two new members recommended by the Secretary and thirty-four by the Chairman of the local Committee of Arrangements were elected. The Chairman of the Committee on Necrology reported the names of thirteen members who had died since the last annual meeting.

The routine of business having been completed the Association proceeded to the reading and consideration of papers, and consumed the remainder of the session chiefly on matters pertaining to the sanitary condition of the household or family residences.

Tenement Houses: This subject was presented in an interesting paper by Dr. C. W. Chancellor, of Baltimore, who, after setting forth the evil effects of overcrowding in a large part of the tenements occupied by the poor in all our cities, claimed that houses which were unfit for habitation should be declared public nuisances and their owners compelled either to put them in proper condition or remove them. He

urged that overcrowding should be strictly prohibited under a heavy penalty, and houses used for crime at once closed and the re-establishment of similar houses elsewhere in the cities prevented by the due enforcement of proper regulations. To that purpose the municipal authority ought to have the hearty coöperation and consistent support of public opinion. When it was necessary to purchase unsanitary houses to effect public improvements the authorities should be compelled to pay only a price commensurate with the letting value of the property for legitimate purposes, and not the added value in consequence of the owners winking at the use of their property for illegal and immoral purposes or the consequence of their property being overcrowded and let to more persons than it was capable of properly accommodating. In conclusion, Dr. Chancellor urged that local authorities should be clothed with powers enabling them to successfully grapple with the evils of overcrowding and the evils arising from the occupation of unsanitary dwellings.

This was followed by a paper on "The Hygiene of the Habitations of the Poor," by Maj. Samuel A. Robinson, Inspector of Plumbing in the District of Columbia. It gave many practical suggestions concerning the construction of dwellings—claiming that no dwelling should be constructed on damp ground until it had been thoroughly drained, and emanations prevented by a layer of cement over the surface—that delf wares should be used in preference to cast-iron and other materials in the construction of drains, water-closets, sinks, etc., and that the simplest form of construction was the best. Like the author of the preceding paper, he claimed that the municipal authorities should exercise a most stringent supervision over all these matters. This was followed by a paper on "The Sanitary Survey of a House," by Dr. Wm. K. Newton, of Paterson, N. J., which related chiefly to the duties of sanitary inspection officers.

The subject of "Heating and Ventilation" was presented in a paper by Dr. Charles O. Curtman, of St. Louis, who, after comparing the various systems in operation at the present day, gave preference to the hot-air principle as the one best adapted for public buildings. A moderate degree of discussion was elicited on some of the topics presented in these several papers, but without developing additional facts of importance.

Dr. Thornton W. Parker, of U. S. Army, read a paper on "The Sanitary Management of Railway Cars and Stations," in which he set forth the necessity of requiring each railroad company to have special hospital cars for the accommodation of the sick

and the protection of travellers from contagious diseases. Also, that in the depots of all the large cities there should be an organized system of sanitary inspection, etc.

The remaining paper of the first day's session was on "The Hygiene of Occupations," by Dr. Geo. H. Rohe, of Baltimore. In presenting statistics on the subject, he gave the following from a report prepared for the Massachusetts Legislature, covering 31 years eight months, from May 1, 1843, to December 31, 1874:

The total number of deaths during that period was 144,954, and the average age of each individual 50.9 years. The list was divided into 10 classes, and showed that of the total number of deaths 21,832 were cultivators of the soil, with an average age of 65.29 years; active mechanics abroad, 10,093, with an average age of 56.17; active mechanics in shops, 16,576, with an average age of 47.57; less active mechanics in shops, 17,233, with an average age of 43.87; laborers, 28,058, with an average life of 47.41; men employed on the ocean, 8,044, average age 46.44; merchants, financiers and agents, 15,965, with an average of 48.95 years; professional men, 5,175, with an average length of life of 50.81, and females, 3,343, with an average age of 39.17.

The evening session of the first day was occupied first with the hearing of addresses of welcome by the Mayor of St. Louis and the Governor of Missouri, after which the President of the Association, Dr. Albert L. Gihon, delivered the annual address, in which the "Sanitary Responsibilities of the Citizen" were discussed with his well-known ability and emphasis. These evening exercises were attended by a large audience of ladies and gentlemen.

CONFERENCE OF STATE BOARDS OF HEALTH AND CHOLERA.—Simultaneous with the assembling of the American Public Health Association in St. Louis, there was held in the same city a conference of members of the several State Boards of Health. The attention of the conference was chiefly occupied with the subject of the prevention of cholera, and the deliberations ended in the adoption of a report, the chief points in which were the positive declarations that "there are three essential factors to the presence of cholera in this country as an epidemic, viz.: Importation of the disease by means of ships directly or indirectly from its *only* place of origin in India; local unsanitary conditions favorable for the reception and development of the disease; and persons sick with the disease in some of its stages, or things

affected by such sick persons to carry it from place to place." With equal positiveness the report asserts that "*the cause of cholera exists in the discharges of persons affected with the disease, or in things infected by such discharges.*"

With these positive views, the remedies recommended are, of course, thorough quarantine, State and national; systematic inspection both at home and foreign ports; thorough local sanitation; and if the disease comes, as complete isolation of patients as possible, and thorough disinfection or destruction of all infected articles.

We shall give our readers the report in full as soon as we have space for it, merely adding that some positions are more easily assumed than proved or reconciled with all the known facts.

SOCIETY PROCEEDINGS.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated meeting, Oct. 2, 1884. The President, R. A. Cleemann, M.D., in the chair.

Dr. B. F. Baer exhibited specimens from a case of *Submucous and Interstitial Fibro-cystic Tumor of the Uterus in which Hæmorrhage was absent*. Mrs. H., aged 36 years, has had two children, the youngest being 12 years of age. Four years ago she suffered from severe metrorrhagia which was caused by a submucous and interstitial fibroma of the uterus. This was removed, and after passing through a severe attack of periuterine inflammation, she recovered. After the removal of the growth her catamenial periods became regular in time and quantity, and she remained well until about one year ago, when she began to have a very fetid watery discharge in the intermenstrual periods with sacral pain and uterine tenesmus. On July 17 her physician, Dr. R. Armstrong, of Lock Haven, requested me to see her with him, when examination showed the cervix to be twice its normal size with swollen and gaping lips, making the os and cervical canal quite patulous. The body of the uterus was as large as at the third month of gestation, but it was not symmetrically developed, being larger on the left than on the right side. The left broad ligament was indurated and seemed to be the seat of an old inflammatory process. Pain had been present in this region since the operation. The sound met with an obstruction at the internal os and was deflected to the right, passing to a depth of nearly four inches. It could be made to pass around a mass of some kind in the cavity of the uterus, giving an indistinct sensation of the presence of an abnormal growth. I expressed the opinion that although there had been no hæmorrhage there was a submucous or polypoid fibroma present, and advised its removal. Seven tents were introduced, and twenty-four hours later ether was administered, when with the assistance of

Drs. Armstrong, Walls and Ball, I proceeded to remove the tents and explore the uterine cavity. On passing my finger within the internal os, I detected a smooth oval-shaped mass of tissue resembling in consistency the inverted uterus enlarged to about double its normal size. I carried my finger up with some difficulty, and found the base or attachment of the tumor to be located at the fundus of the uterus where it was narrowed somewhat, forming a sort of pedicle. The tumor felt rather soft for a fibroma, and this, together with its shape, caused me to suspect inversion of the uterus, and when I remembered that the organ is sometimes inverted by the operation for the removal of an interstitial fibroid which requires great traction, as was necessary in this case four years previously, I became much more anxious to investigate fully before attempting to remove the mass. By very careful and thorough bimanual manipulation I convinced myself that the uterus was not inverted, there was no indentation anywhere on its surface, I therefore felt warranted in adjusting the wire of an écraseur around its attachment, and proceeded to tighten it, but the traction and manipulation which were necessary in placing the noose broke the surface of the tumor and exposed a peculiar looking membrane which resembled the peritonæum. I was alarmed at this, fearing that I had really to deal with a partially inverted womb, and that the smooth membranous surface was the peritonæum. I removed the écraseur, the wire of which had broken, and then passed one finger into the bladder and another into the rectum, for the purpose of determining more certainly the condition of the peritoneal surface of the uterus. Now while an assistant made traction on the supposed tumor, I was enabled to satisfy myself fully that the organ was not inverted. I then removed the tumor by enucleation.

As you will see in the specimen which I present, there are a number of cysts. These cysts contained the semi-opaque coagulable fluid usually found in fibro-cysts, and gave to the tumor its softness which, together with its shape and the appearance of the cyst-walls when its surface was broken, made it resemble an inverted uterus. The patient made a good recovery.

The case is very unusual for the reason that although the uterine cavity was distended by a large submucous tumor which was becoming polypoid, not the slightest hæmorrhage resulted. I do not remember to have met with a similar case. I have, however, met with cases of small polypi where there was no hæmorrhage, two indeed were discovered after the menopause had been fully established and are worthy of record, because of the reflex symptoms which they seemed to induce.

Uterine Polypus in which Hæmorrhage was absent but which gave rise to Symptoms of Pregnancy. Mrs. C. was 46 years of age, she had been married twenty years, but had never been pregnant. The menopause had occurred one year previous to the date at which I saw her. Soon after the cessation of the catamenia her abdomen began to enlarge, and she thought she was pregnant, various irregular reflex symptoms of pregnancy developed and she became so convinced

that she engaged the services of an accoucheur and nurse, and went into labor in due time. Her physician, my friend Dr. John H. Musser, was unable to discover the least physical sign of gestation nor anything else which should give rise to the almost perfect labor-like pains which she seemed to have at irregular intervals. He informed her that she was not pregnant. She became indignant and asked him to call another physician to confirm what he said. He consented, and requested me to see the patient. I excluded pregnancy, but found in the cervical canal a fibrous polypus not larger than an ordinary marble. This I at once removed and the pains and other signs of gestation immediately subsided.

This was one of those cases of spurious pregnancy which we sometimes see developed in a sterile woman about the period of the menopause. The desire for offspring is strong. The cessation of the menses starts the delusion and it is kept in existence and made to grow by being constantly fed by a morbidly susceptible nervous system. But there was a local irritation here to account for the reflex symptoms of gestation, as I believe there is in the majority of these rare and interesting cases. It is three years since this patient was under treatment, and there has been no return of the reflex disturbance.

The other case to which I wished to refer occurred in the practice of my friend, Dr. B. Trautman, who kindly asked me to see the patient with him.

Uterine Polypus in which Hæmorrhage was absent, but which seemed to indicate severe reflex Head Symptoms. Mrs. K., æt. 52 years, has had two children, the youngest being twenty-five years of age. The menopause had occurred four years previously and she did not complain of the slightest local symptom of uterine disease; but the flushings and other nervous manifestations which often attend this period, had not yet subsided. The disturbances, however, which concerned her most, and for which she consulted the doctor, were a pain and pressure of a very aggravated form on the top of the head. Many remedies had been prescribed for the relief of this but with only temporary benefit. A uterine examination was made and a polypus resembling in size a small walnut discovered in the canal of the cervix. This was removed some months ago, and I believe the patient has been relieved of the headache and other reflex symptoms which seemed to result from its presence.

The influence which these small growths have on the nervous system is something remarkable, but the absence of hæmorrhage, especially in the first case, is more notable when we recall its size and location, and remember that death has resulted from the hæmorrhage caused by polypi not larger than a pea, as recorded by Locock, Klob, Courty and others. I have no doubt some of you can recall cases, as I can, where death would doubtless have resulted from the hæmorrhage produced by a small polypus, had not the cause of it been removed. The following is an illustrative case:

Uterine Polypus attended with great Hæmorrhage. Mrs. P. consulted me on September 20, 1883. She was 30 years of age and has been married eight years

but has been sterile. Two years ago she began to suffer from menorrhagia with uterine tenesmus. Soon after she lost blood at irregular intervals and in large quantities; during the past year she had not often been free from metrorrhagia or a profuse and offensive leucorrhœa. The hæmorrhage would sometimes last a whole month continuously and leave her so prostrated and anæmic that it was thought she could not rally. She had lost thirty pounds in weight and was blanched in appearance.

I will confess that I was surprised to find, on examination, that my patient had a polypus not larger than a Concord grape; but the mucous membrane of the cavity of the uterus was hypertrophied and granular. The pedicle was attached far up in the cavity of the uterus. The tumor was removed by means of the curette. The patient now menstruates regularly. This case contrasts strongly with the three others in its hæmorrhagic character, and it presents the history commonly met with in these growths. There is no doubt that the location of the tumor has great influence in the causation of hæmorrhage in these cases, much greater than the size of the growth; but much also depends upon its histological character and the condition of the endometrium. Thus when a fibroid tumor or polypus is situated in the cavity of the uterus proper, more hæmorrhage is likely to result than when it grows from the tissues of the cervix, because if located in the former position it is often of the muscular variety, and therefore more vascular, and the mucous membrane of the uterine cavity, which is the direct source of the hæmorrhage, is usually hypertrophied and granular as in the last case narrated. Moreover when the cavity of the uterus is the seat of a polypus, the uterine and pelvic circulation is stimulated by its presence, somewhat in the manner in which it is affected by the presence of a fecundated ovum which has been blighted; it is a foreign body and the uterus tries to expel it, but by the effort the circulation is excited in that direction, and hæmorrhage results. My first case, however, furnishes an exception to the rule that hæmorrhage attends when the tumor occupies the uterine cavity, but as tenesmus was present, it is possible that hæmorrhage might have occurred later had the tumor been allowed to remain.

Dr. Goodell remarked that the question of hæmorrhage in polypus is a curious one. It seems less likely when the tumor is in the body of the uterus, and checks the amount of circulation by exciting tonic contractions, than when it is protruding into the vagina like the clapper of a bell. In one case, where the hæmorrhage had produced extreme anæmia, dialysed iron was given to relieve the anæmia, and it also checked the hæmorrhage. In another case, operation was refused and death resulted from hæmorrhage three days after the visit.

Rapid Dilatation of the Uterine Canal. By Wm. Goodell, M.D.: For many years I enlarged or straightened the uterine canal, according to the requirements of the case, either by tents or by Sims's operation, and preferably by the former. Having had several serious warnings in the shape of inflammation following these operations, I began to perform

them with fear and trembling. Yet nothing very untoward happened until the year 1878, when two grievous mishaps befell me.

A charming young lady, the centre of a large circle of admiring friends, came from a neighboring State to consult me about a dysmenorrhœa which grew worse and worse every year. The cervix was so bent forward, and the stenosis of its canal *per se* as well as by angulation was so marked that I unhesitatingly performed Sims's operation. Within a few days septicæmia set in, soon the parotid glands swelled up, and on the ninth day she died. True it is, that at the same time two piles also were tied, but this latter operation I had, and have, performed so many times with impunity, that I was, and am still, disposed to attribute the blood-poisoning to traumatism of the cervix and not to that of the rectum. Hardly had I time to recover from this severe blow, when a case of exhausting menorrhagia fell into my hands. The lady was the young bride of a husband well advanced in life, who doted on her as only old men dote on much younger wives. I dilated the cervical canal with tents and curetted many vegetations from the endometrium. A furious peritonitis set in and in less than three days this young wife lay dead and the husband was frantic with grief.

The anguish which I felt at the death of these two ladies, and the heart-rending scenes which I witnessed at their bedsides—scenes which I cannot now recall without emotion—urged me to try any remedy that gave promise of efficiency combined with greater safety. In the search for a substitute, I tried rapid dilatation, which Ellinger and others had proposed, and since that year—that *annus iræ*—I have not once performed Sims's operation for dysmenorrhœa, and I have so narrowed the field for the use of tents that I now very rarely resort to them. In short, rapid dilatation has proved, in my hands, so safe and so efficient an operation that I wish to urge its claims before this Society.

The instruments which I would recommend are two Ellinger dilators of different sizes. These are the best, on account of the parallel action of their blades. The smaller of these dilators has slender blades, and it pilots the way for the other, which is more powerful, and with blades that do not feather. I have had the beaks of these dilators changed from an obtuse angle to a slight curve, so that it can be reversed within the womb. The lighter instrument needs only a ratchet in the handles, but the stronger one should have a screw with which to bring the handles together. Lest the beak should hit the fundus uteri and seriously injure it when the instrument is opened, the blades are made no longer than two inches, and are armed with a shoulder which prevents further penetration. The larger instrument opens to an outside width of one and a half inches, and it has a graduated arc in the handles, by which the divergence of the blades can be read off. The instruments which I now exhibit to you, and which I can recommend highly, have been made under my supervision by Messrs. J. H. Gemrig & Son, of this city.

In a case of dysmenorrhœa or of sterility from flexion or from stenosis, my mode of performing the

operation of rapid dilatation is as follows: The patient is thoroughly anesthetized, and a suppository containing 1 grain of the aqueous extract of opium is slipped into the rectum. She is then placed on her back and drawn to the edge of the bed, the knees being supported by her nurse. The light must be good, so that the operator may clearly see what he is about. By the aid of a strong tenaculum, applied through my bivalve speculum, the cervix is steadied and the smaller dilator is introduced as far as it will go. Upon gently stretching open that portion of the canal which it occupies, the stricture above so yields that when the instrument is closed it can be made to pass up higher. Thus by repetitions of this manœuvre, little by little, in a few minutes' time a cervical canal is tunnelled out which before could not admit the finest probe. Should the os externum be a mere pin-hole or be too small to admit the beak of the dilator, it is enlarged by the closed blades of a straight pair of scissors, which are introduced with a boring motion. As soon as the cavity of the womb is gained the handles are brought together. The small dilator being now withdrawn, the larger one is introduced, and the handles are then slowly screwed together. If the flexion be very marked, this instrument, after being withdrawn, should be reintroduced with its curve reversed to that of the flexion, and the final dilatation then made. But in doing this the operator must take good care not to rotate the womb on its axis, and not to mistake the twist for a reversal of flexion. The ether is now withheld, and the dilator kept *in situ* until the patient begins to flinch, when the instrument is closed and removed. A few drops of blood trickle out of the os. Occasionally a slight flow of blood will last for several days after the operation, simulating the menstrual flux. Often this flux is precipitated or renewed, if the operation follows or precedes it too soon. The best time for dilatation is, therefore, midway between two monthly periods.

When compared with the cutting operation this one looks like rough usage, yet the woman rarely needs more than two or three suppositories, and complains merely of soreness for one or two days. To forestall any tendency to metritis, she is kept in bed until all tenderness has disappeared. Pain is met by rectal suppositories of opium and by large poultices laid over the abdomen. I have seen slight pelvic disturbance arise from this operation, but it has always been readily controlled and has not given alarm.

In the great majority of cases I dilate the canal, not to the fullest capacity of the instrument, but to one and a quarter inches. Sometimes in an infantile cervix which does not readily yield and might give way, the handles are not screwed down more than three-quarters of an inch or an inch. Tearing of the cervix has happened in two of my cases. In one, that of a virgin, the cervix was split half way down to the vaginal junction. The other case was that of a multipara, whose uterine canal had been nearly closed up by applications of silver nitrate, made by her physician with the view of curing what he supposed was an "ulceration of the os," but which was a bilateral laceration. The tissues, rendered cicatricial

and brittle by the caustic, were torn by the dilator for about half an inch on the right side also. Here the hæmorrhage was free enough to need styptic applications and a tampon. I could have stopped it by wire sutures, but this was not done, as it would have defeated the object of the operation.

For slight dilatations such as for the office treatment of antelexions and of stenosis, or for the introduction of the curette, or of the applicator armed with cotton, the more delicate instrument is quite strong enough, and an anæsthetic is not needed. Sometimes, in a very sharply antelexed womb the dilator can not be made to pass the os externum. This difficulty is overcome by first passing in a surgeon's probe, and then, along it as a guide, the dilator.

After a forcible dilatation under ether, the cervical canal rarely returns to its previously angular or contracted condition. Since lateral extension of elastic bodies antagonizes their length, the cervix shortens and widens; and the plasma provisionally thrown out by the submucous lesions sustained by the dilated part serves still further to thicken and stiffen its tissues. In other words, the stem-like neck of the pear-shaped womb is shortened, widened, strengthened and straightened. Hence, for straightening out antelexed or congenitally retroflexed wombs, and for dilating and shortening the canal in cases of sterility or dysmenorrhœa, arising from stenosis or from a conical cervix, the dilator will be found a most efficient instrument. In its results it is not infallible. I have twice been obliged to repeat the operation, and would like to have done so in several other cases had the women permitted it. In a very few instances I have been forced, as a final resort, to nick a pin-hole os externum; but I had not then learned how far I could safely stretch open the uterine canal, and the operation of dilatation was not so efficiently performed by me as it is now through a larger and riper experience.

But it is not to cases of dysmenorrhœa that I limit the operation of rapid dilatation. As stated before, I use it to stretch open the canal for the admission of the curette and of sponge-tents or for the purpose of making applications to the uterine cavity. In cases needing the irrigation of the uterine cavity, I first dilate the canal with this instrument and introduce the nozzle of the syringe between the separated blades. This gives a free avenue for the escape of the liquid, and robs of its dangers this form of intra-uterine medication. I also resort to the dilator in order to explore the womb with the finger. For instance, in any given case of menorrhagia in which a polypus or some other uterine growth is suspected, instead of using tents, I put the woman under an anæsthetic, and after the rapid dilatation of the cervical canal to the utmost capacity of the instrument—viz.: one and a half inches—am enabled to pass my finger up to the fundus. This is accomplished either by drawing down and steadying the womb by a vulsella forceps; or in thin subjects by forcing the womb down upon the finger through supra-pubic pressure on its fundus. In this way I have over and over again, at one sitting, discovered

a uterine growth, twisted it off and removed it. Usually in these cases I experience more difficulty in removing the polypus or other growth through the small canal than in twisting it off from its uterine attachment. It often has to be wire-drawn before it can be removed, and sometimes the os uteri has needed a few nicks. Usually, when the menorrhagia is free, the cervical tissue is so loose that there is no difficulty in the introduction of the index finger up to the fundus, but sometimes only its tip can be made to pass the os internum. Yet even this limited degree of penetration is commonly quite enough to decide the presence of an inside growth. If it is not enough, I invariably search for a growth with a small pair of fenestrated forceps, and I have repeatedly seized and removed one, the existence of which was merely suspected. After such operations the uterine cavity is thoroughly washed out with a solution of carbolic acid or of potassium permanganate.

I am sorry to say that I have not kept full records of all my cases of rapid dilatation. For instance, I have never recorded those office cases of dilatation in which ether was not given. Nor has any note been made of cases in which dilatation was performed under ether for curetting, for digital exploration of the endometrium, or for the removal of uterine growths. I have tabulated merely cases of dysmenorrhœa in single or in married women. In the married, with but three exceptions, which will be noted, painful menstruation was accompanied by sterility.

Including all the cases of dilatation performed under ether, I must have had over three hundred. I have limited myself to these cases because the use of an anæsthetic implies full dilatation—one in which serious injury, if ever, would most likely be sustained. Yet there has not been a death or a case even of severe inflammation in my practice, and the results have been most satisfactory—far more so than when the cutting operation was performed by me. The following are the statistics of my cases of dysmenorrhœa:

Unmarried	80
Married.....	88
	—
	168

Of the unmarried eighteen were unheard from after the operation, leaving sixty-two from which any data could be obtained. Of these, thirty-eight were cured, seventeen more or less improved, and seven not improved at all. Of these seven that were not benefited by the operation, five subsequently had their ovaries removed; one of them by another physician and four by myself; of the latter one died. In each one the ovaries had become so altered by cystic or by interstitial degeneration as to make the dysmenorrhœa otherwise incurable. Of the seventeen improved, there was one on whom oöphorectomy was also performed; for although the dysmenorrhœa was greatly relieved by dilatation, ovarian insanity and menorrhagia were not. The operation was a successful one and my patient was not only cured of her hæmorrhages, but she regained her reason. Out of

these cases the majority, although not wholly cured, were greatly improved. For example, one of them was formerly bedridden during the whole period of her menstrual flux and had then to take large doses of morphia. She also suffered at these times from hæmatemesis and epistaxis. Since the operation she experiences pain for merely two hours, needs no anodyne, and has lost her ectopic hæmorrhages. Her gain in health and flesh has been great. Another one who was wholly crippled by her sufferings and made nervous by the dread of them is now a busy nurse. For one hour at every period she suffers a great deal but she is too much afraid of taking ether to have a second dilatation performed.

Of those cured, two had Sims's operation performed previously without benefit, and were afterwards dilated; two were dilated twice before a cure could be brought about. The history of several cases merits more than a mere allusion. The sufferings of one of my patients at every monthly period had always been great; but while she was at a boarding school they grew so intense as to cause furious delirium at those times. This finally developed into permanent insanity with suicidal impulses. While in this condition she was placed in my hands. After rapid dilatation of the cervical canal, the dysmenorrhœa wholly disappeared. The exemption from pain toned down some of her more extravagant delusions, but she did not wholly regain her reason until a few months afterwards. She is now free from all menstrual pain and in the complete possession of her mental faculties.

A Hebrew lady whose health had suffered from dreadful dysmenorrhœa was improved so much at one sitting that her physician and friends were amazed. Not long afterward he asked me to perform the same operation upon another one of his patients, who was, if anything, worse. Her sufferings were so intense that he wrote, "I fear that another period might kill her," and urged an immediate operation. The cervix in this case was conical and very dense. Fearing a tearing of the parts I screwed the instrument slowly up to one and a quarter inches and kept up this amount of dilatation for some twenty minutes. The cervix sustained no injury. The canal has since remained patulous and she is free from all menstrual pain.

Of the married, fifty-three were heard from. Of these, thirty-nine were cured, ten improved, and four unimproved. Out of these fifty-three cases, nine were not in a condition to conceive, three of them from fibroid tumors, two from destructive applications of nitrate of silver to a lacerated cervix; three from being over forty-one years of age, and one from being a widow. This leaves but forty-four capable of conception, and of these eight, or a little over 18 per cent., became pregnant. But the ratio is in fact larger, for several of my patients fearing pregnancy, employed preventive measures after the operation. Then again, I believe that others who consulted me merely for painful menstruation have not reported their subsequent pregnancies. For instance, two months ago I learned through the merest accident that the wife of a clergyman, whose cervical canal I

dilated six years ago, has since been making up for lost time by giving birth to twins within a year after the operation, and later to several other children. She had been married eight years before she came to me and had had her cervical canal dilated by tents and slit up with Peaslee's metrotome by a skilful surgeon. I have also had several cases of pregnancy following office dilations of the uterine canal, in which ether was not given and consequently the lumen of the canal was not much enlarged. But such slight operations were not deemed worthy of record, and they therefore have no statistical value.

Dr. Harris inquired about the danger of lighting up a former ovaritis by dilatation. The operation is successful, but that is its danger.

Dr. Goodell has not hesitated to operate, but always uses opium first, and by the time the operation is over the patient is under its influence. He keeps them in bed and under the opium until all tenderness has passed entirely away.

Dr. Wm. Goodell exhibited a *Dermoid Cyst of the right Ovary*. A saleswoman, aged 27, was obliged to give up her situation because she found herself unable to stand for any length of time. Her physician discovered a pelvic tumor, and called in Dr. Goodell to see her. The diagnosis was obscure, but he leaned to a fibroid degeneration of the right ovary. The woman was otherwise well, suffering no pain whatever except when she was in the upright position. The operation was performed on September 8, and the tumor turned out to be a dermoid cyst. Being enveloped in the broad ligament, it was removed with difficulty. It is stuffed with hair and contains a plate of bone, the sharp edge of which was readily felt per vaginam; but it threw no light on the diagnosis, as it was mistaken for a fibroid spur. His patient did uniformly well, and is now out of bed. He stated that in his experience these tumors are very vulnerable, and often resent even so slight an operation as aspiration, inflammation and suppuration quickly setting in. A physician had to-day brought to his office a young woman who had been tapped last June with a trocar. Long hairs and much sebaceous matter escaped through the opening, which had not yet healed up, and it was for this reason that he had been consulted. Upon passing a uterine sound he struck a foreign body, which from its density and the sharp click it gave, he was disposed to think was a tooth. He advised dilatation of the fistulous track and the removal of the offending body.

Two Cases of Oophorectomy. Dr. Goodell also exhibited the ovaries which he had removed on September 17 and 29 from two patients who also were doing well. He stated that the amount of tissue change in these ovaries was very slight, and yet the suffering of each patient had been great. One had been an invalid for several years and bedridden for the past six months. She had lost much flesh, and was always groaning from left ovarian pain unless under the influence of large doses of morphia administered hypodermically. The left ovary was found to be undergoing cystic degeneration, but the right one was so sound that in its removal he was glad to have the backing of Prof. W. S. Playfair, of London, who was

present at the operation. For he believed that in most cases needing oöphorectomy the results usually showed failures unless both ovaries were removed and the menopause established. Convalescence after the operation had been retarded by great and painful swelling of both parotid glands, which developed without any marked rise in the temperature and without acceleration of pulse, and declined without supuration—behaving exactly like mumps. This made his third case of parotitis following the removal of the ovaries. Not one had ended fatally, and from the very slight febrile movement, he thought that the complication was not symptomatic—as in blood-poisoning—but sympathetic, and that a strong kinship, recognized by laymen, existed between the sexual organs and the cervical glands. Since the operation all pelvic pain had ceased.

The other patient was a poor woman, aged 30, the mother of seven children. She was sent to him by Dr. Geo. S. Hull, of Chambersburg, Pa. Three years ago she began to suffer from double ovaralgia. The pain never left her wholly, but it began to increase in severity a week before the period, culminated during the flux, and faded off afterwards. Large doses of anodynes were also needed in this case, and she was unable to work. The case was clearly one of ovarian dysmenorrhœa, and he believed she would be permanently cured.

Dr. Chas. H. Thomas asked Dr. Goodell his experience of the results of oöphorectomy. What proportion of cases are relieved?

Dr. Goodell could not reply definitely. He intends to report his cases before this Society at some future time. In the majority of cases, menstruation ceases, and that element of trouble being removed the patient is to that extent always improved. The neurasthenia resulting from previous suffering may remain, but it is far more amenable to treatment after the cause has been taken away. One such case has occurred to him recently. Dysmenorrhœa caused a virtual insanity with a mind constantly wandering. The removal of the ovaries at once cured the dysmenorrhœa. The patient is now able again to walk and the mind is improving. The operation removes the major element.

Dr. Thomas has now in his care a case which he thinks typical. The patient is a literary woman, overworked and crushed by family anxieties and depressing emotions. He prescribed rest and feeding. Massage proved of but little use and electricity yielded negative results. Forced feeding became impossible. During menstruation she suffered for two or three hours with moderate dysmenorrhœa. Signs of ovaritis developed with swelling and hardening in the right iliac region. The patient was etherized, and a careful examination resulted in finding nothing materially wrong. As soon as anæsthesia was complete all the induration and tumefaction disappeared. There was an ulcer of the rectum and moderate ante-flexion of the uterus. The ulcer has since been cured, but there is no sensible relief. She suffers from a violent pain in the right ovary, extending to the coccyx and across the abdomen; it is cutting in its character at all times, and terribly severe. Form-

erly it ceased at night, but does not now. Hypodermic injections of morphia night and morning are necessary. Riding increases the pain which often extends down the right leg. She cannot sit up long without increasing the pain, which is evidently getting worse day by day. She has been totally disabled for nearly ten months. Is this pain hysterical? Can it be relieved by oöphorectomy?

Dr. Goodell remarked that oöphorectomy is, in any case, a question requiring serious consideration. In the cases just related by him, the patients had neither the means nor the time for prolonged treatment. Whenever possible, everything should be tried before resorting to an operation. One bedridden case under his care, very analogous to Dr. Thomas's, had been relieved by the long-continued use of the constant current passed through the affected ovary. A feeble current was kept up for many hours, sometimes for a whole night at a time. The patient ultimately got well, bore several children afterward, and is now earning her living by teaching.

CHICAGO MEDICAL SOCIETY.

Dr. D. A. K. Steele, President. The regular semi-monthly meeting of this Society was held at the Grand Pacific Hotel on the evening of October 6, 1884.

Dr. John Bartlett, Chairman of the Committee on National Sanitation, reported that while they had agreed on the substance of the proposed resolutions to be submitted for presentation to Congress, they were not in shape to report to the Society, although signed by most of the members. He therefore asked for further time to consider the matter, which was accorded.

Dr. John H. Rauch, Secretary of the Illinois State Board of Health, had read the resolutions prepared by the committee, and as he had been invited by one of its members to address the meeting on their importance, and that of national coöperation with State and municipal governments in arresting the spread of epidemics, he said that matters should be so arranged that there would be concert of action in all municipal cities and State Boards with a national health organization; that the national government should have control of inter-State quarantine, he had no doubts. The trouble all arises out of inefficient maritime quarantine. Illinois was specially interested in this from the St. Lawrence river to the Rio Grande river, and from the Atlantic ocean to the Pacific ocean, for this State pays more internal revenue tax than any other State in the Union, New York not excepted. Cholera may arrive at Montreal or Quebec, and be brought to this city and State over the Grand Trunk railroad, the Michigan Central railroad, or Michigan Southern railroad, and we have authority to stop these trains at the State line only, and prevent them entering the State of Illinois. New York controlled that port exclusively, and Illinois had no authority to interfere, while her interest in keeping out diseases was just as great as that of New York. The Illinois Board of Health was prepared to

prevent the entry of infectious and contagious diseases, no matter what contingency might arise, but it would be better if she could depend upon the aid of her sister States who were equally interested. Two-thirds of the number of emigrants coming to this country arrive at the port of New York. The emigrant inspection service carried on by the National Board of Health a few years ago, under the auspices of the national government, was done at a cost of only \$50,000, when some forty odd thousand emigrants were vaccinated on the trains, and there was no detention. The National Board of Health no longer exists except in name, the last Congress having cut off all appropriations, consequently we are not in as good shape to ward off epidemics as we were three or four years ago. An endeavor to protect the States cannot be well done, on account of inefficient maritime quarantine, and the only resource we have at present to cope with these diseases is for the different States to act in good faith and compact with each other. An illustration was cited by the speaker to prove his statement correct, where in 1878-79, along the banks of the Mississippi and Ohio rivers, epidemics prevailed; that since the organization of the Sanitary Council of States along these rivers, infectious diseases and all other diseases are much less.

The speaker then recited the history of the National Board of Health, its origin, the inefficiency of our laws, etc., and cited as further illustrations, how inadequate the surgeon of this port, and the one at Cairo would be to antagonize or cope with any form of epidemic; that instead of this being only under the control of the State, it should be controlled by the national government. Now is the time to prepare to secure legislation, instead of waiting until after the heels of an epidemic, as has been done heretofore. Those who have charge of sanitary interests in the different States should study the causes of disease, investigate the subject, and through thorough co-operation with a national health bureau, we would be well prepared to prevent the advent of cholera next year. The machinery of no one man can be made to work or control the state of commerce satisfactorily, nor can this be done by one State alone, more States should be represented and concert of action of all those in authority should prevail. The United States Treasury is entirely independent of States in this respect. A conference of the boards of health of the several States and Territories will be held at St. Louis next week, having for its object the coöperation of all authorities for the purpose of controlling epidemics and contagious diseases. He thought that some plan would be evolved that would prove more satisfactory to all, and do away with the petty jealousies that have hampered the action of the national health bureau. The general feeling prevails that we are going to have cholera in this country next year, and now is the time to prepare for it as the resolutions call for. Dr. J. H. Hollister said that as a member of the committee he should decline to attempt to instruct Congress as to its duties in the matter, but thought that a memorial presented by this Society would be the better mode of expression. If our memorial to Congress

is only to express a desire as to what is most wanted by the public, then we, as medical gentlemen, have done our part. It is a subject that takes hold of common interests, and how to render efficient aid suitably but not unnecessarily is something that requires more wisdom than can be gained by temporary discussion. He thought our wisest men should meet in conference and unite on some practical method and then urge legislative action. The speaker asked Dr. Rauch, to what extent are States moving in this direction of having State Boards of Health organized? and to what extent does their authority reach? He was answered, that Massachusetts, New Hampshire, Connecticut, New York, New Jersey, Maryland, West Virginia, Virginia, Indiana, Illinois, Michigan, Kentucky, Tennessee, Louisiana, Mississippi, Arkansas, Alabama, Iowa, Wisconsin, Minnesota and Missouri, each have their State Board of Health. Ohio, Pennsylvania, Maine and Vermont have no State Boards of Health. Lower Canada has none. But that the Ontario Board of Health is in good shape. The Michigan Board of Health is an advisory one. The Illinois Board of Health controls quarantine and can call on sheriffs and constables to obey her dictation. The boards of Missouri and Minnesota are nearly like ours, New York's board is partly like ours in authority. Indiana's board is nearly like ours, only better, for there they have County Boards of Health. The Boards of Health of Maryland and Virginia are also very efficient. Dr. L. H. Montgomery alluded to the merits of the National Board of Health, to the efficient services it had rendered in the past, and hoped it would be adequately provided for in the future. He had spoken to the representative in the Congressional district where he resides upon the subject, and was informed by the member that he would be glad to do his part and use his influence toward securing the granting of legislation for the establishment of some form of a national sanitary organization. The speaker was also assured by the honorable gentleman that he had been, and at present is a friend of the National Board of Health, for its services were performed with a degree of celerity and exactness that pleased everybody in the States. Regarding memorializing Congress, as Dr. Hollister alluded to, there is a clause in the resolutions providing for this.

Every State and Territory in the Union should be represented on this board by the appointment of some one representative medical gentleman to it, for, as Dr. DeWolf said, inter-State observation. Indeed we might do more if needs be than transmit a memorial to Congress, but petition, or appeal to our national legislators to appropriate sufficient means and appliances to sustain some form of National Health Association, which he believed is the sentiment of at least nine-tenths of the physicians and all the people.

Dr. R. E. Starkweather had hoped that the committee were prepared to submit their resolutions this evening. He as one of its members endorsed every word they contained, even at the risk of their being (as possibly they were in one place) tautological. He hoped the committee would be able to perfect them before the close of the week. Dr. Rauch

in conclusion stated that he intended to speak to some extent upon this subject at the meeting of the State Boards of Health to be held at St. Louis next week. A special meeting will probably be held at Washington in December of all the State sanitary boards, at which time this subject will receive especial attention. The Society tendered a vote of thanks to Dr. Rauch for his address and information given. The committee on resolutions was requested to meet immediately after the close of this meeting, which was then adjourned.

LISTON H. MONTGOMERY, M.D.,
Secretary.

At a regular meeting of the Washington Obstetrical and Gynæcological Society, held October 17, 1884, the following officers were elected for the ensuing year:

President.....Samuel C. Busey, M.D.
Vice-Presidents..... { W. W. Johnston, M.D., and
 { J. Taber Johnson, M.D.
Recording Secretary...C. H. A. Kleinschmidt, M.D.
Corresponding Secretary...Samuel S. Adams, M.D.
Treasurer.....Geo. Byrd Harrison, M.D.
Committee on Business..... { C. E. Hagner, M.D.
 { Lachlan Tyler, M.D.
 { S. S. Adams, M.D.
Committee on Admissions.. { J. R. Bromwell, M.D.
 { H. H. Barker, M.D.
 { G. N. Acker, M.D.
Com. on Publications { T. C. Smith, M.D.
 { T. E. McArdle, M.D.
 { C. H. A. Kleinschmidt, M.D.

STATE MEDICINE.

MICHIGAN STATE BOARD OF HEALTH.

Reported for the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION:

The regular quarterly meeting of the Michigan State Board of Health was held at Lansing, Oct. 7, 1884, the following members being present: Henry F. Lyster, M.D., of Detroit; J. H. Kellogg, M.D., of Battle Creek; C. V. Tyler, M.D., of Bay City; and Henry B. Baker, M.D., Secretary.

The Secretary's report of property, etc., for the fiscal year ending Sept. 20, 1884, showed that large accessions had been made to the library by gift and exchange, and a lesser number by purchase, and that unusually large distributions of public health documents had been made during the year.

Prof. R. C. Kedzie presented nine samples of drinking water taken from the public water supplies of Bay City, West Bay City, Grand Haven and Ludington, all of which showed large quantities of organic matter and other impurities. Prof. Kedzie was granted till Nov. 1 to complete his paper on "Potable and Culinary Waters in Michigan, with especial reference to contamination by sawdust" for publication in the Report of the Board for 1884. Dr. Kedzie was also requested to make a special report on the

use of explosive substances for heating and lighting purposes.

It was decided to hold a sanitary convention at East Saginaw in December, and a committee was appointed to confer with a local committee as to date, programme, etc.

At a request of the Board of Correction and Charities, committees were appointed to examine and report on the sanitary condition of the State House of Correction at Ionia, and on the sanitary bearings of the use of boiler-iron for cells in jails.

The Secretary continued his report on outbreaks of cheese-poisoning. Seven outbreaks in Michigan had been reported this year, in which there were 190 cases of sickness, but no deaths. The symptoms following the eating of the cheese were very similar in all cases, consisting of pain in the stomach, cramping of muscles, coldness of extremities, and great prostration, with violent retching and purging, lasting for several hours. In most cases the larger the amount of cheese eaten, the more violent were the symptoms. Samples of the Lowell cheese had an acid reaction and a peculiar strong odor, believed to be due to caprillic acid or capraic acid; examined with a one-tenth inch immersion objective, the cheese was found to contain the mycelium of a mold, and to be swarming with several kinds of actively moving bacteria. Samples of the cheese were sent to Dr. V. C. Vaughan, of Michigan University, and to Prof. T. J. Burrill, of Illinois State Industrial University, for further examination and experiment.

Further time was given to the committee on textbooks on physiology and hygiene. The Secretary called attention to a sanitary house-to-house inspection which had been made recently in the city of Ann Arbor. It is believed that this is the first systematic inspection of the kind ever made in this State.

A paper on Typhoid Fever was presented by the Secretary, and was approved for publication in the Annual Report of this Board.

The State has been free from small-pox during the quarter.

The recent report that pleuro-pneumonia exists among cattle in the vicinity of Nashville, Mich., proved on inquiry to be unfounded. During the quarter glanders was reported present among horses in Delta county. Letters were sent to health officers or supervisors of all townships where the disease was reported to exist, urging prompt action on the part of the local boards of health to exterminate the disease. It is believed that there are fewer cases than were at first reported. As one result of the correspondence, two of the infected horses were shot by their owner.

The Secretary reported the preparation, publication, and distribution of 12,000 copies of the document on the Prevention and Restriction of Cholera. A similar document on cholera in its relations to railroads had also been prepared at the request of the Commissioner of Railroads, and had been printed and distributed by the Commissioner, in connection with a circular from his office to all railroad officials in Michigan.

A list of the names and addresses of the health officers of Michigan has been printed and a copy

sent to each local board of health. The document on the Restriction and Prevention of Diphtheria has been revised with reference to new laws and reprinted. The new compilation of the public health laws has been distributed to every health officer in the State,—a class of persons who do not receive the session laws.

HEALTH IN MICHIGAN, SEPTEMBER, 1884.

Reports to the State Board of Health, Lansing, by observers in different parts of the State, show the diseases which caused most sickness in Michigan during the month of September (four weeks ending Sept. 27), 1884, as follows:

Diseases Arranged in Order of Greatest Prevalence.	Number of Weekly Reports Received, 184.	
	Per Cent. of Reports Stating Presence of Disease.	Per Cent. of Reports Stating Presence of Disease.
Intermittent fever.....	84	84
Diarrhœa.....	79	88
Consumption of lungs.....	62	62
Rheumatism.....	61	61
Remittent fever.....	61	59
Neuralgia.....	58	57
Bronchitis.....	49	44
Dysentery.....	48	56
Cholera morbus.....	42	62
Typho-malarial fever.....	41	27
Cholera infantum.....	33	51
Tonsillitis.....	35	31
Influenza.....	28	24
Typhoid fever (Enteric).....	22	15
Diphtheria.....	22	19
Whooping-cough.....	21	26
Erysipelas.....	19	22
Pneumonia.....	18	13
Inflammation of bowels.....	16	21
Scarlet fever.....	12	11
Inflammation of brain.....	7	8
Measles.....	6	10
Cerebro-spinal meningitis.....	6	5
Puerperal fever.....	5	6
Membranous croup.....	5	3

For the month of September, 1884, the reports indicate that typho-malarial fever and typhoid fever increased, and that cholera morbus, cholera infantum, diarrhœa, and dysentery decreased in prevalence compared with August, 1884.

Compared with the average for the month of September in the six years 1879-1884, intermittent fever, typho-malarial fever, diphtheria, pneumonia, and remittent fever were less prevalent in September, 1884. There was no marked increase in the prevalence of any disease reported in the month of September, 1884, compared with the average of that month.

For the month of September, 1884, compared with the average of corresponding months for the six years 1879-1884, the temperature was higher, the absolute humidity was more, and the relative humidity and the day and the night ozone less.

Including reports by regular observers and others, diphtheria was reported in Michigan in the month of September, 1884, at 25 places, namely: Armada, Bloomfield, Detroit, Douglas, East Saginaw, Edmore, Fowlerville, Flint, Grand Rapids, Hastings, Handy, Ionia, Ishpeming, Ithaca, Kalamazoo, Marquette, Medon, Muskegon, Port Huron, Prairie

Ronde, Romeo, Sand Lake, South Haven, Vassar, Wyandotte. Scarlet fever at 27 places: Cadillac, Detroit, Dorr, Dowagiac, Fairfield, Grand Rapids, Howard City, Ionia, Jerome, Kalamazoo, Monroe, Muir, Muskegon, Swartz Creek, St. John, Vicksburg, Wexford. Measles at Detroit and Whitehall.

HENRY B. BAKER,
Secretary.

LANSING, Oct. 2, 1884.

DOMESTIC CORRESPONDENCE.

OVARIOTOMY.

TO THE EDITOR:

Dear Sir.—In your issue of Sept. 20th I am reported (p. 321) as saying: "Since the 1st of October last I have performed five cases of ovariectomy—one at the University of Ann Arbor in the presence of the class; one in a cottage by the roadside; and three other cases. And my five patients have recovered."

A professional brother who was cognizant of and to some extent interested in some of these cases has kindly pointed out to me that one of them was done on Sept. 25 instead of October 1, and that a case which terminated fatally was done in the early part of October. The remarks made by me in the Obstetrical Section of the American Medical Association were entirely extemporaneous, and it seems that I must have inadvertently transposed these two cases, which had been operated upon within a few days of each other. By going back five days further in my experience, and saying *since Sept. 25* I have performed *six* ovariectomies, one before the class at Ann Arbor and *five* in "cottages by the wayside," and of that number five recovered and one died, I would have been *perfectly correct*. I might have added that the one fatal case, in point of surroundings, nurses, etc., was the most favorably situated of all. (It was, however, a case in which the tumor was largely composed of solid sarcomatous structure, had many adhesions, together with a bad general condition of the patient mentally as well as physically).

As my remarks reported in your issue referred to were rather of a controversial nature, I have thought it necessary to make this full and candid statement in order that even the appearance of inaccuracy might be avoided.

Having the fullest confidence in the justness of the point which I aimed to make, and having the highest respect for the audience I had the honor of addressing, nothing could have been further from my intention than to weaken my argument and insult my hearers by the presentation of statements or figures not absolutely in accordance with the truth.

I am, dear sir, truly yours,
DONALD MACLEAN,
72 Lafayette Avenue, Detroit.

Oct. 9, 1884.

BOOK REVIEWS.

SEXUAL NEURASTHENIA, (nervous exhaustion) its Hygiene, Causes, Symptoms and Treatment, with a Chapter on Diet for the Nervous. By GEO. M. BEARD, A.M., M.D., late Lecturer University of City of New York, etc., etc. (Posthumous manuscript). New York: E. B. Treat & Co. Pp. 269. Price, \$2.

These posthumous papers have been edited by A. D. Rockwell, M.D., an intimate associate and co-worker with Dr. Beard.

Under the term *neurasthenia*, the latter was one of the first among medical writers to describe the various phases of nervous exhaustion now so well recognized as forms of the same disease, and to mark out more simple paths of treatment.

The tonic use of electricity was first clearly set forth by these writers.

Very properly much space in the present work has been given to the subject of sexual hygiene. The relation of sexual neurasthenia to other diseases also receives careful consideration.

In our opinion, the opening chapter on the varieties of general neurasthenia is one of the most satisfactory in the book.

Concerning the chapter on Treatment, this cannot be said, although here, as in all parts, the book is far superior to Dr. Hammond's.

Beyond the mental effect produced, there is grave question of the therapeutic value of local treatment—soluble bougies, sounds and powders, rectal treatment, cauterizing and soothing injections, localized electrization, etc., etc. General medication is carefully discussed, and its indications most intelligently set forth. There is throughout the book a certain carefulness and fairness of statement which lend a real interest to the author's style.

E. W. A.

THE RELATION OF ANIMAL DISEASES TO THE PUBLIC HEALTH, AND THEIR PREVENTION. By FRANK S. BILLINGS, D.V.S., Grad. Vet. Inst. Berlin, etc., etc. N. Y.: D. Appleton & Co. 1884. Pp. 446.

This is a timely work, inasmuch as public attention has of late been arrested by the recent outbreaks of hog cholera and of pleuro-pneumonia in our own States, and by the wonderful discovery of protection by vaccination against anthrax and even hydrophobia by Pasteur.

The work treats of the *Prevention of Diseases* but not of their *Treatment*, which of course makes it valuable to the medical and general public rather than to veterinarians proper.

It is in fact a work which ordinarily intelligent people of all classes of tastes will find instructive, because it opens out topics to which most of them are sadly inattentive.

The great majority of educated men are now quite well informed in such sanitary matters as pertain to house drainage, correct plumbing, ventilation, and the like, because a vast amount of useful literature has been disseminated on these topics.

But as to the true nature and prevalence of the infectious and parasitic diseases communicated by domestic animals to men, the same class of persons know little and care less, never having been brought to realize their increasing prevalence.

The author deems it proper to use some decided and severe language in characterizing the efforts or want of efforts of sanitarians in America to meet the threatened dangers of glanders and other contagious diseases.

He does so in the belief that the evils so severely combated are not "straw men," imaginary creations, but "actual evils that, unless prevented, will work most serious injury to the country in the not distant future.

The work is divided into three parts viz.: Part I, *Diseases of Domestic Animals*. Part II, *History of Veterinary Medicine*. Part III, *The Means of Prevention*.

The last part contains the following chapters:

"A National Veterinary Police System;" "The Foundation of Veterinary Schools in the United States;" "State Veterinary Schools;" "A National Veterinary Institute."

One of the most interesting chapters is that on Trichiniasis, in which it is conclusively shown that American hogs are more affected than European.

The author's analysis of the conflicting mass of evidence on this question is judicious and impartial, and he is able to sift out much error and misrepresentation on the part of those whose judgment has been swayed by self-interest in forming their conclusions.

Very explicit directions are given in the mode of discovering the trichinæ by the microscope, and the objects likely to be mistaken for them are pointed out.

Hog cholera, anthrax, Texas fever, glanders (in the horse and in man), etc., receive also most careful and critical attention.

That this work will spread much useful information and be of public benefit is certain.

MISCELLANEOUS.

PROGRAMME OF THE NINTH ANNUAL MEETING OF THE AMERICAN ACADEMY OF MEDICINE.

The sessions will be held in Hopkins Hall, Johns Hopkins University, Baltimore, Maryland, Tuesday and Wednesday, October 28 and 29, 1884. Benj. Lee, M.D., Philadelphia, President; R. J. Dunglison, M.D., Philadelphia, Secretary; Chas. McIntyre, Jr., M.D., Easton, Pa., Assistant Secretary.

TUESDAY, OCTOBER 28, 3 P. M.

Opening of session with prayer; reading of minutes of last annual meeting; report of Council; election of Fellows; appointment of committee on nominations; reading of papers: "The Relation of the Medical Colleges to Preliminary Education. By Peter D. Keyser, A.M., M.D., of Philadelphia, Pa.;" "The Examination of Applicants for License to Practice, a Means of Raising the Standard of Medical Education." By Edward Jackson, A.M., M.D., of Phila-

delphia, Pa.; "The Role of Bacteria in Infectious Diseases." By Henry O. Marcy, A.M., M.D., of Boston, Mass.; "The Trade Aspect of Medicine." By Albert H. Gihon, A.M., M.D., Medical Director U. S. Navy; "The Induction Coil; Its Varieties and the Differential Indications for their Use." By A. D. Rockwell, A.M., M.D., of New York, N. Y. Report of Treasurer; unfinished business; new business.

AT EIGHT O'CLOCK, P. M.

Address by Benjamin Lee, A.M., M.D., of Philadelphia, Pa., President, on "Differentiation the Test of Civilization: The Specialist and his Education."

WEDNESDAY, OCTOBER 29, 10 A. M.

New business; report of Committee on Nominations; reading of papers: "The Teaching Derived from Observations in 137 Abdominal Sections." By R. Stansbury Sutton, A.M., M.D., LL.D., of Pittsburgh, Pa.; "Some Comparative Results of Treatment of Chronic Articular Osteitis of the Hip." By Virgil P. Gibney, A.M., M.D., of New York, N. Y. "The Place of the Physician in Literature." By Charles C. Bombaugh, A.M., M.D., of Baltimore, Md.; "The Aim in Treatment of Angular Curvature of the Spine." By T. M. Ludlow Chrystie, A.M., M.D., of New York, N. Y.; "Physiology in Its More Public Relations" (Public health, physical culture, family institution, true civilization). By Nathan Allen, A.M., M.D., of Lowell, Mass.; "Statistics of Glaucoma." By Herman Knapp, A.M., M.D., New York, N. Y.; "Specialties and Their Relation to the Medical Profession." By L. Duncan Bulkley, A.M., M.D., of New York, N. Y.; "Report on Laws Regulating the Practice of Medicine in the United States and Canada." By Richard J. Dunglison, A.M., M.D., of Philadelphia, Pa., and H. O. Marcy, A.M., M.D., of Boston, Mass. New business; Induction of President-elect; appointment of additional Members of Council; unfinished business; adjournment.

The Annual Collation will take place at the Athenæum Club, corner of Charles and Franklin streets, Baltimore, on Tuesday evening, October 28, at half-past nine o'clock, immediately after the President's Address. Fellows desiring to participate will please forward two dollars to Dr. C. C. Bombaugh, P. O. box 498, Baltimore, Maryland.

Dr. J. S. Billings, Surgeon U. S. Army, and a Fellow of the Academy, has kindly offered to show the new Johns Hopkins Hospital, on the afternoon of Wednesday, October 29, to those Fellows of the Academy who may desire to see it.

OFFICIAL NOTICE.

ANNUAL DUES from members of the Association—*Five Dollars* per annum—are payable directly to the Treasurer. Such payment entitles them to receive the JOURNAL of the Association for one year.

SUBSCRIPTIONS TO THE JOURNAL from those who are not members should be forwarded to the office of publication, Chicago.

BACK VOLUMES OF THE TRANSACTIONS may be procured, at reduced rates, by addressing the Treasurer.

THE INDEX to the 33 Volumes of Transactions will

be forwarded, postpaid, on receipt of *One Dollar* by the Treasurer.

According to a resolution passed May 9, 1884, at the Washington meeting, continuous payment of Annual Dues is required, to retain permanent membership.

RICHARD J. DUNGLISON, M.D.,
Treasurer.

Lock Box 1274, Philadelphia, Pa.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM OCTOBER 11, 1884, TO OCTOBER 17, 1884.

Norris, Basil, Lieut.-Colonel and Surgeon, relieved from duty as attending surgeon, Washington, D. C., and ordered for duty as Medical Director Div. of the Pacific and Dept. of Cal., relieving Surgeon E. I. Baily. Col. Baily, on being relieved, will assume the duties of attending surgeon at San Francisco, Cal.

Spencer, Wm. C. Major and Surgeon, from Dept. of Dakota to Dept. of the East.

Goddard, Chas. E., Major and Surgeon, to be relieved from duty at Jefferson Bks., Mo., and to report for duty in department of Dakota.

McClellan, Ely, Major and Surgeon, from department of the East to duty at cavalry depot, Jefferson Bks., Mo. (S. O. 242, A. G. O., Oct. 15, 1884.)

McKee, Jas. C., Major and Surgeon, granted leave of absence for one month with permission to apply at division headquarters for one month's extension. (Par. 1, S. O. 149, Dept. Col., Oct. 3, 1884.)

Loring, Leonard Y., Captain and Assistant-Surgeon, from Dept. of the East to Dept. Cal.

Harvey, Philip F., Captain and Assistant-Surgeon, from Dept. of Dakota to duty in Attending Surgeon's office, Washington, D. C., relieving Robert W. Shufeldt, Captain and Assistant-Surgeon, who, on being relieved, will report to commanding general Dept. Mo. for duty. (S. O. 237, A. G. O., Oct. 9, 1884.)

Porter, J. Y., Captain and Assistant-Surgeon, granted leave of absence for one month, on surgeon's certificate of disability, with permission to leave the limits of the department. (Par. 3, S. O. 138, Hdqrs. Dept. Texas, Oct. 9, 1884, confirms telegraphic order of same date.)

OFFICIAL LIST OF CHANGES IN MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING OCTOBER 18, 1884.

Brush, Geo. R., Surgeon, to temporary duty at the Naval Laboratory, Oct. 11, 1884.

Burbank, Chas. H., Medical Inspector, detached from the Brooklyn and placed on waiting orders, Oct. 15, 1884.

Clark, John H., Surgeon, detached from the Lackawanna and detailed as fleet surgeon of the Pacific Station, Oct. 17, 1884.

Cooke, George C., Surgeon, to the Lackawanna, Oct. 17, 1884.

THE RELATION OF MICRO-ORGANISMS TO SURGICAL LESIONS.

BY HENRY O. MARCY, A.M., M.D., OF BOSTON.

Read to the Section of Surgery and Anatomy of the American Medical Association, May, 1884.

The positive demonstration of the important factor of bacterial growths in surgical lesions would seem no longer wanting. The recognition of this in the evolution of the systems of modern wound treatment is apparent.

The ill effects of the retention in wounds and cavities of the secretions contaminated with putrefactive bacteria have long been recognized, yet, it has remained for modern investigators to demonstrate that this ill effect is owing to germ development. It would have appeared easy of inference, that this was due in some way to atmospheric, and since the knowledge of the causes of fermentation, to a particulate organic infection, since very severe lesions, attended with abundant exudation, commonly recover without supuration, when the skin covering the wound is unbroken. When these exudations undergo fermentation from the growth therein of micro-organisms, there is generally developed an entirely new and different class of symptoms, both local and constitutional.

I am ready to admit that many questions of great magnitude remain unsettled, that many subjects connected therewith are shrouded in doubt and obscurity, and that many fields of great promise remain yet for exploration. While this may temper our zeal and cause us to examine with double caution our premises and conclusions, it can not the less stimulate every thoughtful student to better endeavor and renewed effort.

Dr. Pilcher, in his recent excellent work upon "The Treatment of Wounds," defines aseptic wounds to "include all which are preserved from contamination by poisonous materials, whether such poison be applied directly to it, or be generated in it by the action of germs that gain access to it and find within it the conditions favorable for their growth. An aseptic condition in a wound may be obtained, either by the protection which the wound receives from the first against the access of any septic agent, or by the

power of living tissues to resist and destroy septic agents, or by the application to the wound of substances which destroy them. Examples of the first class are presented in subcutaneous wounds, and in operative wounds which are inflicted with certain precautions; examples of the second class are seen in all open wounds in which union by first intention is secured, notwithstanding at the time of their infliction they were freely exposed to ordinary air; examples of the third class are presented by wounds in which the application of antiseptic substances has been successful in arresting the action of whatever septic agents may have previously gained access to them. Asepsis in a wound is of the highest importance. As long as it is maintained, no decomposition of the secretions of the wound takes place, no sloughing of killed or partly killed tissue occurs. When the proper cares to favor the nutrition of the wounded tissue are rendered, the healing of the wound progresses without pain, inflammation, or suppuration, and the least possible amount of cicatricial tissue is produced. To secure an aseptic condition in a wound, or to approach it as nearly as possible, is the first and most important indication in wound treatment."

I have myself elsewhere given the definition somewhat epigrammatically, as a wound surgically clean, and this for our present purpose would serve for the distinction between aseptic and septic wounds. Although seemingly lost sight of in many of the heated discussions upon this subject, the great fundamental factor of repair, the *individual vital force*, under conditions favorable, or otherwise, must ever hold the first place.

This, however thoughtfully considered, can never be fully resolved and in individual instances expressed in known terms, but remains somewhat as an X factor in the equation of life's processes, like the estimate of a business man's fortune, subject to modifying influences, both inherent and extraneous, and never to be fully inventoried, until the estate is finally settled. These varying factors may be catalogued, as race, age, idiosyncrasies, mental state, constitutional condition, disease, hygienic surroundings, etc.

Bioplastic or living matter possesses in itself, in greater or less degree, the power of resisting extraneous influences. This power to maintain the equilibrium of the active, functioning state of the organism, although possessed in a greater degree in the higher and more complex forms of development, is ever subject to the influence of its surroundings.

These must be the more important to the individual having suffered devitalization from injuries. Hence, the thought long bestowed upon the sanitation of the wounded, pure air, sunlight, careful cleanliness of person, clothing, room, etc. In a general way all these may be considered antiseptic conditions of the best character, yet pure air does not destroy the particles of infection, it only dilutes them. The sunshine and fresh air add to the bioplastic power of the tissues and give increase of individualistic function to resist the influence of deleterious agencies.

Time fails to pass even in rapid review the painstaking labors and researches for the ultimate causes of the changes which result in the disorders of repair. Most of us remember the long and seemingly fruitless discussion upon the question of spontaneous generation. The result of all this has been the final demonstration to the acceptance of the scientific world of the particulate theory of fermentation. We are especially indebted to the researches of Pasteur, Tyndall and Lister, for the setting at rest this vexed question, and to the latter, for the application of the deduction, that from such causes there resulted dangers to wounds and often to life.

The best methods by which to limit, lessen and control, if not to destroy the causes of these dangers was the self-imposed task of the enthusiastic innovator who, true to the divinity of his inspiration, has labored all these years with a singleness of purpose rarely surpassed.

The very meaning of the Greek word *septikos* signifies, that which *causes* putrefaction, and per consequent, antiseptic can have but the one meaning, that which is directed against the *causes*, not the effects of putrefaction. If it be true, that putrefaction cannot take place without fermentation, and fermentation is almost without exception caused by the growth of the lowest orders of the spore-producing plants, it would seem simple to formulate, that to the rôle of these micro-organisms should be ascribed the putrefactive changes and their deleterious consequences, incident to open wounds. Thus these organisms, so minute as to have escaped, in the main, the notice of most observers in the early days of microscopic training and study, or as at the most incidental and unimportant, have recently acquired an interest of primary character not alone to the surgeon and physician, but also in no less degree to the sanitarian.

The best illustration of an aseptic wound is one where nature herself has given it the safest protection from deleterious external causes, by keeping it still covered by the unbroken integuments. A subcutaneous injury has from time immemorial been recognized, even by superficial observers, as one of distinctive differences of danger and course of repair, from one where the injury is simply augmented by the laceration of the skin. None have contended that it was the simple factorage of broken integument that rendered the difference, but the causes have been more commonly sought in the various modifications induced by atmospheric exposure and consequent chemical changes.

Defects of bioplastic power, both constitutional

and local, result in disorders of repair; defects of apposition prolong the process and make extra demands for reparative material; but in defects of *protection* are found conditions which produce arrest of reproduction and destruction of the adjacent tissues. It is clearly established that the disturbing elements arising from atmospheric contact come only from the organic, living particles which it holds in suspension (germs), and these spores under favorable conditions rapidly germinate. These minute organisms are seemingly omnipresent. They develop in the secretions which issue from the animal economy, infest the skin, literally devouring its waste, a hundred feasting upon a single epithelial scale, and they reproduce in myriads in the alimentary canal. Notwithstanding all this, these organisms are never found in the tissues of the healthy living body, and to a certain extent, these tissues are endowed with the power to resist their action and even to produce their destruction when brought in contact. It must be ascribed to this power in living matter, that the germs which have gained access to the tissues through a wound often do not develop, when speedy and complete approximation of the parts has been effected.

This has long been recognized as primary union in wounds, and has often been held in illustration that antiseptic methods were, in at least certain conditions, unnecessary, and that these minute beings, after all, could not be capable of such dire disaster as has been claimed to result from their development. Given a wound where approximation fails, and a fluid exudation fills a hidden recess, and here we find most favorable conditions for germination after such atmospheric infection, and a long train of deleterious results, frequently ending in death, ensues.

The form of germs which produce fermentation may be classified under three general types—the micrococcus, the bacillus, and the yeast cell. Varieties known as bacteria of different forms may be referred to one or another of these types. The yeast plant only develops in the fermentation of saccharine materials, and plays no part in surgical affections. Bacilli and micrococci require albuminoid compounds for their development. Both forms are usually found in open wounds. When the micrococci only are present, we have decomposition without odor, but the development of bacilli is always accompanied with odor more or less fetid. According to Ogston, the occurrence of a putrid odor is absolutely sure to indicate the presence of some of the varieties of the rod-bacteria. According to Cheyne, the more putrid the discharge the more numerous and smaller are the bacilli. These organisms have less inherent vitality than micrococci. They limit their invasion to material already devitalized, and are never found in the living tissue. These bacilli are comparatively easily exterminated from a wound, by the removal of the decomposing material necessary for their consumption. They are also quite readily acted upon by the various germicides and destroyed.

The spherical organisms, micrococci, on the contrary, are much more difficult of extermination. They reproduce in chains and masses, and in the latter form are found frequently colonizing in different parts of

the body; thus they not infrequently obstruct and dilate a capillary vessel, and cause widely disseminated abscesses, as in pyæmia. They vary greatly in number. Ogston estimated that in one specimen of pus one cubic millimetre contained 45,000,000, while two other specimens of the same bulk contained less than 1,000.

They are cultivated without the production of any especial odor, and generally their presence in a wound is not indicated by any change perceptible to the olfactory sense, except perhaps a slightly sour smell. There can be little doubt that there are varieties of micrococci identical in appearance, as exhibited by any means yet devised, but which nevertheless possess extremely different capabilities and characteristics. Some are comparatively harmless, others in the highest degree virulent.

Sternberg states: "Some are pathogenic, others are not; some develop in the blood of certain animals, others will not. Different species multiply in different media, and are destroyed at different temperatures. A nutrient medium which has been exhausted for one micrococcus may not be exhausted for another."

Cheyne describes and figures micrococci developing in wounds in large numbers without causing any serious injury. These varieties, when injected into the bodies of animals, produce entirely different results. Some develop and cause local abscesses, or a rapid and fatal blood-poisoning, while other specimens scarcely produce even any local suppuration. The inflammation and subsequent blood changes are usually far more active in the pus from open wounds than from acute abscesses.

According to Ogston the grouping of the micrococci seems to modify the result, and the chain form rarely if ever passes into that called zoöglea or masses. In the erysipelatus type, affecting the lymphatics, the chain form predominates, while in suppurative inflammation in the tissues the forms are grouped.

Fehleisen, of Berlin, published last year the result of his studies upon erysipelas and demonstrated the active factorage of the form of micrococci developing in chains in erysipelas. He not only examined them during life, but he cultivated them and with equal success inoculated the cultures, producing the disease in its typical forms in man and animals. I have cultivated the micrococcus of erysipelas from several sources. It reproduces in marvellous numbers with extreme rapidity. My inoculation experiments failed, but they have been too limited to be of any practical value.

The researches of Koch, Pasteur, Ogston, Cheyne, Sternberg, Klebs, and others scarcely less known, can only be referred to, but all more or less clearly point to the demonstration that there are different varieties of micrococci, not distinguishable in form, possessing widely different characteristics. The origin of the micro-organisms found in certain locations presents a problem of very difficult solution.

A few months since, a woman in excellent general health felt something, as she expressed it, "give away in the bowels." Peritonitis rapidly developed and death supervened in forty hours. The autopsy

showed an ovarian cyst, not larger than an egg, partially empty. There were several pints of a slightly opalescent, flocculent serum in the abdominal cavity. The fluid was swarming with a large bacillus which multiplied with extraordinary rapidity in culture tubes. This bacillus was also found in the contents of the cyst. The cyst was evidently an old one, with a wall thick and friable.

Only a few weeks since, an ovariectomy furnished this interesting history: I removed a compound cyst with multiple adhesions. The cysts were thin-walled and several were broken in the removal. The cleansing of the peritonæum was made with care by sponges moistened with 1-1000 bichloride of mercury. Examination of the urine previous to operation gave no evidence of renal disease. Albumen with casts appeared in the urine at the close of the second day. Suppression of urine followed and death ensued between the third and fourth days. At autopsy there was no evidence of peritonitis, only a very little reddish serum in retro-uterine pouch, which contained active micrococci. The kidney was in a state of acute parenchymatous nephritis and the capillaries were filled with masses of micrococci. The tumor had been preserved in a 1-1000 solution of bichloride of mercury and in a number of the unopened smaller cysts were numerous micrococci.

The inferential evidence that the patient's death was due to infection from this source appears very strong.

Dr. Drysdale, of Philadelphia, who has very probably studied the morphological conditions of ovarian fluid more carefully than any other, writes me, "he has no recollection of finding micro-organisms in ovarian fluid uncontaminated by atmospheric exposure." It is equally difficult to explain the origin of the micrococcus of pus uniformly found in acute abscesses where the integuments covering them are still unbroken. The evidence is demonstrative that the blood of healthy animals does not contain micro-organisms. In a series of abscesses, eighty-two in number, examined by Ogston with due care, no organisms were found in thirteen purely chronic. In four subacute and sixty-five acute abscesses micro-organisms were found. They were in chains, zoöglea masses, and in groups of three or four.

I have more ordinarily found them in short chains, twos or fours, or groups of three or four, rather than in zoöglea masses. It is not known if the forms presented are of significance, very probably only showing the forms of growth by subdivision.

Although much remains to be studied and settled beyond dispute, the proof, that micrococci are the essential cause of suppuration, is rendered very strong by the results of inoculation, by which it has been shown that pus devoid of micro-organisms, for example, that subjected to heat or an efficient germicide, or the pus from a chronic abscess, is innocuous when injected into the tissue of animals, while pus containing micrococci, even in minute doses of a minim or more, invariably occasions well-marked disease. Interesting as is the subject we must not pursue this line of inquiry farther, simply stating that experimental proof

is constantly accumulating to show that the inflammatory and other changes which ensue in wounds, producing often the most serious and dangerous consequences, are with few exceptions the result of the vital activity of new organisms.

The result of the observations and experiments of Ogston has led him to conclude that septicæmia, pyæmia, and septic pyæmia are one and the same disease, and that their sole and invariable cause is micrococcal poisoning.

Belfield, in his interesting lectures given last year in New York city, sums up the question as follows: "A review of the evidence already considered shows, then, that infectious diseases, identical in clinical and anatomical appearances with the various forms denominated septicæmia in man, have been induced in the mouse and rabbit by inoculation with animal tissues in various stages of putrefaction; that the resulting infection is just as certain if the putrid substances be previously boiled and thereby deprived of living organisms. On the other hand, it is certain that *per se* innocuous culture fluids, infusions of beef, etc., acquire after inoculation with minute quantities of infected blood or tissue, the same septic properties, provided such blood or tissue contain living bacteria; it is further certain that this multiplication of the septic substance in such liquid is a concomitant of the vital action of the organisms therein contained; it is further demonstrated that these organisms can and do not alone multiply in the septic material, but, when isolated by successive cultures from all the accompanying animal tissues, induce independently fatal infectious diseases. The same principle, vital activity of bacteria, pervades all these phenomena; for the artificial induction of septic diseases has been, in all these experiments, originally accomplished by the incorporation into the animal of putrid tissues, with or without bacteria. Now, since putrefaction must be regarded, in the present state of our knowledge, as impossible without the presence of these organisms, it is evident that sepsis, putrid infection, was in every case due, directly or indirectly, to the action of bacteria; since even the boiled substances used by Panum and Rosenberger, and the sepsin obtained from rotten yeast by Bergmann and Schneideberg, had acquired their septic properties through putrefaction; *i. e.*, through the action of bacteria. Hence we are logically driven by all this work, to the belief that septicæmia implies the introduction into the animal, either of living bacteria, or of a substance which has acquired noxious properties through previous vital activity of these organisms."

The most valuable of recent contributions upon the relation of micrococci to wounds, abscesses, and septic processes, is the report to the Scientific Grants Committee by W. Watson Cheyne and published in the *British Medical Journal* during September and October, 1884. I should do the subject injustice without giving briefly his conclusions:

1. "There are various kinds of micrococci found in wounds treated aseptically, differing markedly from each other in their effects on animals. They agree in growing best at the temperature of the body, and

in causing acidity and sweaty smell in the fluids in which they grow. The experiments show that cultivations may be carried on in fluids with accuracy, provided the precautions mentioned be observed.

2. The micrococci tested in these experiments grew best in materials exposed to oxygen gas. They grew only with difficulty in the absence of oxygen. Eggs were not good pabulum.

3. Their effect on animals was not altered by growth with or without oxygen.

4. The effects of these micrococci on rabbits and man were not similar, some of the most virulent forms for rabbits causing no deleterious effect in wounds in man.

5. The kidney is apparently an important excreting organ for organisms.

6. Organisms not capable of growing in the blood may yet cause serious effects by growing in the excretory canals. This may explain some cases of pyelitis.

7. Where an organism is not markedly pathogenic, it may be necessary to introduce a large quantity before morbid changes are set up.

8. Suppuration is not always due to micrococci, it may be caused by chemical irritants, such as croton oil.

9. Micrococci are always present in acute abscesses, and are probably the cause of them.

10. In some cases, the micrococci are the primary cause of inflammation and suppuration, as in pyæmic abscesses; generally, however, they begin to act after inflammation has been previously induced.

11. This inflammation may be caused by an injury, by the absorption of chemically irritating substances from wounds, by cold, etc.

12. There are several different kinds of micrococci associated with suppuration.

13. Micrococci cause suppuration by the production of a chemically irritating substance which, if applied to the tissues in a concentrated form, causes necrosis of the tissue, but if more dilute, causes inflammation and suppuration.

14. The conditions in wounds and abscesses are not the same, inasmuch as in the former there is opportunity for mechanical and chemical irritants to work.

15. There is no reason for denying the existence of "antiseptic suppuration."

16. Tension may also cause suppuration, but it is perhaps most frequently aided by the growth of micrococci. These organisms need not be of a very virulent kind. It is also probable that the products of inflammation are themselves irritating and capable of exciting or keeping up inflammation.

17. The micro-organisms of septicæmia, of pyæmia, and erysipelas, are different from one another and from those of abscesses. In erysipelas, the micrococci grow in the lymphatic spaces. In pyæmia, they grow in the blood to form colonies and emboli. In septicæmia, they may only grow locally, the symptoms being due to the absorption of their ptomaines; or if they grow in the blood they do not form colonies and emboli. Septicæmia may also be due to other organisms besides micrococci.

18. There are no facts to support the view that it is the same micrococcus which, under different conditions, causes these various diseases.

The experiments of conversion of innocent into malignant forms, and *vice versa*, are unreliable.

In a previous contribution, "Upon the best Methods of Wound Treatment," I endeavored to show that the best methods were those based upon a broad, comprehensive knowledge of a scientific character, including such factorage as we have here under discussion, and that the too commonly held ideas of antiseptic surgery, as consisting of carbolic acid applied as spray or in dressing, were not only superficial and misleading, but distinctly incorrect and injurious. Such imperfect knowledge of any scientific truths must have its fruitage only in evil, leading to a distrust in methods, at the best only half understood, and the results obtained, where protection in wounds has not been secured, are falsely reported in proof that antiseptic surgery is only the fashion of the hour, an exploded theory which should be relegated to the long list of isms and pathies which have for so long justly placed our profession in derision.

A CASE OF HEMIPLEGIA.

RECOVERY—DEATH NEARLY FOUR YEARS LATER FROM
ANEURISM JUST ABOVE THE ARCH OF THE AORTA—
AUTOPSY REVEALS THE SITE OF THE OLD LE-
SION IN THE MIDDLE OF THE LEFT HALF
OF THE CORPUS-CALLOSUM.

BY AUGUSTUS P. CLARKE, M.D., CAMBRIDGE, MASS.

Read before the Cambridge Society for Medical Improvement.

I was called January 26, 1879, to attend J. T., (colored) aged 64 years. He had been a slave in Virginia, but escaped when quite a young man. His health had always been good; he was a laborer; he was married many years ago, but his wife had had no children by him. He could not remember of ever having been sick, but was a very hard-working man, often engaging in heavy work such as he obtained at wharfs. He was also engaged often in moving furniture. For the most part he was accustomed to walk two and three miles to and from his work instead of riding, and this practice he continued daily.

When first called (January 26, 1879), I learned that the patient that morning arose early and had been to a baker's shop about a mile from his house. On his return he went into his basement for coal, and there was heard to fall upon the floor. His wife quickly descended, and there found him in a "fit," snoring and breathing heavily, and he was unconscious. I was immediately summoned, and I reached his house before 10 A. M. Patient was in bed, still unconscious, and the right pupil very much contracted (small), while the left one was largely dilated. The muscles of the face, throat and neck of the right side were

affected. Deglutition was somewhat difficult, that is, in attempting to swallow water or other liquids. There was preternatural heat about the head. There was some irregularity—or some tumultuous action in the upper part of the chest in front, though no distinct murmur or souffle was there observed in connection with the heart's sounds. Pulse full and somewhat increased in frequency, and both at the wrists were alike. Temperature did not vary much from normal. The patient had vomited after he was first taken, although for the most part insensible. The patient remained unconscious the greater part of that day, but gradually returned to consciousness. The right arm and leg, as well as the right side of the face, were hemiplegic.

The right leg and arm at first were completely useless. The patient was kept under observation until March 11 following, when he was able to go about with the aid of a cane, although the right side remained affected for quite a while. The leg, as is usual in such cases, recovered much sooner than the arm. The arm, however, the following summer greatly improved. He became anxious for something to do, so he had a small store built on his ground near his house, where he sold small articles, such as fruit, candies and some groceries. After a year or so he had so far recovered the use of his arm and leg as to be able to attend to his regular work as laborer or jobber about wharfs and stores. During the past year he had been very well, often walking in and out of Boston as heretofore, and being about all day at work, returning late in the afternoon or evening, not complaining but seeming to be in good health, except the difficulty in his chest; sometimes urgent breathing, shortness of breath, but he was able to lie in bed, but was obliged to lie upon his left side altogether. During cold weather he suffered considerably from coldness of his arm, and occasionally there was numbness of his right leg. These symptoms never prevented him from attending to his regular duties connected with his occupation. Friday, October 6, 1882, he had been engaged in removing heavy goods, such as large boxes and a stove, from an apothecary's store; he had lifted many boxes and other heavy weights into an express wagon. He then ate his dinner, which he carried with him. Soon after, as he began to work again, he was noticed to fall and become unconscious. A bucket of cold water was dashed upon his head and face; he then vomited what was in his stomach. He was immediately convulsed. Some stimulant was given him, which he swallowed or was poured into him, but the amount given I learned was not large. I might here say that the patient was always a temperate man, and was averse to stimulants of all sorts. He was immediately brought home to Cambridge, where I saw him early in the afternoon. He was in great measure unconscious; was lying on his back in bed. His respiration was somewhat labored, but not distinctly stertorous. Pulse at the wrists (both) quite regular and full, but seemingly slightly compressible, or more so than normal, partaking of a vibratory or undulating character, but this feature was not a marked one. There was no real thrill nor hardness; nor was the pulse

intermittent, but were alike. Both pupils were small, the right one a little larger than the left; but as the arcus in each eye was so marked, the shade of face obstructing, and the eyelids inclined to be closed, it was not easy to observe their true condition, for in attempting this he was disturbed, then the pupils grew larger and varied. He was sensible to the touch or pinch upon the skin; he would move either arm or leg when pinched or pricked. He could not at first swallow, or only very imperfectly. The left side of his mouth and face was affected, and he inclined his head to the left. He was said to have borne some weight upon both legs when taken out of the carriage when brought home, while being brought into his house.

He frequently put his right hand to his head as if in pain, but did not move his left one. That evening he was able to swallow a little, but not much afterwards. Next morning the left side showed signs of paralysis, he did not move the left arm or leg, and at length he did not respond to the prick or pinch made on that side while sensible to that test when made on the right side. The patient soon became more comatose, his respiration stertorous, more rapid or frequent (44 per minute) and labored, and marked dullness on percussion extending over the greater part of the chest anteriorly, attended with subcrepitant râles during the inspiratory movement, resembling pneumonia in its earlier stages. Micturition occurred at regular intervals and good action of the bowels was obtained by the administration of a few drops of croton oil upon the tongue; temperature varied little from normal. The pulse at last became irregular and the patient died seventy hours after the attack commenced. Autopsy of body 24 hours after death. Present, Drs. Clarke and Holt. Found more blood than usual in vessels of scalp; considerable dark blood flowed from inside of the skull on removal of calvaria; the dura mater was more adherent than normal, but this membrane presented no unusual appearance. There was a little appearance of watery effusion of the pia-mater, or along the line of the vessels and it was there a little opaque, but otherwise this membrane was clear and transparent. The vessels at base of the brain were empty; they were somewhat atheromatous in spots. No unusual amount of fluid in the ventricles. The cerebrum was a little softer on the right side; the vessels contained not so much blood. There was a brownish-yellow spot—darker in the centre, in the middle of the left corpus callosum. This was about one-half inch in diameter. It was much harder than other parts of the corpus callosum. This spot must have been the site of the old hæmorrhage or clot which occurred January 26, 1879. The other great ganglia were normal in appearance. On opening the cavity of the chest a large bunch was discovered immediately behind the sternum. This was so soft that it was torn open on removal. This proved to be the arch of the aorta largely dilated, to the inside of which was attached a large clot, rounded, firm, and about one and one-half inches in diameter. This was split in two parts but the parts were hanging together. There was a recently formed clot extending to the vessels of the

neck. Both sides of the heart contained fluid blood, and a large amount of blood flowed from the cut ends of the vessels. This organ was in every way healthy. The lungs were of a dark bluish-black color, except in front, where they were paler. Both were slightly adherent to the pleura at the top. Section showed these organs engorged with blood and very oedematous. There was a large cyst on the left kidney. The cut surface of the kidneys showed a slight granular appearance, otherwise normal. All of the other organs not described were normal. In recounting the symptoms and history of this case several important features present themselves for our consideration. First, the serious or dangerous character of the attack, which was a hemiplegia and which occurred nearly four years before his death, and from the effects of this attack it would seem that he entirely recovered were it not for the coldness and numbness of the arm and leg occasionally experienced.

On more careful inquiry into his mental condition we learned that certain peculiarities appeared that were not noticeable before; such as moroseness, a certain irritability of temper and dread of coming to want, and the like, though he made the best possible provision for his widow in case of his death. Reference to the record of the autopsy shows that the brain (middle of the left corpus callosum) had sustained a lesion from which he had not fully recovered. It is not impossible that the presence of such an aneurism may have contributed somewhat to this mental change. The next important feature in the case was the existence of so large an aneurism which gave him so little inconvenience, not materially interfering with his daily avocation until the day of the fatal attack. Another interesting phase in this case was the nature of the symptoms which characterized the last attack. This attack was accompanied by hemiplegic symptoms, though the autopsy revealed no direct lesion of the brain to account for such phenomena. Undoubtedly it was in consequence of the plugging of the vessels of the neck, and more especially above the innominate (in the right carotid artery), cutting off all supply of blood and thus starving, as it were, the brain on that side. This condition would more likely result in a man of his age, where anastomosis is not so free, from the obliteration of capillaries, and also from organic changes in the small arteries and in the arterioles. Such a condition, as Reynolds has mentioned in his *System of Medicine*, is more likely to occur to those advanced in age. Another interesting element in the case was, that though the right carotid was occluded, the subclavian given off from the innominate escaped the lesion, and the only evidence at either wrist (and I examined the pulse of each) was a sort of vibratory or undulating movement and the pulse a little more compressible than the normal, but, as already stated, this was not at first very marked. The localization of the old lesion which was in the middle of the left side of the corpus callosum is worthy of consideration in this case. Most authors speaking of the parts of the motor and sensory tracts where lesions from cerebral hæmorrhage induced hemiplegia, make mention

usually of the corpus striatum, thalamus opticus, crus cerebri, pons Varolii and the medulla oblongata, and occasionally the cerebellum. The corpora striata of course being the superior ganglia of the cerebrum and the thalami optici the inferior cerebral, these ganglia form part of the floor of the central cavity of the lateral ventricles, while the under surface of the corpus callosum forms the roof of those ventricles. Thus the corpus callosum is situated much higher in the hemispheres than the other parts or the ganglia mentioned, and not only above the part where the great decussation takes place, but above where the cranial nerves emerging from the sensory-motor tract have special points of decussation.

We might remark here, that there were no indications that the facial (portio dura) and the hypoglossal (ninth pair) of nerves of the left side had suffered, as there was no paralysis either of the left side of the face or of the side of the tongue, and the autopsy revealed that there was no injury of the pons or ganglia below the decussation. Another point of physiological interest is that, though the corpus callosum may not be a ganglionic centre, yet the nerve fibres after their decussation in the pons and other ganglia of a higher level, must preserve their integrity and continuity, as they enter and become so incorporated as to characterize this peculiar body before they take a radiated course towards the cerebral surface to become invested with cortical or gray substance. An interesting point in the case was that the first paralysis could not have been due to lesion of the gray or cortical substance, as the corpus callosum is composed of nerve fibres like those of the medullary substance. A few grayish streaks and thin deposits of gray substance, consisting of cell nuclei and clear vesicles deposited among the white fibres occur, however, even in this body; but these are not what are called cerebral convulsions and psycho-motor centres. Charcot has asserted that paralysis is owing to the destruction of the gray matter of the cerebral convulsions.

Ferrier, the representative authority of a long line of French and German and other very recent physiologists, has brought to our attention somewhat after the manner of Gall and others, that certain psycho-motor centres reside alone in the gray substance of the cerebral convulsions, and it is by the destruction or lesion of any one of these parts or centres that certain special paralysis or loss of function occurs. More recent experiments of Goltz upon dogs and other animals showed that even very extensive destruction of the gray substance does not result in muscular paralysis or loss of such psycho-motor function. So the question is still far from being settled. The case reported would seem rather to favor the views of Goltz than otherwise. I can not forbear to mention still another feature of interest. It is this: although the old lesion was no doubt due to cerebral hæmorrhage, the arteries of that part had not undergone any sensible atheromatous change; indeed it was only at the base of the brain that the vessels even "were somewhat atheromatous in spots." This is in accordance with what Charcot, Dalton, Seguin and others have so recently pointed out, that cere-

bral hæmorrhage is quite as likely to occur in the young as in the old. A mere organic change in the vessels is all that is essential to produce such hæmorrhage. Finally this case, as far as it goes, proves rather the prevailing opinion regarding the decussation of nerve fibres than the doctrine taught by M. Pitres¹ that there are individual variations of the decussations of the pyramidal tract as maintained by Türk and Fleming.

A CALCAREOUS CALCULUS IN THE SUBSTANCE OF THE LIVER.

BY WILLIAM A. BYRD, M.D., QUINCY, ILLINOIS.

Read in Section of Surgery and Anatomy, American Medical Association, May, 1884.

It will not be necessary for me at this place to write of the genesis of calculi in general, but to call your attention to the fact that although frequently found in the urinary bladder, kidneys, and other portions of the body, that any concretions other than biliary calculi are so seldom found in the liver that any mention of the fact has to be sought for in works upon general pathology, and mention is then made in a vague manner, as the following from a "Manual of General Pathology" by Ernst Wagner, American Edition, p. 319: "Sometimes calcification arises in consequence of metastases. In extensive resorption of earthy salts from the bones (extended caries, numerous carcinomata of the bones, etc.), and the prevented excretion of them through the kidneys, the lime-salts, *e. g.*, are deposited in other parts of the organism; most frequently in the pyramids of the kidneys (as infarctions); more rarely in the lung tissue, in the mucous membrane of the stomach, still more rarely in that of the intestine, in the mucous membrane of the ethmoidal and sphenoidal cells, in the dura mater, liver, in the cerebral vessels. The parts affected thereby assume for the most part a pumice-stone consistency."

I will report to you a case and exhibit the specimen removed. On the 27th day of January, 1884, I was called to see Joshua A—, a laboring man aged 31, who had been sick for four months. I found him emaciated to some extent, having night sweats and rigors, a pulse of 106 of fair volume, bowels acting well and appetite excellent, skin sallow, but not discolored enough to be called jaundice. There was considerable dullness over the liver on the right side, extending to two inches below the ribs. I thought I could detect fluctuation between the ninth and tenth ribs, and having met with several abscesses in that location I passed in a narrow bistoury which gave exit to a flow of pus. I then enlarged the opening to an inch and a half in length, giving vent to nearly a pint of pus, inserted a drainage-tube, and ordered tonics.

¹See JOURNAL OF THE AMERICAN MED. ASSOCIATION, vol. iii, p. 353.

This man had been at work where the land was low and subject to malarial influences, besides was living in a basement in a low, unhealthy part of the city. He was first taken with a chill, and was treated for malarial fever by several physicians, but did not improve. He had pain, but not of a severe type, over the region of the liver all the time. The last attendant before I saw him was a fellow claiming to be an electrical physician. He informed him that he could soon relieve him of the pain in the side with electricity, and put on a disk of copper and zinc plates over site of the greatest pain, binding it pretty firmly. The hard metal pressing against the skin caused considerable irritation and pain, and it was to see what was the matter that his wife called me in as I was passing. The suppuration continuing profuse, and being desirous of showing the senior members of the class an abscess of the liver, accompanied by ten of them I called on the patient February 19, 1884. Passing a probe gently through the opening to show the class how large the cavity of the abscess was, a hard substance was struck. I called their attention to it as probably a piece of necrosed rib, as in a case of liver abscess seen by me some three years before I removed three inches of necrosed rib from it. A forceps was passed in and the substance seized and drawn to the opening. Being too large to be extracted through the opening, I exsected an inch and a half of the tenth rib and removed the calculus I here show you. It was broken in extraction, but you see that it is a good deal larger than the end of my thumb. All the fragments were not saved on account of the impossibility of gathering them out of the blood clots. As it is it weighs 115 grains.

The wound and abscess cavity were thoroughly washed out, and the washing ordered to be repeated night and morning and the tonics continued. A probe could be passed into the liver toward the median line of the body for $5\frac{1}{2}$ inches. The patient continued to improve rapidly, and the wound now does not discharge over one or two drachms of pus daily, and he has been able to row a skiff across the Mississippi river. When I first removed the mass, I wondered if it could possibly be a portion of a body of one of the vertebræ necrosed, causing ulceration and abscess of the liver; but a more careful examination proved that hypothesis untenable, as it was not bone at all, but an earthy calculus. This calculus could not have arisen in this case as described by Wagner, as the man had no necrosis of the bone, nor cancer of the bone, but had been healthy previous to the time he was first attacked with a chill. If it was the result of the drying up of an old abscess, how did it happen that an abscess so large as in its drying to produce so large a stone as this caused so little constitutional trouble? Yet such might have been the case, since I have seen some very large abscesses of the liver cause but little trouble, and for a long time elude diagnosis even in the hands of able men. It may have been caused by a thrombus in one of the arteries, causing death to the part supplied, and calcification ensued, as it often does under like circumstances elsewhere.

This case I consider unique, and finding no speci-

men of the kind in the vast Army Medical Museum at Washington, I shall present this one to it, that it may be studied by any one who may so desire.

P. S.—The subjoined letter was received since reading the above paper, and may be of interest in connection with the rest of the report:

{ SURGEON GENERAL'S OFFICE,
ARMY MEDICAL MUSEUM,
WASHINGTON, D. C., May 14th, 1884.

DR. WM. A. BYRD, No. 416 Jersey St., Quincy, Ill.:

Dear Sir:—The calcareous substance removed by you from the parenchyma of the liver of J. Abner, of your city, has been analysed and found to be a calcic phosphate calculus. The specimen has been deposited in the Pathological Section of the Army Medical Museum.

I am, sir, very respectfully your ob't serv't,
By order of the Surgeon General,
W. M. MATTHEWS,
Assistant Surgeon U. S. Army.

REMARKS ON THE TREATMENT OF SYPHILIS BY HYPODERMATIC INJECTIONS OF COR- ROSIVE SUBLIMATE.

BY JOHN V. SHOEMAKER, A.M., M.D., PHILADELPHIA.

Read in the International Medical Congress, Section on Syphilis,
August, 1884.

The hypodermatic injections of mercuric chloride for the treatment of syphilis have been received with great caution in the United States of America, notwithstanding that Dr. Lewin's book on the subject had been there translated and republished. I was one of the first to take up that treatment there, and reëncouraged by my success with it, read a paper on the subject before the meeting of the American Medical Association at St. Paul, Minn., in 1882. I analyzed there a number of cases treated in this manner by me at the Philadelphia hospital for skin diseases. I have since then practiced it freely and with even greater success than before. Syphiloderma of all descriptions were made to yield under this treatment and no disadvantages of any consequence were experienced in its course. While I have experimented with the various additions and modifications of the original Lewin's mercuric bichloride injections, I have invariably given them up in preference to the method suggested by Lewin in using a simple watery solution of corrosive sublimate. I have found, however, that the treatment could be carried very much further and larger doses readily borne, and necessary for a thorough cure, than pointed out by him. I have invariably carried daily increased injections to the point where they produced systemic effect, and have in many instances made, and found it necessary to make, injections of as much as half grain (3 centigrammes) per day. These strong injections were readily borne, providing they were sufficiently dilute, not less than half drachm (2 cubic centimetres) being employed for an injection containing half grain (3 centigrammes) of corrosive sublimate. When these daily large in-

jections were reached, the systemic effect of mercury soon became apparent as ptyalism, intestinal irritation and occasional tremor, which, however, soon subsided on ceasing with the injections, administration of potassium chlorate and occasionally the exhibition of potassium iodide, which, although acting as an adjuvant in the treatment did not serve to augment the systemic effect of the mercuric bichloride, but rather diminished its characteristic symptoms. Stimulation by milk punches, supporting treatment with ferrous iodide, were often found of great utility, but generally after twenty-four to thirty daily injections, the syphilitic symptoms had disappeared, and where the increasing dose had been persistently continued, the relapses proved a rare exception indeed. I attribute the effect of this treatment to a formation of mercuric albuminate in the cellular tissue, which, insoluble to the liquids of the organism, gradually dissolved under the peptonizing action found everywhere in the body, and thus produced a peptonized mercuric albuminate readily assimilable and eliminable in and through all parts of the body.

I am led to this inference from the fact, that otherwise toxic doses, were innocent if injected under the skin, and if it were not for local irritation I think even larger doses than I have mentioned could be borne without toxic effect. The local effect of the injections seems to bear out my views. Even large doses produce, at best, a lump which, though producing a somewhat erythematous condition of the skin, never suppurates or gives rise to deeper inflammation. I am free to say that in the thousands of injections I have so made, I have never met with an abscess or serious inflammation, though the lumps of mercuric albuminate could be detected for several days. The only precaution I observe is to use a clean gold needle, and to inject deep enough into the sub-cellular or connective tissue where there is plenty of free and convertible albuminous substance. Though the pain in these injections is always a disadvantage, if the solution is sufficiently dilute it will be lessened to a considerable degree, or augmented if more concentrated. No addition of any kind has in my hands lessened this, although I have with advantage administered $\frac{1}{4}$ of a grain ($1\frac{1}{2}$ centigrammes) of morphine sulphate into the arm hypodermatically prior to the injection of the corrosive sublimate. I regard it as necessary, to bring syphilis to an abeyance and to obviate an early relapse, to constantly increase the strength of the mercuric chloride until its constitutional symptoms, and then continuing with its use in a less vigorous manner until all symptoms have disappeared, sustaining the patient during this period with aliment, stimulants and medication. Conducted in this manner, I regard the treatment of syphilis by hypodermatic injections of corrosive sublimate, as more rapid, reliable, cleanly and less dangerous than either the internal exhibition of mercurials or iodides, or the combination of the two; or the nasty, filthy, inunction treatment, either with or without variations. In no cases have I found it necessary to use more than twenty to thirty injections, though I have frequently continued the after treatment for a month or two with decided doses of potassium iodide.

THE VALUE OF CARBOLIZED WATER FOR THE PREVENTION OF SHOCK IN LITHOLOPAXY, WITH THE RESULTS OF NINETEEN CASES.

BY EDMUND ANDREWS, M.D., LL.D.,

PROFESSOR OF CLINICAL SURGERY IN CHICAGO MEDICAL COLLEGE.

Presented to the Section of Surgery and Anatomy of American Medical Association, May, 1884.

The power of carbolic acid to benumb the sensibility of the nerves, when applied locally, is well known. For several years I have acted on this hint in the new operation of litholopaxy, with the view of blunting the impressibility of the urethral and vesical nerves, so as to make them tolerate the prolonged use of instruments without shock. For this purpose I provide a large supply of warm carbolized water, of the strength of from $1\frac{1}{2}$ to 2 per cent., and use this exclusively, both to distend the bladder during the crushing of the stone and to wash out the fragments. The result is so gratifying that I cannot but attach great value to this method. I have tried it in nineteen cases, with only one death. The patients averaged nearly 60 years of age, and most of the stones were large. One patient of the age of 69 years, with a stone weighing over $2\frac{1}{2}$ ounces, was under the operation for about an hour and a half. There was not even a chill following this severe procedure, and he recovered without a single dangerous symptom.

One stone in a young man was of oxalate of lime and over an inch in diameter, and so hard that the first fracture required nearly the entire strength of my hands. He recovered without difficulty, and walked about town in eight days. Other cases were equally striking.

The acid seems to act favorably by blunting the nervous susceptibility to shock, and also by leaving the bladder in a thoroughly antiseptic condition, highly favorable for preventing inflammatory action.

PAINLESS INCISIONS BY INSTRUMENTS ADVANCING WITH A SLOW, IMPERCEPTIBLE MOTION.

BY EDMUND ANDREWS, M.D., LL. D.,

PROFESSOR OF CLINICAL SURGERY IN CHICAGO MEDICAL COLLEGE.

At a former meeting I called the attention of the Association to the painlessness of incisions and injuries when made by circular saws, bullets and other objects moving at a rate exceeding 200 feet in a second. I also detailed some experiments with a revolving knife made to move by a powerful spring at a similar velocity.

A careful study of certain classes of surgical injuries, seems to show that pain exists only when the traumatic agent moves at a certain intermediate range of velocity, and that wounds made by objects moving on the one hand at a very high speed, or, on the other hand, at a very slow, imperceptible rate of motion, are nearly painless—often entirely so.

Practical application of this law has long been made in surgery, where a fine rubber thread is made slowly and painlessly to cut through the sphincter in cases of *fistula in ano*, or to divide the pedicle of a tumor.

I have lately commenced experiments with an instrument having an exactly measured and very slow rate of motion.

The apparatus is a thin sharp knife made to advance with a spring, whose velocity is held in check and regulated by an attached watch movement. When applied to the surface with bandages, the knife advances into the flesh of the patient with a perfectly regular motion at the rate of one inch in six hours.

The instrument having been only recently finished, I can as yet report but few experiments, but I have gone far enough to prove that at this velocity there is no clearly defined pain, but only a slight sense of uneasiness, which does not even prevent the patient from falling asleep, if he happens to be so inclined, as he was in one of my cases.

My theory is that at this slow rate the pressure of the thin advancing blade benumbs each nerve twig before it actually divides it, as slow pressure on any larger nerve deprives it of sensibility, and that the slight uneasiness before mentioned is caused by this slow pressure, and not by the actual division of the nerve fibres.

Although the painlessness obtained by high and low velocities can never entirely supersede the regular anæsthetics, yet I hope to show at a future meeting that there is a wide group of minor operations where this principle is applicable for the prevention of surgical pain, and to present instruments of practical value for this purpose.

MEDICAL PROGRESS.

SURGERY.

THE SURGICAL AND ORTHOPEDIC TREATMENT OF INFANTILE PARALYSIS.—Bernard Roth, F.R.C.S., in a paper read before the British Medical Association (*British Medical Journal*), gives special attention to the use of massage and movements, both voluntary and involuntary, in the treatment of infantile paralysis after the acute stage has passed, to improve the power of those affected muscles which have still some voluntary power left; and to prevent the onset of any deformity, or, if this has already occurred, to reduce it to a minimum. The first thing done is to correct the lowering of temperature, nearly always present, of the limb or limbs. If one leg is affected, the parents should be told not to be satisfied unless it is as warm as the healthy one; quick sponging with tepid water, good rubbing and drying, and extra clothing, such as loosely knitted woolen stockings, thick cloth leggings, or, best of all, cloth leggings lined with cat skin or other fur. Baths 98–100° F. for 10–20 minutes every evening. A small barrel on end answers admirably. This to be followed by a rapid sponging of the whole body with cold water.

Massage more frequently an hour twice daily by *kneading*, a combination of grasping, and large pinching and pressure, with the two hands used alternately, one after the other, so that whatever is left of the wasted muscle is thoroughly squeezed and moved about. The skin to be protected from abrasion by lubrication with olive oil, or vaseline.

Circular friction by the thumb is done as follows: The operator's thumb-end is firmly placed on any given spot, and while considerable pressure is exerted, describes small circles, ten times from right to left, and ten times from left to right. A spot an inch higher or lower, or to one side, is then treated in the same way, and so on until every part of the muscle has been thoroughly manipulated.

Fulling acts less directly on the muscles, but rather on the whole of the tissues of the paralytic limb; it is effected by rapid to-and-fro alternate gliding of the two palms on opposite sides of the limb, which is at the same time as firmly compressed as possible. If the leg is to be "fulled," the operator begins close to the groin and gradually works his way down to the foot, moving the hands rapidly to and fro the whole time. The first time, the hands should be on the outer and inner aspect of the leg; the next, they should be placed higher on one side and lower on the other; the third time, this position is reversed; and, finally, the hands are placed posteriorly and anteriorly to the limb. After five minutes of such manipulation a dozen or two firm *strokings-down* of the leg end the rubbing.

With this the so-called Swedish exercises or medical gymnastics makes the treatment complete. The latter varies according to the part to be influenced and consists in making each muscle or group of muscles contract and then gradually relax, at first actively and then against resistance by the surgeon. With the *hip-joint* the patient lies prone and raises the leg, with the knee kept extended, from off the ground—if too weak, the hand under the knee assists the movement. Circumduction follows of the hip from right to left, and *vice versa*, ten or twelve times each way—its severity being increased by pressure of the hand against the back of the heel. *Knee-joint*. Here the patient lying supine has the knees flexed, and the legs hanging vertically over the end of the padded table on which he lies, and exercises the extensors by slowly extending one knee, when too weak the foot is supported. *Ankle-joint*. Here the leg is supported on a chair, the foot projecting; flexion, extension, adduction, abduction and circumduction are executed either voluntarily by the patient or passively by the surgeon. The *shoulder-joint*. The patient lying on the back, circumduction from before backwards, the elbow and wrist being kept extended voluntarily or by a wooden splint. To bring the scapular muscles into action, the patient, lying supine, with the arms down by the side of the trunk, or abducted at right angles to the body, or extended upwards by the side of the head, is told to resist the arms being brought forward from either of the above positions, and then voluntarily returned to the initial position against gradually yielding resistance. *Elbow-joint*. The upper arm being fixed against the table, flexion or extension is easily resisted by the

hand. Throughout all these exercises, care should be taken that, while the patient is trying to contract, he is prevented involuntarily contracting other stronger or normal muscles which should be kept at rest.

He further recommends to equalize the length of the two legs where one has become shortened, by a thicker sole on the boot of the shorter, to bandage the sound arm to the side for some hours daily, where one arm only is paralyzed, and to stop at once all unnatural modes of progression. If the toes are much deformed, stockings with toes will be found efficacious. Suspenders and never garters should be worn. Milk entering largely into the food, tepid water enemata on alternate days, and fresh air several hours daily, complete in brief, his mode of treatment.

TETANUS PRODUCED BY HYPODERMIC INJECTIONS.

—Dr. Pietro Rossi reports in the *Gazzetta degli Ospitali* (*Lancet*) a case in which tetanus followed repeated injections of hydrochlorate of quinine. The patient was a youth, aged 18, of lymphatic temperament, affected with incipient pulmonary tuberculosis. Hydrochlorate of quinine was injected every other day, sometimes twice a day, with much constitutional benefit; but each puncture was followed by slight local irritation, with circumscribed redness and pain under pressure. These symptoms only lasted a day or two. In consequence of febrile exacerbation, the injections were repeated twice a day for three days, alternately in the arm and forearm of the same side. Each time the solution of hydrochlorate of quinine was the same in strength, bulk, and temperature. Four days after the last injection the pain increased at one of the punctures, which became red and turgid. These symptoms were allayed by repeated poultices, and no fever supervened; but the patient complained of great weakness, and of difficulty in moving the jaws when eating. Chloral was at once freely administered by the mouth; but in the course of a few hours all the symptoms of tetanus were developed—trismus, opisthotonos, and pharyngeal constriction, preventing deglutition. Chloral clysters in large doses proved unavailing. Muscular spasms of the trunk increased in frequency and violence, and death occurred suddenly, thirty hours after the appearance of the first tetanic symptoms.

ABSCESS OF COWPER'S GLANDS. — M. Verneuil (*Progrès Méd.*) reports the case of a man, aged 62 years, who came under his care at La Pitié. For some time he had had symptoms of dysuria. These finally became very pronounced; urination became extremely painful, and the desire frequent. Examination showed a stricture of the membranous portion of the urethra. M. Verneuil diagnosed stricture of the urethra, and ordered a bath and a purgative, and next day passed a No. 3 bougie, the size being then changed every two days, until a No. 9 was passed. This was soon followed by an attack of orchitis, and this by an exudation into the tunica vaginalis, which afterwards became encysted. Dilatation of the urethra was kept up, and the patient left the hospital

able to pass a No. 15. He returned in about three weeks, with a large swelling of the right side of the scrotum; this was due to abscess formation, which opened in five days. Three days afterward the patient died. The autopsy showed the bladder small and retracted, and its walls thickened. A No. 7 sound could be passed per urethram. Near the prostate a small quantity of pus was found. On dissection, a small cavity was found, filled with phlegmonous, greenish pus. It was situated at the posterior part of the urethra, and behind with the bulb of the urethra and the perineal muscles, above with the prostate, and below with the bulb. In the opinion of Verneuil and Cornil, this was a case of abscess of Cowper's glands.—*Midland Med. Miscellany*.

REMOVAL OF A GALL-STONE FROM THE ILEUM.—

Dr. Wm. E. Taylor communicated to the Naval Medical Society (Proceedings) the details of a case in which the symptoms led to a diagnosis of internal strangulation of the bowel, from the presence of obstinate constipation and stercoraceous vomiting. Upon being placed under chloroform an incision from the umbilicus to the symphysis pubis opened the cavity of the abdomen, a moderate distension of the small intestines with congestion, and circumscribed patches of plastic peritonitis were found. A band surrounding the ileum was encountered, which was thickened and inflamed at that point, but as the lumen of the gut was only partially occluded, it seemed certain that it could not be the sole cause. It was divided, and following the distended gut down, a hard, pear-shaped body was found firmly impacted in the ileum at its lower portion, say, some 12 or 18 inches from its lower end. This body was situated with its small end pointing downwards, fitted as tight as a cork, not even allowing wind to pass it. It could not be moved, nor could the fingers make any impression on it by any *safe* pressure. A needle was introduced through the wall of the gut, but it was too hard to be broken. The intestine was opened by an incision an inch in length, and a pear-shaped gall-stone nearly two inches in length and one inch in diameter was removed. The incisions were closed and antiseptic dressings applied. The patient stood the operation well, and had a natural movement of the bowels at the end of 36 hours, but died of exhaustion on the fifth day after the operation without any evidences of peritonitis.

Dr. Taylor's conclusions were that there must have been an inflammation of the gall-bladder, and that adhesions had formed between it and the duodenum, followed by an ulcerative process, and, finally, a perforation of the adherent wall, and through this the stone had escaped into the intestine. An examination showed the gall-bladder to be thickened and closely adherent to the duodenum, with an opening nearly an inch in diameter leading through into the bowel, the peritoneal cavity being shut off by the adhesions. The post-mortem showed that the intestinal wound was so far healed as to prevent the escape of its contents. The wound in the abdomen had not taken on much repair.

MEDICINE.

ON THE DIFFERENT KINDS OF SUBJECTIVE AURAL SOUNDS AND THEIR TREATMENT.—Dr. Ladreit de Lacharrière has an article on this subject in the *Annales des Maladies de L'Oreille, du Larynx, etc.* He refers first to the influence which this tinnitus aurium exerts on the minds of many patients, giving melancholia to many and even causing suicide. If proper attention be given to the recital by patients of the character of these sounds, they will be found to represent a certain number of types which preserve absolutely distinct characteristics. These are sometimes vague sounds like that of the shell, or the distant roll of a drum or rumble of a carriage, which are either constant or increase at times. A second type is that of rustling, like the air stirring leaves—or more marked, like the escape of a jet of steam. A third type is that of musical sounds—approaching in character sometimes those of the preceding ones, but always having a musical tone, such as noises analogous to musical instruments, to the striking of metal plates, to the sound of bells, with the airs which one has heard constantly repeating themselves. The fourth type is that in which the subjective sensation presents pulsatile beatings, in two forms, one subjective, properly speaking, the other pseudo-subjective, in which the physician and patient both perceive the sound. These sounds have been classified as follows :

1. Sounds characteristic of occlusion of the natural passages, the auditory canal and the Eustachian tube.

2. Sounds produced by the exaggeration of the pressure in the labyrinth by the parts in the middle ear.

3. Sounds in the labyrinth produced by disturbance or lesion in the internal ear.

4. Sounds developed in the neighborhood of the ear and heard by the physician.

1. Sounds by occlusion of the natural passages, either from a temporary cause as the presence of a foreign body, or from a more durable lesion, are marked as uniform and continuous and compared to the distant roll of a drum, rumbling of a wagon, or that of the cavity of a large shell held to the ear. These are the result of internal sounds which, from the occlusion, have been reinforced to an extent rendering them appreciable by the auditory nerve.

2. Sounds produced by exaggeration of the pressure in the labyrinth, may be demonstrated in the healthy subject, by pressing on the handle of the malleus with a blunt hard substance, when a sound like that of the rustling of leaves, of the falling of a torrent or cascade, will be heard. These sounds are in no ways musical, and their cause lies in the exaggerated pressure upon the fenestra ovalis, as when a foreign body presses against the handle of the malleus, or when complete occlusion of the Eustachian tube provokes a degeneration of the membrana tympani, and causes a modification in the position of the chain of bones. This is observed in hyperæmia with retraction of these bones; in shortening of the tendon of the tensor tympani, as seen in median otitis with cedema of the mucous membrane of the

tympanum, in certain catarrhal affections of the same region, in the hyperæmia present in serious cases of fever, and where the irritation of the pharyngeal mucous membrane is propagated to the tympanum. These sounds may be permanent, if tympanic adhesions or ankylosis of the bones occur; they may be intermittent if produced by spasms of the muscle, or by temporary hyperæmia.

3. Slight or serious affections of the labyrinth, transitory or permanent, accompanied by subjective sounds, whilst the auditory nerve has not lost all sensibility. These sounds are variable, but all partake of a musical character, that is to say they have a sonority which can be represented by a musical note. The most common sound is that comparable to the whistle of a locomotive. When non-musical sounds are heard at the same time, there are certainly multiple locations of modifications of the organ of hearing. These sounds affect patients most markedly, they may even give rise to thoughts of suicide, they are analogous to the sounds produced by stringed instruments, such as the harp and the violin detonations, bell ringing, percussion of metallic instruments, the singing of birds, etc. It is impossible from our present imperfect knowledge of the physiology and pathological anatomy of the internal ear, for us to class all of these various sounds with their corresponding lesions, but the nature of the sounds frequently enables us to decide what is the nature of the affection. We know, for example, that congestion of the labyrinth due to a febrile condition like typhoid fever, or to a neurosis like migraine, may give rise to pulsatile sounds isochronous with the beats of the pulse, and that these characters always belong to vascular developments of a varicose nature. In hæmorrhage of the labyrinth, the sounds become very violent and painful. In chronic labyrinthitis otitis the noises become incessant. The other lesions that are most frequent are fatty, fibrous or amyloid degeneration of the auditory nerve, hypertrophy of the labyrinthine membrane, and traces of a chronic exudative inflammation with a production of calcareous salts and pigmentary deposits.

These sounds are sometimes produced by such external causes as the discharge of a gun, or the production of some lively emotion—as in the case of a woman who awoke to see her child's cradle in flames, a nervous affection ensued which was cured in the course of eighteen months, but the sound of the crackling of the flames still remained. It is evident that the sounds which result from an excitation of the auditory nerve vary in intensity according to the general and moral condition of the patients, to their surroundings, and to their little excesses. An excitability of the nerves causes sometimes an increase in the sounds when the eyelids, the temples and the cheeks are touched—particularly during the process of shaving.

Schwartz was among the first to recognize the relations between these sounds and certain forms of mental disease characterized by hallucinations of hearing. He, with Kopp, in 1869 examined 97 cases of insanity; 41 were troubled with ear affections, that is subjective sounds and acoustic illusions or

hallucinations; 26 were affected by noises without deafness—among them 7 had hyperæmia of the handle of the malleus, 6 ceruminous collections, in only 2 did the noises cease with the removal of the condition, but the hallucinations persisted; in 7 there were noises without hallucinations. Of those remaining 18 had hallucinations without noises, and 22 presented none of these symptoms.

The noises which ensue upon the administration of sulphate of quinine and salicylate of sodium are probably due to congestion of the labyrinth.

Besides these subjective sounds which have been enumerated, there are others due to true sonorous manifestations in the interior of the body, such as the vascular sounds from alterations in the blood, as chlorosis and anæmia. In aneurism of the basilar artery there is often a pulsatile sound at the occiput. Rayer records a case where it was isochronous with the heart-beats; it was not possible to discover the situation of the aneurism, it seemed as if the noise had its origin in a modification of the parts to which were sent the branches of the posterior auricular artery. According to Hirtl, there exists constantly in man, between the two branches of the stapes, a capillary which passes to the promontory; might not affections of the tympanum frequently induce alterations in this vessel? M. Lacharrière has often relieved patients of pulsatile sounds by compression of the external carotid.

As to treatment, a reëstablishment of the permeability of the external auditory canal and the Eustachian tube will relieve the sounds in the first category.

Insufflation of the tympanum whether simple or with medicaments, in reëstablishing the suppleness of the organs of the middle ear, will relieve the noises due to an exaggerated pressure on the fenestra ovale. Paracentesis of the tympanum and section of the tendon of the tensor tympani may, in rebellious cases, become necessary; but it is well first to try the use internally of iodide of potassium and arsenic; of instillation in the external auditory canal of iodide of potassium, sulphate of zinc, chlorhydrate of pilocarpine, the neutral sulphate of atropia, which have, according to the character of the cases, given good results.

In labyrinthine affections, repeated revulsives applied to the mastoid apophyses, and the internal use of iodide of potassium, mercury, arsenic and aconite according to the morbid antecedents of the patient, seem often to have good effect. Large doses of sulphate of quinine may relieve the intolerable noises and vertigo, but at the expense of loss of sensibility in the auditory nerve. Finally, the application of the continuous electric current is beneficial, particularly in passive congestion from vascular atony; it excites vascular contractility and causes the blood stasis to disappear. It has been of great service, and is used by placing a pole upon each external auditory meatus, taking care to place the negative pole on the ear which is most particularly affected. The current affects all the contained parts, and when interrupted the patient experiences a shock, and sensation of light, showing the optic chiasm to be involved. No

endurable bad feelings or other trouble have been produced by this method. Gaiffe's battery was the one most commonly used, with chloride of silver, and the intensity of the current was never greater than 16 to 18 elements.

WEIGERT'S METHOD OF STAINING.—Dr. Strassmann, at a recent meeting of the Berlin Medical Society, presented some sections of the spinal cord stained according to Weigert's method, which is as follows (*British Med. Jour.*): A solution of hæmatoxylin is prepared with water and alcohol; the sections are kept immersed in it during an hour, and the temperature is maintained between 40° and 50° Cent., 104° and 122° F. They are then removed from the solution, washed and placed for three hours in a 2 per cent. alkaline solution, or in one of potassium ferrocyanide. Afterward they are submitted to the influence of alcohol, xylol, and Canadian balsam, as in the usual method. In sections thus prepared, nerve fibres with a myeline sheath are stained blue, the neuroglia pale yellow, and the ganglia cells brown. This method throws into relief the nerve fibres with a myeline sheath. Strassmann presented other preparations which brought out clearly the structural change in the spinal cord in a case of tabes dorsalis recently studied and described by Lissauer and Weigert. In sections of the cord, in a case of secondary degeneration following caries of the vertebrae, Clarke's columns are manifest. In their normal condition they present the aspect of brown rings brought out in strong relief on a light background; close to them a groundwork of fibrillæ, which are more closely packed than in the posterior columns. The ganglia cells are imprisoned in the meshes of this network. In the preparation of tabes dorsalis, Clarke's columns appear as light rings against a dark background; microscopic examination shows that a large quantity of nerve fibres with a myeline sheath have disappeared. The same structural change is found in the histological preparations when this new method is adopted.

DISINFECTING THE SPUTA OF PHTHISIS.—Dr. J. Sormani, Professor of Hygiene at the University of Pavia, gave some interesting details at the Hygienic Congress of Hague concerning experiments made this year on 150 guinea-pigs with the sputa from phthisis. The object in each case was to ascertain what chemical or other methods would neutralize the bacillus, which it was previously ascertained existed in large numbers in the sputa. The results of these experiments were summarized in the following manner. (*Lancet*):

1. The bacilli of tuberculosis were generally very difficult to destroy. Dryness, exposure to oxygen, putrefaction, and most disinfectants failed to produce any effect.
2. A temperature of 100° C. only killed the bacilli after at least five minutes of ebullition.
3. The artificial digestion of bacilli showed that they were the last of all living organisms to be destroyed by the gastric juices or chloridric acid. A very active digestion is necessary to kill this microbe. A healthy man may destroy the bacilli in his stomach,

but an infant or an adult with his digestive faculties impaired would easily allow the germ to pass the stomach intact, and retain its virulence in the intestinal tube. This determined enteric ulcerations, etc. 4. The bacillus of tuberculosis can be preserved intact for a whole year when mixed with water. It is probable, though not proved, that it has retained its virulence during that time. Thus, drinking water may become the means of propagating tuberculosis. It is probable that contaminated linen retains its virulence for five or six months. 5. Alcohol does not destroy the germ, and hard drinkers often suffer from tuberculosis. 6. Cod-liver oil, ozone, oxygenated preparations, and other similar remedies have no effect in killing the bacillus, nor are benzoate of soda, salicylate of soda, sulphate of zinc and carbolic acid, iodide of silver, bromide, camphor, etc., of much greater use. They injure, perhaps, but do not absolutely destroy the bacillus, at least not in the doses that can be taken without danger. 7. A more decisive action may be attributed to creasote, eucalyptol, pure carbolic acid, the naphthols, and bichloride of mercury. 8. For disinfecting spittoons, carbolic acid solution at five per cent. is thought sufficient, and Dr. Sormani asserts that the breath never contains any bacillus. He also suggested that essences of turpentine or eucalyptol should be diffused in houses as an agent for the destruction of this special germ.

NOTE ON A CASE OF CHYLIFORM EFFUSION OF THE PERITONÆUM.—Dr. Maurice Letulle, in the *Revue de Médecine*, gives a case of chyliform ascites in a child eight years of age with a mitral affection of rheumatic origin. Cardiac cachexia. Asystolic. Enormous liver. Anasarca; double hydrothorax. Paracentesis of the abdomen gives issue to two quarts of a milky fluid. The microscope showed this to contain an enormous quantity of emulsionized fat, some red globules and leucocytes. Dr. Letulle argues that the term chyliform ascites is not proper as applied to this condition and concludes:

1. That all cases of chyliform ascites to the present time which were submitted to post-mortem examination, are cases of chronic tuberculous, cancerous or neo-membranous peritonitis.

2. The presence of chronic inflammatory lesions, represents one of the most constant elements in the genesis of peritonitis and pleurisy with chyliform effusion.

3. That the granulo-fatty change of the effused inflammatory products (fibrine and leucocytes) suffices, probably, for the composition of the whole of the emulsionized fat suspended in the pleural or peritoneal serum.

PURULENT INFECTION OF PUERPERAL ORIGIN IN MAN.—Drs. Gaucher and Bourrier give a case in the *Revue de Médecine*, of a man 30 years of age, a rubber by profession, whose wife was confined by a midwife July 5, had fever and died of puerperal disease July 9. This man, the patient, had tended his wife until her confinement, when he lost his appetite, was fatigued, febrile, and had general malaise July 8; pain, redness, and swelling in the left forearm, and poste-

rior portion of the left thigh, chills and sweats. July 10, he entered the hospital with a temperature of about 103.0°, subicteric facies, yellow conjunctivæ, frequent respiration, painful cough with expectoration of yellowish viscid material, and evidences of pulmonary congestion. Abdomen not tympanitic, gurgling on pressure in the right iliac fossa, stools normal, enlargement of liver, tumefaction of spleen, albuminuria. He remained in the hospital under treatment until Aug. 25, when he was discharged as cured. During that time an abscess formed in the left forearm which was opened July 16. An inflammation set in on the left leg from below the knee to the ankle. An abscess also set in on the right leg just below the knee, which was opened July 20. The right thigh and the left leg had also to be relieved of pus a little later on.

These observers consider that this case represents puerperal fever in man. This man after attending his wife who dies of puerperal fever, is affected by an infectious disease, characterized by chills, fever, albuminuria, tumefaction of the liver and hémaphæic icterus, tumefaction of the spleen, pulmonary congestion and multiple suppurative angioloecitis. No other cause for infection could be assigned.

At the Annual Meeting of the American Academy of Medicine, in Baltimore, held October 28 and 29, 1884, Dr. Albert L. Gihon, of U. S. Navy, was elected President for the ensuing year.

TEXT-BOOK OF MEDICAL JURISPRUDENCE AND TOXICOLOGY. By JOHN J. REESE, M.D., Professor of Medical Jurisprudence and Toxicology in the University of Pennsylvania; Vice-President of the Medical Jurisprudence Society of Philadelphia; Physician to St. Joseph's Hospital; Member of the College of Physicians of Philadelphia; Corresponding Member of the New York Medico-Legal Society. Philadelphia: P. Blakiston, Son & Co., 1012 Walnut street. 1884.

This new work contains 606 fair-sized octavo pages, and is published in good style. The type is plain, and the paper and binding good. The author has been well known as an eminent teacher of the subjects embraced in this volume, and is well qualified, both by scientific attainments and practical experience, for the performance of such a task as he has just completed.

In looking through the work rather hastily, we are satisfied that the topics usually included under the head of Medical Jurisprudence or Forensic Medicine, are well arranged, a fair relative importance given to each, and the whole treated in that clear and concise manner which admirably adapts it to the needs of students both of Law and Medicine. While for detailed references it cannot supersede the more extended works of Casper, Beck, Taylor, Wharton and Stillé, Tardien, and others, yet as a text-book for classes in schools of Medicine and Law it will at once take the first place on the list. Price in cloth \$4, in sheep \$5.

THE
Journal of the American Medical Association.

PUBLISHED WEEKLY.

THE EDITOR of this JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information, should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE..... \$5.00.

SINGLE COPIES..... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 65 RANDOLPH STREET,
CHICAGO, ILLINOIS.

SATURDAY, SEPTEMBER 1, 1884.

AMERICAN PUBLIC HEALTH ASSOCIATION, TWELFTH ANNUAL MEETING.—Last week we gave a summary of the doings of this important organization during the first day of its session recently in St. Louis.

The second day was occupied chiefly with the reading and discussion of the following papers:

Dr. S. O. Richey, of Washington, presented a paper on "The Hygiene of the Eye-Sight of School Children," in which he urged the importance of subjecting every child before admission to any school, to a medical examination of the eyes, first for the purpose of excluding such as might be affected with contagious diseases of those organs; and second, for the purpose of securing better adjustments of the amount of work required, to the capacity of the child for doing it without injury.

Prof. Charles E. Munroe, of the United States Naval Academy, at Annapolis, furnished a paper on "Cotton Seed Oil as a Food;" in which he claimed that the oil was a perfectly wholesome and proper article of food; and would be of much value to the people, if the prejudices against it could be so far overcome that it might be sold in the market under its own name freely.

The next three papers related to school hygiene. One of them was in the form of a report from the Committee on School Hygiene, presented by Prof. D. A. Sargent, of Harvard University. The practical facts presented in this report were obtained chiefly from an inspection of the schools and school-houses in Boston and its vicinity. It stated that all the schools visited by the Committee were defective in some one or more particulars, such as location,

drainage, playgrounds, privies, or ventilation and seating arrangements.

Before submitting to the Association, however, a full report it was suggested that a more general collection of facts and data should be made from all parts of the United States. The suggestions on this subject were approved and the Committee continued with two new members added.

Another paper was by Dr. Felix Formento, of New Orleans. He reviewed the progress of the public school movement in America, and said that it was estimated that there were 9,800,000 children attending the schools. But education was of little value without school hygiene. The study of sanitary conditions had a marked influence upon the whole after life of the children, who should be taught what led to health as they were taught what led to fortune. The physical qualities should be cultivated as much as the mental qualities, and the physical development should precede the mental development. Ignorance or the neglect of hygiene in the school life of children caused many physical infirmities and deformities. The greatest attention should be paid in schools to the sitting postures of the children, to the length of the various lessons, and to the habits of the children. The teaching of calisthenics should be made compulsory in every public school, both for boys and girls, as it was important for the latter as it was for the former. It was not necessary to have a complicated and expensive apparatus. A few horizontal bars and ropes were all that were necessary. Such exercises should be continued only for a short time, and should never be allowed to exhaust or fatigue the children. Hygiene should be made a study in all schools. The children should be impressed with the importance of good health, and taught the best ways of preserving it and promoting it. Through the school children the ideas would reach the family and thus greatly benefit the whole community. He urged that there should be a system of compulsory medical and sanitary inspection in all schools. The work should be intrusted to competent and reliable men, and the cost of the inspection borne by the school boards, or the city and county authorities. The inspections should be made at least twice per month, and in addition to examining the children the inspectors should pay particular attention to the sanitary condition of the school-houses.

The third paper was by Dr. E. C. Elder, Secretary of the State Board of Health of Indiana, in which he showed the urgent need of improvements in regard especially to the location, drainage and surroundings of many of the school-houses of that State. He

claimed that the work of improvement in this line should be actively prosecuted by the State and local Boards of Health in all parts of the country.

The discussion which followed was taken part in by Dr. Raymond, of Brooklyn; Dr. Thompson, of Kentucky; Dr. Reed, of Ohio; Mr. Erastus Brooks, of New York; Dr. P. H. Bryce, of Toronto; Dr. Bell, of New York; Rev. Dr. Jacoke, of Michigan; Mr. R. Moore, of St. Louis; Mr. L. A. Smith, of Washington; Dr. Conn, of New Hampshire; Dr. Wm. Bailey, of Louisville; Dr. Early, of Indiana; Dr. Fee, of Kansas City; Dr. Devron, of New Orleans; Dr. Green, of Pennsylvania, and Dr. J. F. Hibbard, of Richmond, Ind. The discussion was mainly on the sites, ventilation, heating, lighting and sanitary arrangements of school-houses. It was contended that the health of the 7,000,000 of children in the schools of the United States made these questions of the greatest importance to the community.

Dr. V. C. Vaughan, of Ann Arbor, Mich., read a paper on Poisonous Cheese, the facts concerning which have already appeared in this journal under the head of Reports of the Michigan State Board of Health.

This was followed by an important paper by Dr. J. Cheston Morris, of Philadelphia, on the "Milk Supply of Large Cities; the Extent of Adulteration and its Consequences, and Methods of Prevention."

But little of value was added to the facts set forth in the full discussion of this subject, recently given in our columns, under the head of Proceedings of Suffolk District Medical Society of Massachusetts.

The plan of transportation recommended by Dr. Morris was the shipment of milk directly from the farmer to the consumer in quart glass jugs. The advantages of that plan were that the glass jars must necessarily be clean, and the milk free from contamination in transit, as the jars would be sealed. The customer would also get his share of the cream, and it would be to the interest of the producer to send the best article, as his reputation and connection with his customers would depend upon his so doing. The system involved more trouble to the farmer, and a consequent increased cost to the purchaser, but it was to the advantage of the purchaser to pay an increased price for a pure article. He had tried the plan in Philadelphia. It had been a pecuniary success. He therefore recommended it as one of the means by which really pure milk could be obtained, and infant mortality from inferior and adulterated milk reduced.

During the evening session of the Association, Hon. Erastus Brooks read a valuable, though some-

what desultory paper on "The Food we Eat and the Adulterations to which we Submit."

Surgeon Walter Wyman read a paper on the "Hygienic Condition of Sailors Engaged in the Coasting Trade, and especially the Hardships of the Chesapeake Oystermen." He stated that 100,000 people were engaged on Chesapeake Bay, in the oyster business, and that 300,000 people get their living directly from this industry. He stated that there were 1,000 square miles of possible bottom for oyster farming, and that it could be made to pay \$1,000 per acre. The oysters are mostly gathered by dredging, and between the first of November and the following April, embracing the cold season of the year. Those immediately engaged in the dredging suffer severely from exposures to cold, wet and hard labor.

The writer closed by saying, "the life of the oysterman is far from a happy one, and advocated legislation to make it less terrible."

A paper on "Cremation" by Rev. John B. Beugless, Chaplain in the United States Navy, was then presented. It advocated cremation on sanitary grounds; the writer giving full assent to the popular germ theories, and claiming cremation as the only certain method of destroying the microbes.

The closing paper of the evening was by Hon. J. M. Keating, of Memphis, on "Ultimate Sanitation by Fire," in which he advocated the cremation of all suspected articles and sewage as well as the bodies of the dead.

For one hour before the commencement of the evening session the streets and public places were brilliantly illuminated, and the members of the Association given a free ride through the principal streets to witness the brilliancy of the display.

PAPERS FOR THE NEXT ANNUAL MEETING OF THE AMERICAN MEDICAL ASSOCIATION.—At the last annual meeting of the Association, the number and character of the papers presented in the several Sections was greater and of better quality than usual, as may be seen by a glance at what has already been published in the department for original papers in this journal since the meeting in May last. This result was obtained largely through the active solicitation of the President of the Association and of the officers of the Sections. The careful reader will have noticed that the authors of many of the best papers acknowledge the influence of this solicitation in the first lines of their respective papers. We allude to this now, because it is time that the same influence

should be actively exerted in reference to the scientific and practical work that must be done to make the next meeting of the Association as interesting and valuable as the preceding one. The next meeting is to be in New Orleans, the metropolis of the South-West. The President of the Association is the representative of the South-East. If he has not already done so, let him follow the example of his illustrious predecessor, and give his personal attention and influence in aid of the officers of the several Sections to the securing from able writers in all sections of our great country a full supply of well-prepared papers on subjects belonging to every important department of medical science and art. But while we thus call upon those who occupy the places of honor to exert their influence in the direction named, we would urge those who have matter of value at their command not to wait for invitations from any source, but commence early, prepare their papers with care and completeness, and do not fail to give early notice of the title and contents of the same, to the chairman of the Committee of Arrangements, that he may have the materials for completing the programme for the next meeting at least thirty days before the time of meeting.

MEDICAL COLLEGE ENDOWMENTS.—Several times we have had occasion, during the past year, to call attention to the great importance of liberal endowments to well established and properly located medical colleges. And we are now much gratified to learn that Mr. Wm. H. Vanderbilt, of New York, has donated to the College of Physicians and Surgeons of that city the munificent sum of half-a-million of dollars. If this is wisely used by the College, it will be amply sufficient to make the institution thoroughly efficient in all the departments of medical instruction. The authorities of the College, however, should not commit the too common error of spending the whole sum in new buildings and grounds, and have nothing left to sustain efficiently laboratories and workers in the more purely scientific departments of medical instruction. Mr. Vanderbilt has not only set a good example in the liberal amount donated, but also in bestowing it upon one of the oldest medical colleges in this country, and one whose trustees and faculty have been among the foremost in endeavoring to improve the general system of medical instruction. Who among those in this great city (Chicago) whose wealth is counted by millions will follow Mr. Vanderbilt's example, and

donate one or two hundred thousand dollars to the medical college here, which has been the actual pioneer school in advancing and systematizing medical college education in this country. A generous and noble woman, Mrs. Murray, has recently given \$15,000 to aid the Hospital for Diseases of Women and Children, which indirectly aids the Women's Medical College in this city. There are plenty of men and women of wealth in this and every other great city who could, by endowing the more exclusively scientific departments of permanent medical colleges, increase medical knowledge, and render more thorough the education of physicians, and thereby benefit, not a few sick persons who might find shelter in a particular hospital, but the sick of the whole human family, and for all coming time.

STATE BOARDS OF MEDICAL EXAMINERS.—Under the head of State Medicine in the present number of the JOURNAL, is an *Act*, or copy of a law prepared by a committee and endorsed by the Ohio State Medical Society at its last annual meeting, and which will be presented to the next session of the Legislature of that State for adoption as a law regulating the practice of medicine in that commonwealth. The framing and enforcement of proper laws for regulating the education of physicians and the practice of medicine, in such a way as to protect the real interests of the people, without having them liable to develop abuses and evils equal to the benefits they confer, is a work of great difficulty. To establish State Boards of Examiners, and confer on such Boards unlimited power to determine what shall constitute a proper medical education; what branches shall be taught in medical schools; and what schools shall be accepted as in good standing, is not only contrary to the genius of our governments, State and national, but is putting into the hands of a few men a power which they may wisely and honestly exercise in such a way as to elevate the standard of medical education, and thereby benefit the whole people, or they can just as readily wield it in such a way as to lower that standard, and foster both ignorance and oppression. The subject is one which has engaged our attention for nearly half a century, during which we have studied the history, progress and results of medical legislation in this country with much care. The only legitimate principle or pretext on which governments can claim the right to interfere with the choice of any person to study and practice medicine as he pleases, is the apparent necessity

of protecting the people from the injurious effects of ignorance and imposition, the need of medical knowledge on which to found the most important sanitary measures needed in every civilized community, and the need of skilled physicians and surgeons to attend to the wants of those who are serving in the army and navy as instrument of public defense. If it is assumed that these considerations are sufficient to justify government interference, by the enactment of laws for regulating the education of physicians and surgeons, and the practice of their art, then all such laws should be general and impartial in their terms and practical application. They should clearly define, first, what must constitute the minimum of general education required to qualify the student to commence the study of medicine; second, what branches shall constitute the minimum field of medicine to be studied and mastered; third, what shall be the minimum length of time that shall be devoted to the study of the branches named, and how much of it shall be spent in medical colleges and hospitals having certain specified facilities for teaching; and fourth, they should provide a State Board of competent Examiners, to determine whether the provisions of the law relating to these several particulars had been complied with, and to decide by direct examination, whether the candidate for admission or license to practice medicine, had the standard of actual qualifications which the law contemplated and the interests of the people required.

There should be no recognition by the laws, of medical sects or of different schools, nor any distinctions by the Board in the examination of students in relation to certain branches, but all should be examined alike and all required to have a full knowledge of each branch named in the law. Neither should the terms of the law nor the methods of examination by the Board, attempt any interference with the right of each candidate when licensed, to practice his profession in accordance with the dictates of his own judgment and conscience. The only legitimate object of government interference, is to secure for the people a supply of thoroughly educated medical men and women. In doing this it has no more right to make special provision for sects or parties in medicine, than in religion or law; nor is it in accordance with sound policy to debar any particular class of educated medical men from eligibility to appointment on the Boards of Examiners. If our readers will compare these views with the provisions of the proposed law in Ohio, they will readily see wherein we should regard several of those provisions as defective, and very liable to develop mischievous results.

SOCIETY PROCEEDINGS.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

OBSERVATIONS FROM THE STUDY OF ONE HUNDRED AND FORTY-TWO CASES OF HYSTERO-TRACHELORRHAPHY.

BY CHARLES MEIGS WILSON, M.D.

(Continued from last Number.)

Though much has been written on this subject in the past few years, I trust a description of special instruments, a summary of the histories of 142 cases will not be amiss. In view of the exhaustive treatment the subject has received in the hands of many observers, I hesitate to report my own limited experience. One hundred and four of these cases occurred in the practice of Dr. E. Wilson, two in my own, and the balance I witnessed as assistant either in hospital or private practice. I regret that circumstances prevented me from obtaining a full history in all the cases. No one should hesitate in performing the operation, or be unable to recognize the lesion. Yet very frequently gynecologists have sent to them either for an opinion or operation cases diagnosed as eroding ulcers, fungoid vegetations, cancer, etc., which, when the patient is properly examined, prove to be cases of laceration. The touch alone is sufficient to establish the existence of the lesion. If corroborative evidence be required, the patient should be placed in the knee-chest position, and the uterus exposed with a Sims speculum. For in this position if each everted lip be grasped with a tenaculum, by gentle manipulation the natural contour of the cervix can be restored. If this simple feat can be accomplished, the diagnosis is at once established. For in malignant disease, *ulcerations* of the os, etc., this cannot be done. Reeves Jackson considers this test infallible. Formerly many cases of laceration were comprehended under the generic term ulcer. But the description of the lesion and the operation by Dr. Emmet has settled forever the "well-worn controversy which so long divided medical opinion concerning the etiology and pathology of the so-called ulceration of the cervix uteri."

Often times useless and injurious applications are made to the cervix, because the gentlemen having the medical care of the cases do not understand that the cervix is torn. The old-fashioned tubular speculum is still too frequently used. It is now generally conceded that it is useless except where *harsh* treatment is to be applied to the cervix without injury to the vagina. The tubular speculum separates the already everted lips and makes the laceration assume a more angry appearance. Thus faulty methods of examination often obscure the diagnosis. Another difficulty with many physicians is that the symptoms of which the patient complains are too apt to be regarded as the expression of some malady in which the uterus is not involved, unless, indeed, they complain of some vaginal discharge, a condition rarely absent. Again, the train of symptoms which belong to laceration belong equally to many other uterine ailments, and nothing but a carefully conducted ex-

amination can demonstrate that such is the case. The anæmias, debility and other results of laceration, like the results of many other pathological conditions of the pelvic viscera, are often treated by a course of tonics, whilst the underlying cause of all the mischief goes on with its destructive work. When a woman consults a physician, complaining of any of the more marked symptoms, such as cranial, rectal, vesical or pelvic pain, a feeling of weight about the uterus, disordered menstruation, and leucorrhœal discharge, a vaginal examination should be considered an "imperative and essential prerequisite to treatment." The best of investigators is always at hand, namely, the index finger, which, says one of the masters of gynæcic surgery, "when properly educated and used to the full extent of its capability, there are hardly any of the pathological conditions of the pelvic organs in woman which can escape its detective powers." Simpson in England, and Gardner in this country, first called attention to lacerations of the cervix. Emmet, as he himself says in his book, accidentally discovered the lesion in 1862, and devised the operation for its relief. To him belongs the credit of revolutionizing gynæcic surgery. Parturition is the chief cause of the lesion. The pressure of the child's head alone, especially if it be a large one, upon the os, may even in a normal labor be sufficient to lacerate it. If the os be rigid, or as frequently happens, be both rigid and attenuated, the danger is, of course, increased. If the longitudinal and oblique fibres of the uterus have greater contractile force than the circular fibres of the lower segment of the uterus have expansive powers, the force of the contractions of the former exerted upon the foetal body, which rests upon and is engaged with the latter, may lacerate them owing to their non-expansion. In premature labor, the circular fibres of the os not being ready for the dilatation necessary to permit the egress of the contents of the uterus may give way, *i. e.*, there may be sufficient irritation of the uterus to expel its contents by contracting the fundus, but not enough to expand the os. Meddlesome midwifery is a prime cause. By which term I mean, the practice of trying to force back from the presenting portion of the child the margin of the os, without waiting for it to dilate properly; the desire to expedite the labor in every possible way; the premature rupture of the membranes—the physician forgetting that nature's dilator, the "bag of waters," is the best of all. Experience teaches that all labors in which the membranes have been ruptured prematurely, either accidentally or purposely, are apt to be complicated by some laceration of the obstetric canal, especially of the cervix. Unnecessary and unscientific application of the forceps, and traction made with them without a proper knowledge of the pelvic canal and outlet is another factor. That the forceps are responsible for many cases of laceration there can be no doubt. When applied high up or within the uterus, they are exceedingly apt to produce tearing of the cervix. Observations made by Dr. Mundé at the Mt. Sinai Hospital, New York, showed 119 cases of laceration in 700 women examined.

Dr. Hanks, of the Demilt Hospital, found only

eight per cent troubled with laceration. The Mt. Sinai is a Jewish institution and most of its patients Hebrews, these are generally attended by midwives. The Demilt is patronized by the poor of the city generally, and the patients are mostly attended by young graduates, who frequently use the forceps. As far as these observations go they show that the forceps even in inexperienced hands do not do as much to produce laceration, as the often untimely interference of ignorant midwives. Prof. Gross, in one of the last papers he ever wrote, spoke of the frequency with which the forceps were applied, strongly condemning this practice and very justly attributing many of the cases of laceration of the cervix to it. He formulated his views in the words, "the principal causes of laceration are precipitate labor, labor attended with rigidity of the mouth of the womb and *instrumental* labor." Dr. Fundenberg, in an article which appeared in the *Pittsburg Medical Journal*, makes use of this positive language: "I believe that the forceps, when properly applied, is a preventive of laceration of the cervix. * * * * When carefully introduced, for instance, into a rigid os, dilated only sufficiently to receive a narrow blade, the waters being discharged, it preserves the cervix by its inclined plane, from sudden impulse, and imitating the bag of waters in its wedgelike and outward action, it dilates with great and continuous power, with any desirable amount of slowness, and with very great safety." In the 142 cases seen by the writer, the forceps had been used in 49—presumably from the account of the patients at the labor from which their distress dated. Did space permit I should like to quote from other papers in reference to this question. Suffice it to say that the maladroit use of the forceps is responsible for many cases of laceration. The breech presentation is another factor, because of the necessity of rapidly delivering the head. The cervix may also be torn by the shoulders after the head has passed safely through. The injurious practice of giving large and frequent doses of ergot prior to the expulsion of the fetus is another cause—so too are abortions. The predisposing causes include the various forms of induration, whether caused by hyperplastic deposit or malignant disease; all affections of the cervix producing tissue softening, such as epithelioma; or any condition interfering with the natural elasticity of the part, as the cicatrices of previous surgical procedures, or as happened in two of the cases the writer saw of cauterizations, and any syphilitic or strumous taint giving the uterus lack of tone. Dr. E. Wilson lays great stress on the muscular depravity, the result of a constitutional syphilitic taint, and the consequent emaciated condition of os. This muscular degeneration may be the result of many pathological conditions. For example, anæmia, malnutrition, phthisis and the like.

Again, when the uterus is in a state of constant activity, owing to frequent gestation, it is liable to lose tone, and thus pave the way for the exciting cause to light up the trouble. Women are more apt to meet with this accident at the time of their first delivery than subsequently. It occurs also more frequently in rapid labors. Dr. Emmet believes that

partial laceration takes place at the first delivery. Dr. Goodell, Dr. Pallen and Dr. Mundé all record it as being exceedingly common. In 200 women with uterine disease examined by the writer, 19 had laceration of the cervix. The lacerations may extend through any portion of either lip. The writer has found the bilateral to be the most common—the rent being greater upon the left side—and laceration through the posterior lip the rarest form. The fact that a laceration has taken place is seldom noticed at the time of its occurrence. When an examination is made at the completion of the delivery, the parts are so enlarged, soft and yielding, and the os so patulous, that it is difficult to detect a laceration. But if a tear has occurred, the woman soon begins to complain of symptoms which are well nigh pathognomonic. Shortly after she rises from her bed and resumes her ordinary household duties, she notices a more or less constant and generally increasing leucorrhœal discharge. This discharge is thick, viscid and glairy, and sometimes tinged with blood. Sometimes, though rarely, this discharge is absent, or after a time disappears. Pain is a prominent symptom. It is generally of a dull and aching character. It is frequently referred to the lumbar region. Headache is a marked symptom. There is a peculiar sense of weight about the uterus, which is increased along with the pain after exertion. This feeling is augmented when the woman assumes the erect posture. The menstrual flow is, as a rule, increased. It is profuse, longer in duration, and comes on after shorter intervals. There is generally a nasty, glairy, and sometimes semi-purulent discharge during the catamenial intermission. My own observation has taught me that there is generally an increase in duration and amount. When the laceration is recent the increase is so small that it is hardly noticed, but as a rule it increases steadily until it sometimes assumes the character of a sudden and violent uterine hæmorrhage. Patients generally suffer with a feeling of malaise. The general health soon becomes impaired. The digestive system is often the first to suffer. Sexual appetite is usually impaired, sometimes abolished, its gratification always attended with great pain. Insomnia is often present, together with other symptoms of a nervous character.

The writer has seen one case in which hystero-epilepsy was a prominent symptom. The symptoms are usually commensurate with the extent of the eversion of lining membrane of the cervical canal. This membrane when thus exposed loses its delicate epithelial coat, and it chafes against the posterior wall of the vagina. This irritates and inflames the raw surfaces. Hypostatic congestion and engorgement ensue. This prevents proper involution of the uterus and the parts remain enlarged and soft. The heavy uterus inadequately sustained by its supports falls to the floor of the pelvis, dragging the upper portion of the vagina with it. This makes the cervix look elongated when in reality it is shortened. Sometimes cicatrization takes place, and often this plug of cicatricial tissue gives rise to symptoms more distressing than when the parts remain ununited. The mental symptoms are sometimes very grave, amounting to such a degree of men-

tal perturbation as to threaten the sanity of the patient. One of Dr. E. Wilson's patients was for some months in an insane asylum. After her cervix was restored her symptoms gradually subsided and eventually in the space of six weeks entirely disappeared. This woman was deprived of her liberty because her friends refused to have the operation done. Another woman in his practice, a subject of melancholia with uterine symptoms, came very near being spayed. After her cervix was repaired her melancholia and other symptoms vanished entirely. A very curious case of persistent salivation apparently due to laceration, at all events which was cured by restoring the cervix, is reported by Dr. Longyear in vol. xvi, No. 1, of the *American Journal of Obstetrics*. Did space permit I might cite other interesting cases. If the foregoing views in reference to lacerations are correct the indications for treatment are certainly clear. Having decided to resort to surgical means for the relief of his patient, the surgeon must consider whether the patient is in a proper state of health to operate. The same conditions which militate against other surgical procedures are equally operative in cases of trachelorrhaphy, when the uterus is bound down by adhesions or severe inflammation exists, it is dangerous to operate. One case which came under my observation nearly perished from an attack of peritonitis because forcible traction was made to draw down to the ostium vagina a uterus which was fixed and immobile, owing to adhesions the result of a former attack of peritonitis.

For operating the patient should be placed in the dorsal position with her buttocks well drawn down to the edge of the table—an assistant taking charge of each limb. The cervix is exposed with a Sims speculum, grasped with a vulsella and gently brought to the ostium vagina. The needle figure one is passed through the cervix in the median line, from above downwards, it is then armed with a stout piece of silk cord and withdrawn. A blunt-pointed tenaculum is passed up the cervical canal until it engages the cord, a loop of which is withdrawn. This loop is divided and united to each free end, thus forming two loops, the one controlling the anterior, the other the posterior lip. The margins of the tear are now freshened, care being taken to extend the line of incision beyond the angle of the rent, and to cut out any cicatricial tissue that may be present. The hæmorrhage which is never very profuse, and which by depleting the vessels of the uterus, tends to ameliorate the inflammatory conditions often present, is easily controlled by the application of hot sponges. Any one who has seen many operations must have noticed the sudden blanching and softening of the cervix due to the bleeding attending the operation. The late Prof. Gross thought that the benefit of the operation was largely due to this local depletion. I have seen the circumflex artery cut on several occasions, but it never required a ligature to control it. Care should be taken to make the posterior angle of the plug of tissue removed sufficiently acute, to allow of the proper approximation of the lips without tension in the sutures. The lower lip should be denuded

first, otherwise the hæmorrhage will obscure the field. Sufficient mucous membrane should be preserved in the centre to reform the canal. This is not always possible, and when it can not be done, a small piece of carbolized lint should be inserted to prevent union in the line of the canal. This should be removed at the end of twenty-four hours. Otherwise the canal may be occluded. This accident happened in three of the cases of Dr. E. Wilson's series, and the occlusion was overcome with some difficulty. All clots having been removed, and exact hæmostasis having been maintained for some moments, the wound is closed by inserting the needle figure two through both lips, arming it with a wire suture, withdrawing it, freeing the wire, and clamping it with a shot. The ends are then cut off close to the spot. The sutures should be removed by the tenth day—as they are difficult to get at these scissors were devised for that purpose. The vagina should be syringed twice daily with a solution of the mercuric bichloride 1-2000. A Sims speculum should be used to remove the stitches, as there is danger of tearing the freshly united surfaces apart with a bivalve. In three cases I have seen excessive bleeding, all occurring on the third day after the operations. This, however, did not seem to come from the wound, but was regarded as the result of a passive congestion of the endometrium. If the operation is successful, the relief afforded is speedy and sure, and what is more, generally permanent. The operation is simple and free from danger. It often renders sterile women capable of childbearing.

Dr. E. Wilson has confined ten women in whom he had previously performed the operation. In two there was a slight recurrence of the tears. In many cases where coitus was impossible on account of the pain and hæmorrhage it produced, the difficulty has been entirely overcome. In one case only did the operator fail to get a satisfactory result. The cervix was badly torn. It was repaired. The woman was afterwards found to have salpingitis. Though her health improved after the restoration of the cervix, she did not recover. In a future communication to the Society, I hope to show her Fallopian tubes. Allowed to run its course, the sequelæ of laceration are endless—disturbances of the catamenia, dyspareunia, ovaritis, leucorrhœa, subinvolution, grave mental disturbances, and above all epithelioma. In conclusion, gentlemen, permit me to quote the words of a distinguished gynæcologist, "these are no longer the chimeras and hobbies of the specialist, but grave and serious dangers." It is to be hoped that in time to come, a more scientific and certain knowledge of the dangers and difficulties of parturition and the means for their avoidance may enable physicians to avert the accident.

Dr. Baer inquired if the operations were done for the relief of sterility.

Dr. Wilson replied that they were for the relief of general symptoms. Ten of Dr. Ellwood Wilson's cases have since become pregnant.

Dr. Goodell remarked that he had no trouble in removing the stitches. His method was to leave the two lateral upper stitches with long shotted ends; by means of these each side of the cervix can be

drawn into the field of his bivalve speculum and the stitches removed with ease.

Dr. Montgomery bore testimony to the same and to the value of the bivalve speculum over the Sims for that purpose. He had used the double thread through the cervix and had described its uses before this Society at the meeting of Oct. 6, 1881, and published in full in the *Obstetric Gazette*, January, 1882. As regards the quantity of tissue to be removed in closing a laceration, the operator must be governed by the character of the injury, and it might not be possible to have a satisfactory result where there was an anteversion of the uterus, the flexion occurring in the lower part of the cervix, the anterior lip being elongated and hypertrophied, the posterior normal or even atrophied, for in such cases it was impossible to prevent the preponderance of tissue in the enlarged lip. He could readily understand that such a uterus becoming pregnant, at the subsequent labor the long anterior lip would form a segment over the child's head, which would almost certainly result in relaceration.

In the case which Dr. Wilson cites of extensive laceration during labor, the proper treatment would have been to perform a primary operation by the immediate introduction of sutures rather than permit her to be subjected to the necessity of a secondary operation. It would be necessary to introduce the sutures much deeper, and then to make allowance for the subsequent involution.

It is not infrequent that multiple lacerations resemble epitheliomatous disease, and are accompanied by offensive discharge. He had given temporary relief in such a case by the use of chromic acid and tannin locally. The needle used in passing sutures should not be much larger than the wire that is to follow it.

Dr. Wilson questioned the propriety of primary operations on the cervix, and thought the weight of authority against it.

Dr. Montgomery remarked that the first case by Montrose Pallen was a primary operation, and was successful.

Dr. Chas. H. Thomas remarked that at the meeting of this Society held Oct. 6, 1881, he had reported a case of *Laceration of the cervix uteri simulating cauliflower excrescence*, which he had treated 18 years before. The patient was exsanguine from hæmorrhage, which had put her life in great danger. He used glycerole of tannin tampons, and at the end of two weeks she had improved immensely, and the condition finally proved to be a deep laceration with ectropion. Before the treatment she had been seen by six experienced gynæcologists, who declared the condition cancerous, and one of them refused to be convinced that it was not so, saying, within the past four years, that "it had been cancer, it was cancer, and she would die of cancer." When the case was reported, another of the physicians who had originally seen the case inquired of Dr. Thomas if he "proposed to cure uterine cancer by means of glycerole of tannin tampons?" The menopause has since been established, the uterus, examined within the past month, was found atrophied, and the former patient

has been for nearly 20 years a hard-working monthly nurse.

Dr. Goodell thinks it pardonable to make the mistake. With all his experience he had seen two cases which he could not for some time make a certain diagnosis. There was no doubt about the existence of a laceration, but whether the angry looking growths were merely cock's-comb granulations or epithelioma was not so easy to decide. They eventually proved to be the benign.

EYE SYMPTOMS AND CONDITIONS IN BRIGHT'S DISEASE.

BY WM. S. LITTLE, M.D., OF PHILADELPHIA.

Read December 19, 1883, to the Philadelphia County Medical Society.

Among 911 cases of Bright's disease reported by different observers, changes in the retina have been observed to be associated with the kidney affection in 185 of these recorded cases; these statistics show that 25 per cent. of the cases of Bright's disease have internal eye symptoms. The statistics have varied with the several observers; the lowest average exhibiting retinitis present in 11.46 per cent., the highest in 30.15 per cent. of the cases of Bright's disease. A more exact and larger average than 20 per cent. can only be derived from a study of a larger number of cases of Bright's disease with retinitis than have as yet been recorded. The known average of 20 per cent. is sufficient to stimulate observations, and enables us to include eye symptoms among the other various manifestations of the disease under consideration, as they are exhibited by symptoms arising in other important organs and tissues of the body. The recognition of Bright's disease from lesions in the eye, in a case already diagnosed from symptoms in other organs, is not of so much importance for diagnosis, as it is a help in forming a prognosis; nor does the condition existing in the eye demand the therapeutics of special medicine.

A sufficient number of cases, however, are seen in an ophthalmic hospital, having no other symptom of Bright's disease apparent than impaired vision, which the ophthalmoscope shows is due to changes in the retina or of the nerve from disease of the kidney, or it is revealed in cases where vision is good, other ocular conditions being treated, so that in this class of cases the recognition of the lesion becomes important as a means of diagnosis.

The ophthalmic physician will diagnose Bright's disease by means of the ophthalmoscope, almost as frequently among the cases he is called to treat, as the lesion will be found to exist in cases where the eye is thus examined, for additional evidence in already diagnosed cases.

As a pathological change can be seen in the eye-ground during life, as cannot be so well viewed in other parts of the body, the observation of the lesions associated with Bright's disease, or of other diseases, as they are exhibited in the eye, is very interesting and instructive.

Externally, the puffy lower lid is the only symp-

tom, and before Bright's time, it was the first evidence of a more general anasarca, and it was looked upon as a symptom of dropsy, before the kidney was known to be the organ producing the condition. In very rare cases exophthalmus occurs from hæmorrhage into the capsule of Tenon, due to the breaking down of the orbital vessels or an excess of serum in the orbit.

With dropsy after scarlet fever, as well as that accompanying the act of gestation and the puerperal state in women, some internal affection of the eye, impairing the vision, was known to exist, the same as was later known to be present in dropsy associated with kidney disease, from other causes, in both sexes alike.

The optic nerve is not seriously involved, though gray degeneration may exist, and numerous amyloid bodies may be seen with the microscope. The retina does not always present all the stages described; the kidney disease being amenable to treatment, the retina may not undergo any further change; where it is chronic, a like progression ensues in the retina. Marked lesions at times disappear, leaving only a slight trace. The hæmorrhagic state is more severe, the sight not only being lost, but the patient's life endangered.

During gestation the same picture exists, the optic nerve may be more seriously involved. A case recently seen, and having uræmic symptoms, being unconscious two weeks prior to the delivery of the child, it being born dead; had complete atrophy of one optic nerve with retinal lesions extensive; the other nerve partially affected and slight retinal changes, patient almost entirely blind. In another case, with convulsions, only slight changes in each eye near the fovea. In succeeding pregnancies, the conditions may arise again, producing more serious changes in the retina.

The prognosis, as far as the vision is concerned, is serious, when the region of the yellow spot is encroached upon, and yet fair vision may remain after subsidence of the disease.

Can a prognosis as to the duration of the disease or to its fatality be derived from the eye symptoms? Only in the chronic stages of the disease, when retinal hæmorrhages are extensive and repeated, the heart being diseased. Traube considered the heart the immediate cause of these retinal hæmorrhages; but they exist in cases without heart trouble, and in other diseases of the system, and in intraocular conditions. Brain symptoms soon follow in these severe types of retinitis, in chronic kidney disease a general hæmorrhagic condition being developed, or uræmia may ensue. In the acute forms of Bright's disease no prognosis of any value can be formed from the eye symptoms, though severe.

As to treatment of the eye in this disease; what renders the disease of the kidney controllable, is only of advantage to the retina; leeching may be useful if the patient is not too anæmic. For the vitreous opacities, in cases where the disease is under control and the acute condition of the eye abated, electricity is of considerable value, much more so than any plan of medication.

The microscope shows a sclerosis of the retinal fibres, the walls of the blood-vessels degenerated, fatty deposits along the fibres and in the layers of the retina, also in places a pigmentation; the choroidal vessels are implicated as well.

Uræmic amaurosis is rare, Wagner finding one case in 153 of Bright's disease. Graeffe found two cases in thirty-two cases of albuminuric retinitis; it presents no retinal change that is recognizable.

As yet we cannot answer why the retinal changes occur with disease of the kidney. Does the structure of the retina and its proximity to a highly vascular tissue account for it?

INTERNATIONAL MEDICAL CONGRESS OF 1887.

The general committee appointed on the organization of the International Medical Congress to meet in Washington in 1887, is composed of the following members:

Dr. George C. Shattuck,.....Boston.
 Dr. James R. Chadwick,..... "
 Dr. Austin Flint, Sr.,.....New York.
 Dr. L. A. Sayre,..... "
 Dr. A. Jacobi,..... "
 Dr. T. F. Rochester,.....Buffalo, N. Y.
 Dr. S. Weir Mitchell,.....Philadelphia.
 Dr. J. M. DaCosta,..... "
 Dr. Christopher Johnston,....Baltimore.
 Dr. W. C. Van Bibber,..... "
 Dr. S. C. Busey,.....Washington.
 Dr. R. A. Kinloch,.....Charleston.
 Dr. H. F. Campbell,.....Augusta, Ga.
 Dr. J. G. Thomas,.....Savannah, Ga.
 Dr. T. G. Richardson,.....New Orleans.
 Dr. W. W. Dawson,.....Cincinnati.
 Dr. D. W. Yandell,.....Louisville.
 Dr. N. S. Davis,.....Chicago.
 Dr. Hosmer A. Johnson,..... "
 Dr. George J. Englemann,....St. Louis.
 Dr. L. C. Lane,.....San Francisco.
 Dr. John S. Billings,.....United States Army.
 Dr. J. M. Browne,.....United States Navy.
 Dr. R. P. Howard,.....Montreal, Canada.
 Chairman *pro tem.*, Dr. Flint.
 Secretary " " Dr. Billings.

STATE MEDICINE.

AN ACT

To Establish a Medical Board of Examiners and Licensers, and Regulating the Practice of Medicine and Surgery in the State of Ohio, and Defining the Duties and Powers of such Board.

SEC. 1. *Be it enacted by the General Assembly of the State of Ohio,* That there shall be appointed by the Governor a State Board of Medical Examiners in this State, consisting of nine reputable physicians, who shall be graduates of legal Medical Colleges, and who have practiced medicine or surgery for not less than ten years, but none of whom shall be connected in any manner with any Medical School or College;

provided, that in the appointment the several systems of medical practice recognized by the three State medical societies shall be in proper proportion.

SEC. 2. Of the nine members of said Board, three shall serve, in the first instance for three years, three for four years, and three for five years. This period of service shall be determined by lot. All appointments made in said Board of Examiners, at the expiration of the several terms fixed above, shall be uniformly made for the period of five years each. All appointments shall be made, and all vacancies occurring in said Board, from whatever cause, shall be filled without delay, by the Governor, from fifteen persons nominated by each of the several State Medical Societies, (in case such nomination shall be made) of a practitioner of the system of practice that had previously been represented by the seat so vacated.

SEC. 3. The persons so appointed shall take the oath of office prescribed by the seventh Section of the fifteenth Article of the Constitution of the State, before entering upon the duties of their office, and file a certificate of their having done so with the Secretary of State.

SEC. 4. The said Board shall, on a day to be fixed by them, in every two years, elect from their own number a President and Secretary, who shall hold their offices for the term of two years, and until their successors are appointed or elected, and enter upon the duties of their offices. The said Board shall be a corporation, by the name and style of "State Board of Medical Examiners and Licensers of Ohio," and have and use a common seal, and as such corporation may sue and be sued, contract and be contracted with, plead and be impleaded, to the extent to enable it to carry out the powers conferred upon said Board by said Act. Said Board may make and adopt all necessary rules and regulations and by-laws, not inconsistent with the Constitution and laws of this State or of the United States, to enable it to perform its duties and transact its business under the provisions of this act. A majority of said Board shall constitute a quorum for the transaction of business. A meeting of the Board may be called by the President or any three members thereof.

SEC. 5. The said Medical Board shall examine all applicants for license to practice medicine or surgery in this State. They shall meet quarterly, on the second Tuesday in January, April, July and October, and at such meetings shall faithfully examine all candidates referred to them for that purpose by the President of said Board, and the Secretary shall keep a detailed report in writing of all questions and answers of each examination, together with a separate opinion of each examiner as to the qualifications and merits of the candidate in each case. The examinations shall be conducted in writing, except clinical, which may be oral; the President and Secretary of the Board shall have authority to administer oaths, and the Board to take testimony in all matters relating to its duties.

SEC. 6. Such examination shall be in hygiene, anatomy, physiology, histology, pathology, principles and practice of medicine, chemistry, surgery, obstetrics, materia medica and therapeutics, and such

other branches in the several departments of medical science as said Board may agree upon. The question forming such examination shall be the same for each class of candidates offering themselves, with the exception of principles and practice of medicine and therapeutics, in which branches the question for each candidate shall be prepared by the representative in the Board of Examiners of the system of practice to which such candidates wish to be licensed.

SEC. 7. The said reports and action of the examiners shall forever be a part of the public records of said Board.

SEC. 8. Any person, on paying \$25 into the treasury of the State of Ohio, and on presenting a receipt for the same to, and applying to the Secretary of the Board for the aforesaid examination, shall receive an order addressed to the aforesaid Medical Board, instructing them to examine the candidate at the next quarterly examination, providing proof satisfactory to the President is first given, that the candidate is over 21 years of age, of good moral character, and has received a diploma issued to him or her, conferring on him or her the degree of doctor of medicine, from some legally incorporated medical college held to be in good standing by said Medical Board; and should any candidate fail, he shall have the privilege of appearing again before the Board, at the next meeting, without any additional fee.

SEC. 9. The President and Secretary of said Board, after finding that seven members of said Board have voted in favor of such candidate, shall issue to him or her a license to practice medicine and surgery in the State of Ohio.

Said Medical Board may refuse to recommend a license to individuals guilty of unprofessional or dishonorable conduct, and they may revoke a license for like cause, upon a unanimous vote, after giving the accused an opportunity to be heard in his or her defense.

SEC. 10. The Medical Board shall establish rules and regulations as they may deem necessary to insure the faithful execution of this Act.

SEC. 11. On or before the first day of July, A. D. 1885, every person who is a graduate of a reputable Medical College, or legal practitioner, or has complied with Sections eight and nine of this Act, shall, before continuing or commencing to practice, register in the Probate Judge's office, in a book kept by said Judge for such purpose, where he or she practices or intends to practice medicine or surgery, his or her name, residence and place and date of birth, together with the date of his or her diploma, and by what institution granted, with his or her license to practice medicine or surgery within this State; at the same time the person registering (unless a graduate in medicine and surgery of some reputable Medical School or College, or legal practitioner practicing medicine or surgery at the time of the passage of this Act, within the State of Ohio), shall exhibit both license and diploma herein required to the Probate Judge, and all persons shall subscribe and verify by oath or affirmation, before a person duly qualified to administer oaths under the laws of this State, an affidavit containing a plain statement of all the facts as afore-

said, including his or her age, and shall file said affidavit and copy of said diploma with said Probate Judge. The person so registering shall pay to the Probate Judge one dollar, of which sum the said Probate Judge shall receive fifty cents for such registration and other duties prescribed in this Chapter, and the remaining fifty cents shall be paid over by said Judge to the Treasurer of the State of Ohio, within thirty days after its receipt, for the benefit of the Medical Board. Every graduate in medicine and surgery of any reputable medical school or legal practitioner in this State, at the time of the passage of this Act, shall register and comply with all the requirements of this Chapter, except producing a license from the State Board, and every person desiring to practice medicine or surgery after the passage of this Act, who is not a graduate in medicine or surgery of some reputable Medical School, or a legal practitioner practicing medicine or surgery in this State, at the time of its passage, must appear before the Medical Board of Examiners and obtain a license, as is provided in Sections eight and nine of this Act. Nothing in this Act shall be so construed as to prohibit medical consultation in different counties in the State, between legally qualified and registered physicians of this and any other State.

SEC. 12. A person who shall wilfully swear falsely to any statement contained in the affidavit required by Section eleven of this Act, shall be deemed guilty of and subject to conviction and punishment for perjury, and any person or persons who violate any other of the provisions of this Act, or who shall practice medicine or surgery in this State under cover of a diploma or certificate unlawfully issued and illegally obtained, or without a license, as provided for in this Act, shall be guilty of a misdemeanor, and on conviction thereof shall be punished by a fine of not less than \$100 nor more than \$500 for the first offense, and for each subsequent offense by a fine as aforesaid, and by imprisonment not less than thirty days nor more than one year in the county jail, or both. The fine, when collected, shall be paid to the Treasurer of the State for the benefit of the Medical Board.

SEC. 13. For the purpose of this Act, the words "practice medicine or surgery" shall mean to annex the letters M.D. to one's name, or to suggest, recommend, prescribe, direct or employ, as a matter of business, or for a fee, for the use of any person, any drug, medicine, appliance, apparatus, or other agency, whether material or not material, for the treatment, cure, relief or palliation of any real or supposed ailment or disease of mind or body, or for the treatment, cure or relief of any wound, fracture or bodily injury or infirmity, or deformity. And for the purpose of this Act, the words legal practitioner shall mean one who has been reputably engaged in the practice of medicine or surgery in this State for ten consecutive years last past, at the time of the passage of this Act.

SEC. 14. The money paid into the State Treasury under the provisions of this Chapter, shall be appropriated for and assist in defraying the expenses incurred under the provisions of this act.

SEC. 15. Nothing in this act shall apply to com-

missioned medical officers of the United States Army or Navy, or of the U. S. Marine Hospital Service, nor to any members of the house-staff of any legally incorporated hospital during their term of service as such.

SEC. 16. Annually, on or before the fifteenth day of September, every Probate Judge in the State shall furnish a certified copy of the names, address and residence, place of business, and by what authority they are permitted to practice, of all persons practicing medicine or surgery in his county, not previously reported, to the Secretary of the Medical Board, and said Secretary shall record the same in a book to be kept by him for that purpose.

SEC. 17. The Medical Board shall have the power to strike the name of any practitioner of medicine or surgery, guilty of unprofessional or dishonorable conduct, from the registry list, and to refuse to allow his name to be recorded or to practice medicine or surgery in this State, upon unanimous vote, after giving the accused an opportunity to be heard in his defense.

SEC. 18. The Secretary shall receive a salary to be fixed by the Board. The other members of said Board shall each receive \$10 per day and necessary expenses, for each day actually and necessarily employed by them in the discharge of the duties of their office. The State Board shall audit all bills made out in due form and verified by the member rendering the service or incurring the expense of traveling in the performance of the duties of his office. Such bills, when approved by the Governor, shall be paid out of the State Treasury.

SEC. 19. The Governor shall remove any member of the Board for unprofessional or dishonorable conduct, upon the recommendation of two-thirds vote of the Board.

SEC. 20. The sum of \$1,000 per annum, or so much thereof as may be deemed necessary by the Board, is hereby appropriated to meet the necessary and legitimate expenses of the Board, should the fund raised by the provisions of this act not be sufficient to meet such expenses.

SEC. 21. No part of this act shall be considered as applying to those practicing dental surgery or dentistry.

SEC. 22. The Adjutant-General shall procure suitable room for the use of the Board at Columbus.

SEC. 23. All other acts or parts of acts inconsistent with this act are hereby repealed.

SEC. 24. This act shall take effect July 1, A. D. 1885.

FOREIGN CORRESPONDENCE.

LONDON LETTER.

LONDON, October, 1884.

The results of the conference of the Red Cross Associations held at Geneva have, according to Surgeon-General Longmore, given satisfaction to the members who attended it. Amongst the matters discussed was the employment of the electric light for searching for the dead and wounded on the bat-

tle field. Baron Mundy, basing his remarks upon the experiments made at Wichen in October, 1883, and at Aldershot in July last, as well as those undertaken near Geneva during the conference—which have confirmed the practicability of clearing the field of the wounded during the night following a great battle, and burying the dead after establishing their identity, expressed the hope that in future wars the electric light would be employed in all cases in which military commanders permitted its use. The questions “Shall the Associations acquire during peace the articles and apparatus required in war,” and “Is it necessary that the drawings and documents referring to ambulance material should be exchanged between the central committees?” was postponed to the next conference which is to take place in two years, with a view of its being examined by the central committees, as well as one dealing with the principles which should be observed in reports and communications of the central committees.

The influence of emigration in spreading disease has lately been under the careful attention of the Local Government Board. The report of their medical officer, Dr. Blaxall, is of a very exhaustive character. His inquiries took place during the year 1882, the immediate occasion of them being the representations from the United States to the effect that small-pox was believed to have been imported into that country by immigrants from Europe. The question having thus been opened up proved to contain several points of a character at once important and intricate. The tremendous growth of emigration has brought with it a train of sanitary consequences, whose relation to the health of the general community has been somewhat overlooked. During the five years from 1876 to 1881 upwards of 1,300,000 emigrants left the British Isles. This, it must be remembered, they did in large batches, between whom during their period of travel the closest intercourse necessarily existed. In fact it may be said generally that emigration on a large scale is a system containing in itself every element favorable to the spread of infectious disease, the only wonder is that more cases of infection are not distinctly traceable to their movements. That this is not the case shows how much has been done by organized medical inspection. Dr. Blaxall has come to the conclusion that the amount of disease exported by emigrants from the British Isles can not be reckoned as large when the exceptional conditions of the people are taken into account. The report as a whole goes to show that there are still some very desirable improvements which are lacking. The chief of the evils which are distinctly remediable would appear to be the lack of organized relation between the shipping companies and the sanitary authorities. Nor does the system of sanitary inspection of lodgings by the shipping companies appear to be uniformly satisfactory. It appears that there are moments in the emigrant's career when he may not be directly amenable to the local sanitary authorities and when the precautions of the shipping companies are not necessarily adequate. In such cases a consolidation of power appears to be required. Another point on which there is room for

improvement seems to lie in the imperfect sanitary condition of many of the foreign lines of steamers which land immigrants on British shores. Indeed, it is in these cases Dr. Blaxall finds the greatest cause for dissatisfaction. An immense number of foreigners, chiefly Germans, Poles, Russians, Jews and Scandinavians enter England or Scotland for the purpose of reëmbarking for the United States or Canada. These transmigrants are shipped from their own country under a variety of regulations, which lead to considerable complication. The vaccination laws of Sweden only apply to children over two years of age, thus all the precautions taken against the spread of this disease at English ports may be neutralized by the importation of small-pox through the infant of some foreign transmigrant. It must be said, on the other hand, that one frequent source of infection is largely cut off which exists in the case of the ordinary British emigrant. That is the supervision of his lodging, which is arranged by the shipping companies, who have regular houses under strict supervision where the transmigrants are quartered pending the departure of the ocean steamer. In the case of the emigrant there is no such arrangement, and unless he have friends at the port whence he sails, he is usually compelled to find quarters for himself for one night at least, and it may be surmised that latent disease is frequently introduced into the emigrant ships through this cause. Prior to embarkation the emigrants are subjected to strict medical examination at the hands of officers appointed by the Board of Trade. The smallest signs of disease are looked into most minutely, and the condition of the children is particularly ascertained. So far as embarkation from the English ports is concerned, the report leaves one with the impression that authority is at least on the high road to perfectly satisfactory regulations. The Local Government Board state that since this inquiry several improvements have been made at more than one English port. The spread of disease in this manner is, after all, not absolutely preventable. Latent cases will of course pass the strictest scrutiny from time to time. With the terrible evidences of the cholera now before us, it is to be hoped that the Local Government Board and the Board of Trade will continue the work of practical inquiry which they have commenced.

The application of pyrogallic acid in phagedenic chancre is a new treatment, which consists in dressing the sore with an ointment of vaseline and pyrogallic acid, (four parts vaseline, one part pyrogallic acid). This form is not adapted to the treatment of superficial ulcers without deep sinuses. In the latter condition a powder consisting of pyrogallic acid and powdered starch (1-4) should be dusted into all parts of the ulceration. For general use the following formula is useful: Pyrogallic acid, 10 drachms; vaseline 4 ounces; starch, 10 drachms. The dressing must be renewed daily. At the Vienna Hospital, however, the employment of pyrogallic acid in the treatment of skin diseases was attended with fatal results, due to the deoxidizing action of the pyrogallic acid upon the blood-corpuscles. So it must be necessary to use care in its use.

Sir Prescott Hewitt takes the late Mr. Cæsar Hawkins' place as one of Her Majesty's sergeant-surgeons-in-ordinary.

One of the best collections of Wedgwood in the country—namely, that belonging to Dr. Shadford Walker, of Liverpool, the well-known oculist—will be sold at auction next March in London. Dr. Walker, over and above his professional achievements, is noted for three special tasks or hobbies—first for his china, secondly for his illuminated MSS. and thirdly, for his successful cultivation of orchids in the very heart of a smoky city.

DOMESTIC CORRESPONDENCE.

BIOGRAPHICAL SKETCH OF PROFESSOR P. L. PANUM., M.D.,

President of the Eighth International Medical Congress held at Copenhagen, Denmark, 1884, in the month of August, beginning on the 10th and ending on the 16th.

Professor Peter Ludwig Panum was born on the 19th of December, 1820, in a small town called Ronne, on the Danish island Bornholm, in the Baltic Sea, where his father was a physician.

In the year 1840 young Panum was sent to the University of Kiel, and from there went to the University of Copenhagen, where he in 1845 took his degree. As a student he already lectured with great success, and in consequence of his deep devotion to the study of the physiological branches of the science, he commanded universal attention. In 1846 when almost the whole population of the Faroe islands was suffering from the measles, Panum went thither by order of the Danish government, and during his six months' sojourn in that far away place, succeeded in gaining a reputation as a superior and remarkably energetic young man, and made several interesting discoveries in the contagious venom of the measles. Shortly after returning home he went to Berlin, but on the outbreak of the war he again returned to Copenhagen, and was appointed surgeon on board the man of war "Geiser," where he discharged his duties as a brave officer. It is characteristic that Panum never rested in his youth and wanted to be everywhere at once, to take an active part in all affairs of medical interest. When the cholera epidemic in 1850 was ravaging Denmark, he visited all the worst attacked places, and had good opportunities to study that frightful disease; the following year Panum took the Medical-Doctor degree and then went to Paris, where he studied a year under the eminent physiologist, Claude Bernard.

When he returned home he was appointed to the professorship in physiology at the University of Kiel, where he was greatly admired for his scientific endeavors and strong sense of justice, and beloved for his amiability; he was a rare conscientious teacher, and devoted to his profession. He succeeded in filling his pupils with that same enthusiasm that he himself displayed, and brought them not to work mechanically but to throw their whole souls into the

study, for he sincerely believed in the old saying that "when a thing is worth doing at all, it is worth doing well." Though he was quite a young man, he had gained a name through all the important and interesting results of his studies, and from his very youth had been renowned, honored and respected as one of the most prominent physiologists of the day. But through all his career he never once allowed himself to be carried away with his success, neither has he ever, in public or private life, made a display of his accomplishments; has always been and still remains the quiet and unassuming gentleman, the skilful physician and the sober examiner.

It was more particularly in chemical physiology that Panum from boyhood upwards took so great an interest, "the study of the phenomena of the manifestations of life," laws and causes regarding both animals and plants, and above all the human being. In order to acquire the secrets of the manifestations of life the physiologist must first thoroughly understand the building of the system and of each of the special organs, he must also have a thorough knowledge of physics, chemistry and anatomy. Panum has perfected himself in each, and all combined make him the great physiologist he is. It is a grand and noble science to which the professor has devoted his life, a science that interests the whole civilized world. The Congress at Copenhagen proved it. The professor has never once given in, but with persevering energy has always carried his investigations through; when he once has undertaken anything he is sure to do it and to succeed. His great interest in the late Congress was beyond doubt one of the main causes of its success, for he never does a thing in halves.

Sir James Paget, President of the Seventh International Medical Congress, said: We thought the London Congress grand, but this is yet grander, and the most successful ever held. It is characteristic of Panum, and shows his profound physiological interest, that although a professorship at the Copenhagen University from his youth, had been his greatest ambition, he would, when it was offered to him, accept it only on the condition that a physiological laboratory was erected there, and remained in Kiel until he received consent to build one. As leader of this institution he has had a great influence on medical science, and being a strong and hearty man, he will undoubtedly have still more in years to come, using his great faculties for the benefit of humanity.

In a few short sketches, Professor Panum is a loving husband and father, an honored and true man of science, and an amiable colleague and host. He is a member of several scientific societies, and is decorated with the Cross, "Commander of Dannebrog," etc., etc. In 1887 the Professor will visit the United States of America, and cede the presidential dignity to one of his American colleagues. When Dr. Billings, in the name of the American physicians, brought that most cordial invitation, and Washington was proposed as the place for the meeting of the Ninth International Medical Congress in 1887, and enthusiastically accepted, Professor Panum's last words were:

Au revoir, my friends. We meet again in Washington, on the other hemisphere.

TO ALL THE PHYSICIANS OF THE UNITED STATES OF AMERICA,

and especially to those who honored the Copenhagen "International Medical Congress" with their presence,

this Biography is respectfully dedicated,
by the Author,

OTTO HAUBERG-KNUDSEN.

BOOK REVIEWS.

THE NATIONAL DISPENSATORY, Containing the Natural History, Chemistry, Pharmacy, Actions, and Uses of Medicines. Including those Recognized in the Pharmacopœias of the United States, Great Britain, and Germany, with Numerous References to the French Codex. By ALFRED STILLE, M.D., LL.D., Professor Emeritus of the Theory and Practice of Medicine and of Clinical Medicine in the University of Pennsylvania, and JOHN M. MAISCH, Ph.D., Professor of Materia Medica and Botany of the Philadelphia College of Pharmacy. Third Edition, Thoroughly Revised, with Numerous Additions. With 311 Illustrations. Philadelphia: Henry C. Lea's Son & Co. 1884.

This ponderous volume of 1755 pages, is published in the usually good style of the well-known publishing house of Henry C. Lea's Son & Co. The two former editions have made the general merits of the work so well known that an extended notice of this edition is unnecessary.

The present edition bears all the marks of a careful and full revision, in which the latest revision of the several national pharmacopœias has been rendered available. More than 100 pages of additional matter have been added to this edition of the work, making it perhaps as complete and valuable as any work of the kind in the English language. From Jansen, McClurg & Co., Chicago.

DISEASES OF THE THROAT AND NOSE, by MORELL MACKENZIE, M.D. London: 1884. P. Blakiston, Son & Co. Philadelphia. Volume II. Diseases of the Œsophagus, Nose, and Naso-pharynx.

The first volume of this work, which appeared several years ago, is already so well known to the profession that it is unnecessary to commend the present volume.

We may merely state that it treats of the diseases of the œsophagus, nose and naso-pharynx in the same terse and lucid style which characterizes other works by the same author, and in the comprehensive manner observed in the first volume of the present work. Those who have the first volume have been anxiously waiting for the second, and physicians who are not familiar with the first, may rest assured that in this work they will find one of the most satisfactory treatises that has appeared on any special subject for many years.

E. F. I.

THE LOCK-JAW OF INFANTS (TRISMUS NASCENTIUM) OR NINE-DAY FITS, CRYING SPASMS, ETC.; ITS HISTORY, CAUSE, PREVENTION AND CURE. By G. T. HARTIGAN, M.D. Washington, D. C.: 1884. Cloth, 123 pp.

This little volume is the result of the observation and record of 49 cases of spasm in infants. The author's conclusion is that this symptom is the result of pressure caused by the displacement of either the occipital or parietal bones, and that the cure for the disorder is the replacement of these structures either by operation, manipulation, or simple attention to the position of the patient.

He demonstrates that such pressure may be mischievous or possibly fatal, but it would appear that his enthusiasm had carried him a little too far, for in the infant, irritation from many sources may produce convulsions, and certainly the histories given do not warrant the assumption that all other causes than cranial displacements can be eliminated.

Lusk states that a displacement of the occipital bone is a usual consequence of labor, and our author is again weak in the fact that he has not demonstrated by the examination of healthy children that the very slight displacements observed are abnormal.

STUDENT'S MANUAL OF ELECTRO-THERAPEUTICS. By R. W. AMIDON, A.M., M.D. New York: G. P. Putnam's Sons. 1884. Cloth, 93 pp.

The book embodies the lectures delivered in the course on therapeutics at the Woman's Medical College of the New York Infirmary. The author carries out the plan of his work so successfully that a quotation from the preface is the best possible review.

Of the use of electricity he says: "Its showiness, its instantaneous and startling physiological effects, and its name, popularly synonymous with life, have long made and will long continue to make it a fashionable remedy, a cure-all for imaginary diseases, a popular placebo, a gold mine for charlatans and symptom-treating physicians, who let their patients make the diagnosis and suggest the treatment."

In mitigation of these evils the aim of the writer has been, first, to present that amount of the subject of electro-physics necessary to the proper understanding of the construction and use of medical batteries; second, to point out the common, gross physiological effects of electricity; third, to outline the methods of electro-diagnosis; fourth, to determine the kind of electricity and its mode of application indicated in different pathological states.

SHAKESPEARE AS A PHYSICIAN. Comprising every word in any way relating to medicine, surgery or obstetrics, found in the complete works of that writer, with criticisms and comparison of the same with the medical thought of the present day. By G. PORTMAN CHESNEY, M.D. G. H. Chambers & Co. St. Louis. 1884. Cloth, 226 pages.

This volume is published in good style. To those who are familiar with the writings of Shakespeare and admire them, the book should possess much interest, as the comments and interpretations of the author

are calculated to develop more fully the meaning of the text. Those who have time and a taste for looking up the curiosities of medical literature will also find much in this volume to interest them.

MISCELLANEOUS.

OFFICIAL NOTICE.

ANNUAL DUES from members of the Association—*Five Dollars* per annum—are payable directly to the Treasurer. Such payment entitles them to receive the JOURNAL of the Association for one year.

SUBSCRIPTIONS TO THE JOURNAL from those who are not members should be forwarded to the office of publication, Chicago.

BACK VOLUMES OF THE TRANSACTIONS may be procured, at reduced rates, by addressing the Treasurer.

THE INDEX to the 33 Volumes of Transactions will be forwarded, postpaid, on receipt of *One Dollar* by the Treasurer.

According to a resolution passed May 9, 1884, at the Washington meeting, continuous payment of Annual Dues is required, to retain permanent membership.

RICHARD J. DUNGLISON, M.D.,
Treasurer.

Lock Box 1274, Philadelphia, Pa.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM OCTOBER 18, 1884, TO OCTOBER 24, 1884.

Wolverton, W. D., Major and Surgeon, granted one month's leave of absence, to take effect when his services can be spared by his post commander. (Par. 4, S. O. 211, Dept. East, Oct. 16, 1884.)

Vickery, R. S., Major and Surgeon, during temporary absence of Major J. C. McKee, Surgeon U. S. A., Middle Division of the Department, in addition to his other duties, will assume charge of the office of the Middle Division. (G. O. 34, Hdqrs Dept. Col., Oct. 8, 1884.)

Strong, Norton, First Lieutenant and Assistant-Surgeon, assigned to duty at Fort Union, N. M. (S. O. 198, Dept. Mo., Oct. 4, 1884.)

Phillips, Jno. L., First Lieutenant and Assistant-Surgeon, transferred from Dept. of the East to Dept. of Dakota. (S. O. 245, A. G. O., Oct. 18, 1884.)

Winne, C. K., Captain and Assistant-Surgeon, in addition to his duties as Post Surgeon at Benicia Bks., will also attend the sick at Benicia Arsenal, Cal. (S. O. 122, Hdqrs Dept. Cal., Oct. 13, 1884.)

Havard, Valery, Capt. and Assistant-Surgeon, assigned to temporary duty at Fort Schuyler, N. Y. Harbor, N. Y. (Par. 2, S. O. 211, Dept. East, Oct. 16, 1884.)

OFFICIAL LIST OF CHANGES IN MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING OCTOBER 25, 1884.

Bloodgood, Delavan, promoted to the grade of Medical Director, Aug. 22, 1884.

Oberly, Aaron S., promoted to the grade of Medical Inspector, March 28, 1884.

Wells, Henry M., promoted to the grade of Medical Inspector, Aug. 22, 1884.

MALFORMATION OF THE FEMALE SEXUAL ORGANS, RESULTING FROM ARREST OF DEVELOPMENT.

BY B. BERNARD BROWNE, M.D.,

Professor of Gynecology and Obstetrics in the Baltimore Polyclinic and Post-Graduate Medical School; Professor of Diseases of Women in the Woman's Medical College of Baltimore; Fellow of the American Gynecological Society, etc.

Read in the Section of Obstetrics and Diseases of Women, American Medical Association, May, 1884.

We learn the functions of an organ, not only by observing the part it performs when present in the system, but also by noting the consequences of its absence.

The cases which we will consider render it evident that the excitement and increased vitality of the sexual organs by which menstruation is preceded are not dependent, as was once supposed, upon any congestion or distension of the vessels of the uterus, or upon any other change in the condition of that organ.

They also show us that the peculiar external characteristics of the female form, and the possession of sexual sensibility, are not all owing to the uterus, and are in no way connected with its presence or development.

Indeed there can be no doubt that the often quoted aphorism of Van Helmont—*propter solum uterum mulier est id quod est*—is perfectly erroneous, and that the distinguishing attributes of womanhood derive their origin not from the uterus, but from the far more important energies of the ovaries and Fallopian tubes.

As many of the abnormal and pathological conditions of the female sexual organs are the result of defective development, occurring either during the period of intra-uterine growth or at the period of puberty, and as several of the cases which I will relate in this paper are the results of such arrest, it may be well to pass briefly in review the different stages of normal development.

About the sixth week of intra-uterine growth the primary elements of the uterus, consisting of a pair of filamentous organs situated on either side of the inferior portion of the vertebral column, and between it and the Wolffian ducts, make their appearance.

These cords, which at first are solid, afterwards become perforated, and are known as Müller's ducts; out of these the Fallopian tubes, uterus and vagina are developed.

Posterior to Müller's ducts and anterior to the rectum a mass of tissue is developed, which helps to form the recto-vaginal wall above and the perinæum below.

Anteriorly Müller's ducts unite with the lower portion of the bladder, and aid in the formation of the urethra, forming the upper portion of its posterior wall.

At about the seventh week the upper portion of Müller's filaments become slightly enlarged and club-shaped; at the lower end of this enlargement they gradually coalesce, and at this point the round ligament is given off, the upper portion separates and forms the Fallopian tubes, while the lower portion forms the uterus and vagina. The point where the coalescence occurs, and where the round ligaments originate, affords a sure point of demarcation between the uterus and Fallopian tubes which in many cases is of great importance.

At about the eighth week the lower portion of the cords, which are hollow, gradually coalesce until by union they exhibit a right and left cavity separated by a septum.

The lower portion of this septum gradually disappears and the outer walls become somewhat thicker until about the fifth month, when the uterus and vagina are distinctly separate.

The upper portion of the uterus at this period is represented by two diverging horns or processes.

During the sixth and seventh months the uterus becomes more cylindriciform and of greater bulk, its horns diverge less than before, and from being drawn into the substance of the uterus they seem to be disappearing.

At this period the increased bulk becomes more marked in the cervix, its walls exceeding in thickness the walls of the body of the uterus.

During the eighth and ninth months of foetal life the disproportion between the thickness of the walls of the body and neck of the uterus continues, and the substance of the cervix considerably exceeds that of the body of the uterus.

This condition exists at the time of birth and is known as the *uterus foetalis* or *infantilis*. The uterus has now undergone its primary development and its further growth ceases until the period of puberty, when it is to perform its normal function. A few changes, however, do take place in it during this

period, at the time of second dentition, the *palma plicata* of the body of the uterus disappears, and the bulk of the body and cervix become more equal and the organ descends somewhat in the pelvic cavity.

Cases of Amenorrhœa from Congenital Malformation. Miss J. D., age 21, of small stature and delicate physique, has never menstruated nor had any of the premonitory symptoms, the breasts were slightly developed. The external organs of generation were of the ordinary appearance, but when the labia were separated the urethral orifice which was patulous and would admit the tip of the index finger came into view, but the orifice of the vagina was closed, or rather ended in a cul-de-sac about an inch and a quarter deep. The index finger of the right hand was passed gently into the bladder and two fingers in the rectum in order to determine whether the uterus was present or not, when the anterior wall of the rectum was pushed forward by the fingers it came in contact with the finger in the bladder, only the septum being between, no uterus could be felt, in fact about the same sensation was obtained as when the finger in the vagina presses its anterior walls against the finger in the bladder, no ovaries could be detected, the girl had suffered from repeated nasal hæmorrhages, not, however, of a periodical character, she also suffered at times with severe headaches.

In this case the examination revealed the fact that the uterus was not present unless in a very rudimentary form, that although the ovaries could not be felt they were probably partially developed, and that an almost complete arrest of development had taken place in the lower portion of Müller's ducts.

Miss A. R. had suffered for four or five years with periodical headaches, accompanied by intense pain in the abdomen, had never menstruated, although she had taken medicine at various times for the purpose of bringing on her courses. Upon making an examination of the parts the external genital organs were found normal, the hymen which was thick and hard was intact, and nearly closed the vaginal orifice, a small opening only existing in the centre, on passing a sound through this opening a cavity was found beyond which contained no fluid. The hymen was cut through and a small infantile cervix was found projecting into the vagina, the uterus measured only an inch and a half in depth, more than an inch of this belonged to the cervix, the body of the uterus was very thin, and its cavity was not over a quarter of an inch in depth.

Considering this case as one of undeveloped infantile uterus where the arrest of development had taken place either just before or about the time of puberty, some means seemed called for to restore the normal nutrition of the organ and to stimulate it to perform its physiological function.

For this purpose the faradic current was used of moderate strength, the cathode to the cervix, the anode to the spine along the lumbar and sacral regions. The first application was made a few days before the expected time for the return of the periodical headaches, at which time she noticed a slight show of blood, the first she had ever seen; her head-

ache was much diminished and she had only slight pains in the pelvic region.

Her second menstruation occurred more freely, and her general health has much improved; by the third month her menstruation was about normal and her uterus measured $2\frac{1}{4}$ inches. The application was continued once a week for three months; after the first month the cathode was passed *into the uterus*.

Miss M. T., age 19, of small figure and defective development, was brought to me by her aunt, who stated that the girl had never had her courses, but that lately she had been suffering intense pain in the head, which occurred about once a month, and was generally relieved by the occurrence of a hæmorrhage from the nose, which frequently continued for several hours. Upon examination, the uterus was found small, its cavity measuring only one inch, the cervix presenting the appearance of a small nipple projecting into the vagina, the external os was small, admitting with difficulty the smallest probe. The faradic current was used as in the preceding case and in about three months normal menstruation was restored; the girl developed, and her general health became good; the uterus enlarging to about its proper size.

Kussmaul makes the following very practical distinction between the two arrests of extra-uterine development termed *Uterus Fœtalis* and *Uterus Infantilis*.

The uterus fœtalis has the form of that belonging to a fœtus at full term. The body is small, six or nine lines in height, and ten to twelve in breadth; the neck, which forms the greater mass, is from 18 to 20 lines in length. The cavity of such a uterus, especially that of the body, is either wanting or very small.

In those cases, however, which we regard as *uterus infantilis* the organ, on the whole, has the form of a virgin one, but is altogether smaller; the most important anomaly is an excess of connective tissue in its walls, which renders them denser and more resisting, the mucous membrane is paler and thinner, and in many instances the rugæ of the cervical canal are imperfect.

The vaginal portion of such a uterus is either very small or entirely absent. Sometimes its presence is indicated by a wart-like prominence with a slight depression leading to the cervical canal.

Mrs. E. S., age 25, married four years; sterile; suffers from amenorrhœa and excessive pain; has her menses at the regular time, but only a few drops. Her uterus was found anteflexed, the cervix conical and indurated. This condition is a very frequent one in sterile women, and results from an arrest of development taking place at the period of puberty. According to Emmet, flexures of the cervix have their origin at this period, or shortly afterwards, by the balance being lost between the relative growth of the body and cervix.

From the earliest development of the uterus, as a rule, until pregnancy, some degree of anteversion exists. With the uterus in this position, the neck cannot be developed to its full length without forcing the cervix forward in the axis of the vagina in the di-

rection offering the least resistance. As the body of the uterus lies forward, the cervix must become bent upon itself at or near the vaginal junction, and thus the flexure is formed. This must take place or the uterus will become retroverted, the result being determined by the fullness or absence of the posterior cul-de-sac of the vagina.

When the cervix is small enough in diameter to be readily bent upon itself the flexure is formed, but if the contrary be the condition and the cul-de-sac be small, retroversion of the organ will occur. Versions of the uterus when they result from defective development have their origin most frequently in a deficient development in the shape and size of the vagina. In such instances the vagina terminates around a cervix of unusual length without forming a posterior cul-de-sac. The consequence is that the neck of the uterus being too long is necessarily crowded forward in the vagina, in the direction offering the least resistance, and retroversion follows. This result may be considered a mechanical one and due to a congenital curve or defect.

Lateral Versions are seldom congenital, but ordinarily result from shortening of the broad ligament after an attack of cellulitis.

In the two following cases of arrest of development, I had the opportunity of seeing the post-mortem results:

CASE I. A lady, aged 19, who four days previous to her death, had a profuse epistaxis lasting about 48 hours, which, taken with the fact that she had never menstruated, and that the nose bleedings were frequent, induced an examination post-mortem of the organs of generation.

The vulva was natural in formation and appearance, with the *mons veneris* and external surface of the labia major well covered with hair; no clitoris could be perceived. The vagina was a simple cul-de-sac about two inches long. It was destitute of rugæ, hymen and caruncula, and had no communication with an os uteri. The bladder and rectum were firmly adherent to each other instead of being separated by a uterus, which was searched for in vain. The bond of adhesion between the bladder and the rectum was the broad ligament occupying its usual position, of a crescent shape, and embedded in a thin horn of this crescent near the summit about one inch and a half internal to, and on the line with, the iliac fossa, was a nodular body dense in structure of the size of an apricot kernel, to which were attached a perfect ovary, Fallopian tube and round ligament. The parts adjacent to the ovaries were greatly congested. The nodular bodies referred to were what would correspond to the superior cornua of the uterus, and the non-striated muscular fibre found in a section confirmed this impression of its being uterine tissue. In this case the patulous condition of the urethra led to the belief that sexual intercourse had taken place.

Case 2. Mrs. A. P. F., age 34, married 10 years, had never menstruated or manifested any menstrual molimen. She was exceedingly well developed and there was no deficiency of sexual desire or excitability. On the contrary, she had been subject to intense sexual excitement occurring at irregular inter-

vals and generally continuing several days. The mammae, the vulva, the mons veneris, and the pelvis externally were found to be perfectly developed.

The vaginal touch showed that the vagina terminated in a cul-de-sac at a depth of 2 inches. A steel male bougie carried into the bladder could be swept freely to the right and left, and the finger introduced into the rectum, could be felt pressing against it; through the walls of the bladder and rectum a slight elevation on each side of the median line could be felt and was regarded as a rudimentary uterine mass.

On account of the severity of the epileptic seizures her intellect had become gradually impaired.

The post-mortem examination disclosed the following facts. A hard conical nodule was found, on introducing the hand through the abdominal incision, on each side, the two meeting behind the bladder. The finger introduced into the vagina was arrested at about 2 inches, and above this point to the union of the nodules above, a distance of about $1\frac{1}{2}$ inches, nothing existed in the way of fibrous cords, nor the slightest canal.

This was a uterus bipartitus, the body and cornua were solid and contained no cavity.

Complete absence of the uterus has been doubted by many, partly because a more careful study of cases recorded as authentic rendered the presence of rudiments of a uterus presumable or evident, and partly because cases of absence of uterus which are founded simply on examination of living women do not seem sufficiently conclusive, and to this class by far the greatest number of recorded cases belong.

Inasmuch as the Fallopian tubes, uterus and vagina are developed from Müller's ducts, as we have seen, the existence of any, even a small portion of the vagina may be accepted as evidence that the development of the uterus and Fallopian tubes also has at least been attempted, though that development may have been interrupted at any point. Some rudiments of the uterus may therefore be assumed to exist. Notwithstanding this it has been proved that the uterus may be entirely absent, and in such cases the ovaries and tubes may either exist in a rudimentary condition or be also entirely absent. In the former case the rounds ligament branch off at the inner extremities of the ovaries.

If the uterus, ovaries and tubes are absent the external genitals may be either perfect or defective. Whenever the external genitals are perfectly developed, rudiments of a vagina generally exist, and in these cases the urethra is most frequently found very much dilated, so much so that it has frequently served as a vagina.

Emmet reports a case where a surgeon incised a dilated urethra mistaking it for the vagina, and causing incontinence of urine.

An erroneous idea seems to be prevalent that in cases of congenital atresia of the vagina, a patulous urethra always indicates that sexual intercourse has taken place through this organ. This patulous condition of the urethra is the result of an arrest of development and almost invariably accompanies congenital atresia of the vagina, arrest of development has taken place in Müller's ducts, and the anterior

portion of them which joins the bladder and forms the posterior wall of the urethra, is not developed; consequently the opening of the urethra is larger, and is situated below and internal to its normal position—almost in a line with the normal opening of the vagina—and therefore the vagina being closed by atresia, the urethra would more easily receive the male organ. This patulous condition is the primary one, and is the *cause* and not the *result* of penetration. Moreover in cases of *acquired* atresia of the vagina the urethra is never patulous, and sexual intercourse never takes place through it, but on the contrary, the seat of obstruction in the vagina is gradually pushed back by the penis. In these cases of congenital patulous urethra, there is never incontinence of urine.

Morgani, *De sedibus et causis morborum*, Lib. III, Ep. 46, relates two interesting cases of congenital atresia of the vagina with defective development of the uterus and patulous urethra.

The first case he describes as follows: "The vulva of the woman was in a perfect and natural state. But that canal, as they called it in the time of Celsus, into which it opens, and which we now call the vagina, had scarcely run on more than a third part of its proper length, when it suddenly terminated. There was no cicatrix at that place nor below it; the woman herself or her parents could none of them call to mind any ulcer, or any other preceding disorder, in consequence of which the sides of the vagina might have coalesced, for if these parts are ulcerated either from the lues venerea, from the difficult birth or from any other cause where the carelessness of the surgeon or the midwife has coöperated with the disorder, how easily the sides of this canal may grow together. However, not only nothing of that kind had preceded in this woman, but every part moreover, being smooth, shining, and equal when you had opened and dilated the vagina as far as the occlusion, nor indeed did this occlusion in the least give way either to the finger or to the penis of the husband, which had now for three years' space been frequently forced against it."

In Morgani's second case, the woman stated that she was not indeed imperforate, but had so very narrow an aperture, that an eminent physician in a city of great learning, who was at the same time a surgeon, having examined her in early puberty, advised that this aperture should be gradually dilated by introducing such things as were proper for that purpose; but that everything else a more mature age, and a husband, if she should marry, would accomplish. She stated that she had introduced something of the kind recommended, and in some measure had succeeded in dilating somewhat the orifice of the foramen; but could bear no further dilatation, that her husband also, to whom she had been married three years, had by frequent attempts somewhat enlarged the same orifice, but could never enter it. Morgani goes on to state that when he examined the woman and saw the foramen of which she had spoken, he immediately knew that it was the orifice of the urethra out of its situation; and that thanks ought to be given to God, that the woman could not

suffer any further dilatation of that passage, as, if she had, the consequence without doubt, would have been, that she could never have retained her urine. Upon further examination, he found the vagina occluded entirely by a solid thick membrane, and he believed the uterus to be absent.

M. Ad. Burggrave, Professor of Anatomy in the University of Ghent, has recorded in the *Annales d'occulis, et de Gynecol.*, 1839, the two following instances of complete absence of the uterus which had come under his own observation:

In the *first case* the vulva had no vaginal orifice; the urinary meatus was situated in the centre of this latter, the contour of which had been ruptured in the act of copulation, readily permitted the introduction of the finger into a sac, the parietes of which were soft and membranous, and which was easily recognized as the bladder. When a catheter was introduced into this sac and the finger into the rectum at the same time, it was evident that there existed no organ between the intestine and bladder, that these were in immediate contact, as is the case in the male sex.

In the *second case* the absence of the uterus was verified by post-mortem examination. The subject of this was a woman 23 years of age, who died in the Civil Hospital of Ghent, of arachnoiditis.

This woman was of robust constitution and plethoric habit; her mammae were well developed, pelvis large; sexual parts well covered with hair. The vulva presented only a very large meatus, the circumference of which was irregular and furnished with numerous myrtiform caruncles. This meatus led immediately into the bladder, which was in direct contact with the rectum. The ureters, instead of descending toward the base of the vesical triangle, opened immediately within and on the side of the urinary meatus, so that the bladder was situated behind these conduits. The orifices of the urethra were surrounded by sphincters, which were capable of closing them and thus preventing the immediate flow of urine.

Beyond these sphincters the ureters were very much dilated, and this enlargement extends to the kidneys, so that during life these passages had performed the office of reservoirs. The genital apparatus consisted of two ovaries, well formed, situated in the folds of the peritonæum, and containing numerous ova, many of which were in the hydatid state. In the same peritoneal fold, and immediately in front of the ovaries, were the Fallopian tubes; these last had no canal, and were enveloped in a thick mass of erectile tissue. These tubes were joined behind the bladder without communicating one with the other. The subject of this case had never menstruated, and had manifested very marked venereal appetite.

One of the earliest recorded cases of arrest of development and absence of the uterus is related by Realdus Columbus in his work, "*De Re Anatomica*," in 1572. It is described as *vulva rara*.

In Case 2 the condition of the hymen as being dense and hard, and nearly closing the vaginal orifice, is mentioned.

There is another condition which is frequently con-

founded with imperforate hymen; this is an occlusion of the lower portion of the vagina immediately behind the hymen. This occlusion is of embryonic origin, and is caused by defective development of the lower portion of Müller's ducts, and is sometimes improperly described as a double hymen. More frequently, however, it is overlooked or mistaken for the hymen itself, from the fact that it is pressed forward by the accumulated blood in hæmatometra and hæmatokolpos, and lies almost in immediate contact with the hymen.

I will state the following conclusions:

1st. Nearly all the malformations of the female sexual organs, previous to puberty, result from arrest of development.

2nd. As the upper and lower portions of Müller's ducts develop independently of each other, we may find the ovaries developed without the uterus, and *vice versa*.

3rd. Perfect development of the external genital organs and the mammary glands does not preclude defective development of the vagina, uterus or ovaries.

4th. Entire absence of the uterus or the ovaries can only be determined by post-mortem examination or by laparotomy.

5th. A patulous urethra is not the result of sexual intercourse through this organ, but is caused by arrest of development.

6th. In congenital atresia of the vagina a patulous urethra is the rule, in acquired atresia it is the exception.

REMARKS ON THE SURGICAL TREATMENT OF THE MALIGNANT DISEASES OF THE UTERUS.

BY WM. H. BYFORD, M.D., CHICAGO.

Presented to Section of Obstetrics and Diseases of Women of American Medical Association, May, 1884.

The malignant diseases that more frequently attack the uterus are:

1st. Epithelioma.

2nd. Medullary carcinoma; and

3rd. Sarcoma.

They occur, according to my observation, in the order of frequency here mentioned.

Probably not less frequently than the sarcoma is found the epithelial or corroding ulcer. Preparatory to the surgical treatment of these affections I desire to make some observations, particularly as to the tissues first invaded by them, their mode of development and manner of destruction. My idea of an epithelioma is that the deposit occurs on the free surface of the mucous membrane, in its epithelial stratum, and consists essentially of extreme multiplication of epithelial cells which, after great development of the tissue in which the process is going on, die, causing sloughs of greater or less size.

This form of malignant disease (call it cancer or

cancroid, as you please) is located so that the comparatively dense mucous membrane is between it and the more vascular uterine tissues; hence its cells do not readily find their way into the circulation, and it is at first, and long remains, a local affection.

Another peculiarity is that it does not, until quite late, and sometimes it never destroys the deeper portions of the viscus by ulceration.

The direction is to the surface, and the process of necrosis destroys the superficial morbid growth. The disease is one in which the morbid advancement is away from, instead of into, the substance of the organ.

The second variety of malignant disease of the uterus consists in a great multiplication of cells in the lymph spaces beneath the mucous membrane, which are the terminal cavities of the lymphatic vessels. These cells are probably the epithelial cells of the endothelium of these terminal lymphatics. The deposit is therefore behind the mucous membrane, and really has no barrier to resist the entrance of its cells into the lymph current. This circumstance allows of the early migration of the morbid material to the neighboring and even distant organs, almost as early as they commence formation.

These features of the locality of the deposit are the cause of its greater malignancy, and have given rise to the notion that it is of general instead of local origin. There undoubtedly occur cases in which both varieties coexist from the commencement.

Necrosis in the second variety is caused by the distension of the lymph spaces until the small blood-vessels are strangulated by pressure, and nutrition in the mucous membrane to which they are distributed is arrested.

Small sloughs are detached and thus ulceration is inaugurated which continues till all the invaded tissues are destroyed or the patient dies.

In the third variety of malignant diseases—sarcoma—the cells are generated in the fibrous or connective tissue outside the lymphatics, both in the substance of the cervix and its mucous membrane.

The migration or dissemination of the cells in sarcoma is not so easy or early as in the second, but is more so than in the first variety.

If I am right in this explanation of the difference in the origin and progress in the morbid processes of the malignant diseases of the uterus, it will not be difficult from it to determine the cases to which radical surgical proceedings are applicable, and in which the prognosis under treatment is more or less favorable. I believe that curability is sometimes possible in the first and never in the second or third varieties, but in all, surgery constitutes the most effective means of palliation. There are some cases of epithelial cancer that may be effectually extirpated, and a complete cure accomplished.

A regard for truth requires it to be said, however, that the curable cases of epithelioma are a small minority; but on the other hand it may be said that in a majority of cases life may be much prolonged, and great comfort secured while the patient lives.

Almost all of them are, therefore, proper subjects for surgical treatment. Believing that in this variety

alone a complete removal is practicable, how shall we operate?

If removal of the whole uterus either per vaginam or through the abdominal walls is ever justifiable, the operation should be confined to this variety.

The mortality from this operation is, I think, too great, however, for it ever to gain admission to the category of legitimate operations. The statistics of extirpation of the uterus for cancer have been recently successfully appealed to by Dr. J. Reeves Jackson as evidence that the operation is not justifiable.¹ He very properly concludes that extirpation of the cancerous uterus does not lessen suffering, and it shortens the aggregate of life.

It must be stated, however, in this connection, that the statistics are of much less value than they might be; for while the danger of the operation is the same in all forms; on account of want of discrimination in the reports of the kind of cancer operated upon we cannot judge what the success would be if it was practiced for the epithelial variety alone.

If extirpation is to continue in favor with reckless surgeons it is to be hoped that in future more care will be taken in reporting particularly the nature or variety of the cancer operated upon.

It will then be seen, I have no doubt, that the successes will be on the side of peripheral or epithelial cancer, and the greatest number of deaths will range themselves under the head of interstitial or medullary cancer. I feel assured, however, that more observation will cause the operation of extirpation to be expunged from the future list of operations for cancer of the uterus.

The late Dr. J. Marion Sims, as in many other instances of uterine surgery, took the lead in the appropriate radical treatment of cancer of the uterus.²

It is to be regretted, however, that he did not sufficiently indicate the variety of cancer in which he operated, to enable us to know in what cases his process was successful.

Notwithstanding this defect in his reports, to him must be accredited the greatest improvement in the treatment of cancer ever yet made, and in his method we can see the first scientific and successful effort at a radical cure of this almost incurable disease.

In one case of which I was personally cognizant of epithelial or peripheral cancer, he operated over ten years ago, and the patient is now living and apparently free from the disease. His method has since been resorted to by many operators, and, as might have been expected, with varying success, for no surgical procedure will invariably insure a cure in what would seem the most favorable cases.

His method has been modified to some extent by those who have followed him.

It consists in cutting away the whole cervix and as much of the body as will insure the removal of all the disease accessible, followed by thorough and deep cauterization of the whole excised surface. In some cases, as in the one above, this treatment will effect a cure. To perform this operation easily, the patient

should be placed on her back, with the hips brought down so as to project slightly over the end of the table, with the limbs flexed over the abdomen (Simon's position), and the perinæum drawn well back. After this preparation the cervix should be seized by both lips if possible, with a vulsellum, and depressed until considerable tension is apparent—no more force than this is necessary or permissible—and an incision made with the knife or scissors through the mucous membrane at the junction of the vagina and cervix, so as to entirely encircle the latter.

Through this circular incision the neck and body of the uterus may be enucleated to any desirable extent. The connective tissue between the bladder and uterus and the peritonæum covering the uterus is so loose that proper care will enable us to separate the latter from its investments, and the portion of the uterus thus isolated may be cut away. When we are successful in removing half or two-thirds of the uterus from its peritoneal investment it is not proper to apply any caustic, as it would be likely to penetrate the bladder or peritoneal cavity.

It is, however, quite advisable to apply the hot iron to the stump of the uterus, for the double purpose of checking the hæmorrhage and destroying the tissue to a still greater depth.

The iron must be below red heat, or else neither of these objects will be accomplished.

If any considerable hæmorrhage attend or succeed this operation, the cavity should be filled with cotton saturated in a solution of Monsel's iron half strength. This operation is applicable to cases where the disease has not invaded the cavity of the uterus to any considerable extent.

But there are cases where the mucous membrane of the cervix and body is the subject of epithelial degeneration while that covering the external portion of the neck is not affected. The disease is then not generally curable except by complete extirpation of the organ. It may sometimes, however, be effectually removed in its early stages by excavation with the curette and caustics. Later, when the fibrous structure of the organ is softened by the deposit, this cannot be done. The object of the operation is to remove the *whole* mucous membrane with the deposit, and it will require great care to do this. The uterus should be drawn down and fixed with the forceps by seizing the posterior lip, and then a small sharp curette introduced to the fundus, and by forcibly carrying its sharp edge over the whole surface first in one direction and then another until the tissue removed is entirely free from the morbid deposit.

It will often be best to use larger curettes as the scraping proceeds. Judging from my own observation there is not much danger of cutting through the wall of the uterus when the case is one of epithelial degeneration of the mucous membrane instead of cancerous degeneration of the parietes. The latter kind of deposit renders the tissues friable and they break down under the curette. In the cases of pure epithelioma as I have defined the affection, that friability does not exist, and if we go through the wall it is by using too much force.

After we have thus thoroughly removed the disease

¹ Gynæcological Transactions for 1883.

² American Journal of Obstetrics.

from the cavity we should increase the probability of a cure by the introduction of a caustic.

This part of the operation should also be done with a thoroughness that attacks every portion of the cavity.

For this purpose I think the acid nitrate of mercury the best caustic. Small pellets of cotton saturated with the acid, afterwards squeezed as nearly dry as possible, and if prepared several days before used so much the better.

Each one of these should be well secured by strong thread, that they may be easily removed.

The uterine cavity should be packed full of these and then the vagina should be filled with absorbent cotton pressed well up against the cervix.

Chloride of zinc, nitric acid or bromine may be substituted for the acid nitrate, but I believe the mercury in this latter preparation adds to its efficacy.

When we use the caustic in the scraped cavity we should remove it in about twenty-four hours and then keep the parts clean by irrigation.

If there is any return this operation may be repeated as frequently as necessary. In some instances where I have repeated this operation two or three times, I have found the uterine cavity becoming smaller each time. The diseased surface therefore becomes less after each successive operation.

In an excellent paper published in the *American Journal of Obstetrics* for April, 1882, Dr. W. H. Baker, of Boston, gives a flattering account of his success with the operation for the removal of a part of the uterus, per vaginam.

He reports six cases in which after the lapse of five years there was no return; so they are probably entirely cured, and that in thirty cases he has had no deaths.

This encouraging report establishes the *efficacy* and *safety* of the operation when skilfully done.

While I fully accord to Dr. Baker great credit for his labor in this direction, I must be allowed to complain that he has not been sufficiently definite in the description of his cases to enable us to distinguish between those in which the disease began in the mucous membrane, and such as were of interstitial origin; and I protest that no such success can be attained where the deposit was located in the fibrous structure of the uterine walls. I wish also to disclaim any pretension that even in the earliest stages of development all these cases can be cured.

I only desire to be understood as believing that it is the most promising and safest method of treating the disease when confined to the mucous membrane, without any considerable tumefaction and distortion of the cervical parenchyma. My own cases are not very numerous, but among them I think I can count at least six cases of success, and more, in which I have strong hopes that there will be no return of the disease.

In almost all cases and all kinds of malignant diseases of the uterus, surgery is the important palliative means.

While hæmorrhage, pain, mental worry and other conditions contribute to the general result in cancer

of the uterus, nearly all the sufferers die of septicæmia.

The absorption of putrid material connected with the process of necrosis or sloughing of the tissues invaded by the deposit, so poisons the blood that septic fever is sure to be established.

The septic symptoms are influenced in their intensity by the amount of sloughing, and the power of resistance afforded by the constitutional condition of the patient. Usually almost no symptoms present themselves during the time the deposit is going on. When the tissues commence to break down the cancerous cachexia begins to show itself, and cancerous cachexia simply means septicæmia. Its peculiarity depends upon the fact that it is slowly established. When once established it gradually increases in severity until the patient succumbs to its exhausting influence.

In interstitial cancer we may alleviate the symptoms by removing the sloughing surface by the free use of the sharp curette. In many instances where the sloughing surface is large and the sanious discharge very great, shaving off the entire necrosed substance down to the living tissue will arrest the septic symptoms so completely, and relieve the suffering to such a degree, as to inspire the patient with hopes of recovery.

The operation of curetting should be resorted to early and repeated frequently, until the destruction of the organ is so great as to render it impracticable.

The process of removing the necrosed tissue with this instrument, is simple and free from danger. If the cutting is carried only far enough to get away the sloughs down to the underlying living tissue, no blood-vessels will be severed large enough to give rise to serious hæmorrhage.

Probably the greatest danger consists in tearing through into the peritoneal cavity, and wounding the bladder, ureters and rectum. In the advanced stages of the disease, when the deposit extends to these parts, such accidents may be rendered imminent.

They may for the most part be avoided even then, and until far advanced they may always be avoided. Such accidents usually occur as the result of too much pressure upon the instruments, and the effect is not so much by cutting as by tearing the tissues rendered friable by the existence of the deposit in them. The curette should therefore be very sharp, and it must be applied so lightly that the process is one of cutting only.

The instrument ought to be very small as well as sharp, so that it may be carried with facility into all minute sulci of the affected parts.

Every part brought under the instrument must be plainly visible, and the whole operation should be guided by the eye. This may be best accomplished by dilating the vagina well with Simon's instruments and allowing a stream of water to forcibly run into the cavity through an elastic hose connected with an elevated fountain. This current of water, if well directed, will wash out the clots and sloughs so completely that we can all the time see the depth and extent to which the strokes of the instrument extend. I must insist that this operation, thus lightly and

thoroughly done, may be executed without giving the patient any considerable inconvenience, and also that it ought to be often repeated from the time the septic symptoms begin until the sloughing parts can no longer be reached.

I believe that caustics cannot be made half as efficient for this purpose as the curette. The process of curetting the surface of the superficial cancer for removing the sloughing material is also the most efficient means of palliating the symptoms when they cannot be cured. Of course I do not wish to ignore the value of disinfectant applications as palliative measures. After curetting, and sometimes without it, the free and frequent application of the muriated tincture of iron will often so disinfect the surface as to keep in abeyance the septic symptoms for a long time.

The value of this remedy I believe was first taught by the late Sir James Y. Simpson, and so greatly did he esteem the application that he believed in certain cases the advance of the disease might be arrested for an indefinite period.

SUMMARY.

1st. The more common forms of malignant diseases of the uterus are:

(a) Epithelial or superficial cancer, commencing on the free surface of the mucous membrane.

(b) Interstitial (medullary) cancer, commencing in the fibrous structure, the deposit being within the lymph spaces.

(c) The coexistence of these two varieties.

(d) Sarcoma, in which the cells are mingled with the fibres of the connective tissue.

2nd. The superficial cancer can often be removed and consequently cured.

(a) By ablation of the cervix and as much of the body as necessary.

(b) When affecting the mucous membrane of the whole cavity, by thoroughly and repeatedly curetting all the morbid deposit away and cauterizing with acid nitrate of mercury, bromine or chloride of zinc.

3rd. The interstitial variety is incurable by any method of operation or by any means.

4th. Frequent and thorough removal of the necrosed down to the living tissue by the curette is the most efficacious of palliative measures in the latter variety.

POLLUTION OF THE UPPER OHIO, AND THE WATER-SUPPLY OF THE CITIES AND CHIEF TOWNS WITHIN THE FIRST HUNDRED MILES OF ITS COURSE.

BY JAMES E. REEVES, M.D.,

SECRETARY OF THE STATE BOARD OF HEALTH OF WEST VIRGINIA.

Read before the American Public Health Association, at the meeting in St. Louis, October 16th, 1884.

The condition of health and probable duration of life of a people may be correctly measured by the quality and quantity of their water-supply. Indeed,

good health can as little be supported without pure water as without pure air; therefore, of all the diversified and complex relations which man bears to surrounding influences, none are more important than that which relates to the water-supply of the locality in which fortune has placed him.

Considered either in his physical, social, moral, industrial, or political relation, the subject is of transcendent importance, for it involves the main questions of success in life. If he take up his abode in the midst of unsanitary surroundings, the inevitable sequence will be a correspondingly unfavorable influence upon his destiny—a check upon his prosperity, and a blight, more or less serious, upon all those attributes which are usually considered essential to his well-being and happiness.

As a natural corollary, the community which is ignorant or regardless of its sanitary surroundings and vital history, is but feebly defended against "the pestilence that walketh in darkness, and the destruction that wasteth at noonday;" for the wholesome lessons of domestic and civic hygiene afford to such a people no rules and defenses for the person, the domicile, the municipality and the State, nor encouragement to the general prosperity in stimulating the practical applications of science and art, commercial enterprise, manufactures, and popular intelligence. All these are at a low standard, while frequently recurring endemic and epidemic diseases, and a high death-rate, constitute the most prominent features of their culpable history.

River pollution from sewage and other supplies of refuse and corruption in towns and cities has assumed such fearful proportions that the question presses itself upon wise men and sanitarians—"Is industry free to tumble out whatever horror or refuse it may have accumulated into the nearest crystal brook, regardless of gods and men, and little fishes; is free industry free to convert all our creeks and rivers into sewers?" "It is ours," says Dr. Gairdner, "to use air and water, and then pass them on; but woe to the man or the community that detains or imprisons these his servants of the hour in their further execution of God's endless work!"

With these introductory reflections, I now submit the following brief statement of facts relating to the water-supply of the cities and chief towns situated on the banks of the Ohio River within the first hundred miles of its course.

Commencing at the head of the Ohio, there are two cities—Allegheny and Pittsburgh—whose aggregate population is not less than 240,000. Next, Rochester, Pa., a town of 3,500 population; next, East Liverpool, O., with a population of over 6,000; next, Wellsville, O., with a population of 4,500; next, Steubenville, O., with a population of 14,000; next, Martin's Ferry, O., opposite Wheeling, with a population of 4,600. On the West Virginia shore, between Wheeling and Pittsburgh, the principal towns are New Cumberland, with a population of 1,500, and Wellsburg, 16 miles distant from Wheeling, with a population of 2,000; next, Wheeling, with a population of 31,500; next and last, Bellaire, O., with a population of 10,000.

And thus, not including many smaller towns and thriving villages which mark every few miles of the Pennsylvania and Ohio shore, and whose varied industries in manufactures give employment to thousands of laborers, there are above Wheeling four cities and five towns whose aggregate population amounts to 275,000.

Besides refuse representing accumulations of filth of every conceivable character from family domiciles, stables and barnyards, privy vaults and other cess-pools, sewage outlets, and manufacturing establishments, the Ohio River is made the convenient receptacle for the disposal of diseased or worthless carcasses; and thus thousands of tons of corrupting matter are daily thrown into the stream which supplies the water we drink. No wonder then that diarrhoeas and typhoid fever are so common, and the death-rate from these diseases is so high.

But let me be more specific in my statements. Passing Rochester, at the mouth of Beaver River, 26 miles below Allegheny and Pittsburgh, without further record than that its water-supply is from wells contaminated with surface putrilage, and in many instances, no doubt, by leaks from privy vaults and drains from kitchen sinks—and that typhoid fever is a frequent disease in that community,—we come to East Liverpool, 19 miles further down the stream. Here the population is supplied with water pumped from the Ohio and distributed from a reservoir. The supply pipes to the pumps are located about 200 yards above the city, and extend into the river far enough to take the water from the current, below low-water mark. There are but few wells in use; and fewer cases of typhoid fever have occurred since the erection of water-works than before, or when the water-supply was wholly drawn from wells. During those years, house and street epidemics of typhoid fever were not infrequent.

At Wellsville, 4 miles below East Liverpool, a well, or *crib*, as it is called, was made near the river's edge, a year or two ago, for the purpose of securing for the town a sufficient supply of clear water—the authorities believing *clear* water and *pure* water to be convertible terms. This crib, 10x16 feet in the square, and 12 feet deep, was encased with timbers and tightly covered with the same material. From such a "hole in the ground" the water-supply was pumped into a larger basin on the hill. It was confidently expected in that way to procure "pure filtered water from below the bed of the river;" but the supply was found to be so foul and unwholesome that it was not fit for use, and the crib had to be abandoned. Since then, the supply has been drawn directly from the current of the river, above the inflow of the town's refuse, and distributed from a reservoir 300 feet above the river-level. But this better water-supply has not secured the citizens of Wellsville against typhoid fever cases which appear at all seasons of the year.

For the foregoing history of the sanitary situation in East Liverpool and Wellsville, I am indebted to R. H. Hill, Esq., of East Liverpool, and Dr. J. W. Hammond and S. Stevenson, Esq., of Wellsville.

From Steubenville, 20 miles below Wellsville, Dr.

Gustav Shane, of that city, has kindly sent me the following description. He says: "This city is supplied with water pumped from the Ohio River into a large reservoir on a neighboring hill, and from thence direct to the consumer, by mains and cross-mains. The basin or reservoir is made of brick laid in and covered with cement, and of sufficient capacity to supply the ordinary wants of the population—14,000—for about 3 days. The supply is taken at a point *below* both the geographic and population centre of the city, but the receiving-pipes are laid to and beyond the channel so as to avoid contamination from surface drainage and sewage.

"The quality of the water drawn from the mains is apparently good, clear, free from odor, and not unpleasant to the taste except when the river is turbid. But few wells are in use in the main portion of the city; but a part of one ward—on the first river-bench—is supplied with well water.

"The city is not sewered, and the privy system is the time-honored one of deep vaults, which, when full and abandoned, are covered with earth, and in this way the surface is completely honey-combed.

"There are at all seasons of the year cases of typhoid fever occurring sporadically, but the disease has not prevailed as an epidemic for many years. That part of the city in which well-water is used, appears to have the largest percentage of febrile cases, and, I believe, a preponderance of the typhoid type. Dr. Stanton, the oldest practitioner in the city, whose experience antedates the river water-supply, informs me that typhoid fever was much more common under the well-system of water-supply than since the establishment of the water-works. Thirty-five or forty years ago, or before the adoption of the river supply, house and neighborhood epidemics of typhoid fever were quite frequent, whereas, at present, such outbreaks are almost entirely unknown.

"Isolated cases of diphtheria are also constantly occurring, at irregular intervals, in Steubenville, but no general visitation of this disease within the last 15 years. During the winter of 1878 and '79, a fatal neighborhood epidemic of diphtheria occurred, limited by street lines, and embracing about one-fourth of the population of the city. Scarlet fever prevailed at the same time in severe form, and in many instances the two diseases—scarlet fever and diphtheria—were associated in the same patient. There seemed to be no cause for this visitation other than contagion."

The next place on the line of this inquiry is Martin's Ferry, 20 miles below Steubenville, and immediately opposite Wheeling. Here the water-supply is from wells varying in depth from 15 to 50 feet, dug through a rich loam, yellow and blue clay, sand and gravel. The town is not sewered, and in some instances the well and the privy vault are in dangerous proximity. On account of the general topography of the town, and the superficial clay-substratum, all refuse and surface matter which does not find immediate entrance into the well-water supply, is quickly drained into the Ohio river. The result of the unsanitary condition is the constant prevalence of typhoid fever of a grave and fatal type in Martin's Ferry.

And now having reached Wheeling, the chief city in West Virginia, the situation is even more uninviting than the unsanitary pictures we have been inspecting; for it is within the truth to state that, including the population of Martin's Ferry, the refuse from the homes of 10,000 people finds entrance into the Ohio river immediately *above* the point of supply to the water-works' pumps. And if filth from hundreds of households, manufacturing establishments, privy vaults and other cess-pools, horse and cow stables, and the stinking bodies of dead animals, were all of the sources of pollution of the water supply of Wheeling, its citizens might congratulate themselves that, at least, they are not worse off than some of the neighboring cities; but, in addition to the sources of pollution just mentioned, an old and dilapidated cemetery—Mt. Wood—occupying the hill at the northern part of the city, and within a half mile above the water-works, is a highly probable factor of contamination.

The greater part of the coal-measure underlying this cemetery has been removed, and the cap-rocks have broken and sunken, causing large seams or cracks through the hill; and the inclination of the drainage, both surface and subterranean, being towards and into Jonathan's Ravine, at the foot of the hill, which empties its current into the Ohio within the city limits, it is therefore highly probable that the water-supply in the basin is polluted by the corruption escaping from the graves and vaults in Mt. Wood.

The water-works, though greatly improved by new machinery within the last year, occupy the same site upon which they were originally erected more than 40 years ago, when Wheeling was not one-fifth of its present size—31,500.

The basin or reservoir is located on Wheeling Hill, 275 feet above the bed of the Ohio river, and has a capacity of 800,000 gallons. Its small size necessitates constant use of the pumps both day and night to keep the mains full; therefore at all times the quality of the water in the basin is the same as that in the current of the river. In other words, if the water in the river is muddy, the supply in the basin is likewise turbid and disagreeable to drink.

In hope of securing a clear and wholesome water—but unmindful that clear water is not always pure water—the Board of Water Commissioners, last year, concluded to repeat, with some improvements, the experiment made at Wellsville of a crib or well below the bed of the river; and accordingly a hole, 15 feet deep and 20 feet in diameter, was dug through the sand-bar, in the bed of the river, near the Island shore, and about 200 yards above the present point of supply to the basin. This well or crib was substantially walled with brick laid in cement and tightly covered with heavy timbers, bolted to the wall, to prevent all leakage from the current. The water that soon filled this well or crib, by percolation, was so clear and beautiful in appearance that the Board, a few weeks ago, contemplated the immediate establishment of three additional cribs, side by side with the one just described. Fortunately, however, before making such outlay of the public money, and connecting such cribs or wells with the water-works and

the basin, the Board wisely determined to have the waters in the crib and in the basin analyzed; and specimens were forwarded to Dr. Charles Smart, of the U. S. Army, for that purpose. The following is Dr. Smart's report of the analysis:

SURGEON-GENERAL'S OFFICE,
WASHINGTON, D. C.,
September 26, 1884.

DR. JAMES E. REEVES, SECRETARY STATE BOARD OF HEALTH, WHEELING, WEST VIRGINIA: *Dear Sir:*—I have received yours of the 19th inst., invoicing two half-gallon specimens of the water-supply of the city of Wheeling, West Virginia, and requesting me to make an analysis of the water, and to report in such terms as may be authorized by the results of the analysis. The specimens were received in good condition, in green glass bottles securely corked. One was marked "No. 1, Island Crib;" the other, "No. 2, City Reservoir."

No. 1. This water was clear, transparent, and free from color and odor. A slight sediment of a dark color, pulverulent and somewhat granular, had collected in the bottom of the bottle. This sediment consisted of organic matter so disintegrated that its origin could not be discovered; several of the larger granules were composed of the disintegrated matter aggregated on small fragments of cotton fibre. It swarmed with bacteria and bacilli, and showed many minute protoplasmic masses and some larger masses presenting amœboid movements, but contained none of the algæ and infusoria which are so common in waters that are in general use as potable waters. Generally speaking, waters that are free from the actively-moving ciliated infusoria, and that present a comparatively dead microscopic field, are waters that have percolated through a very pure or a very impure soil. In other words, they are very pure spring or very foul well waters. In the one case the field presents silicious particles, diatoms and the filaments of the coniferoid genera; in the other the microscopic appearances are those mentioned as observed in the sediment of the specimen under discussion.

Under laboratory treatment the water was found to give a residue constituting 49 parts in the 100,000. Twenty of these parts were dissipated by heat, and consisted principally of the nitric acid of nitrates. There was but little recent organic matter in the residue—scarcely enough, when ignited, to darken the inorganic film with a fleeting coloration. In this respect the water residue was similar to that of a pure spring-water; but it differed from the latter in the strong nitrous fumes which were evolved during the application of the heat. The presence of the nitric acid was also developed by Sprengel's solution; but it was not considered needful to determine its amount directly, as the operations on the residue indicated that two-thirds of the 49 parts in every 100,000 of the water consisted of nitrates, and the remainder of chlorides, carbonates and sulphates.

The chlorine present amounted to 1.9 parts in 100,000 of the water, which is equivalent to 3.1 parts of chloride of sodium. This is not a large chlorine figure, considered in connection with the

nitrates present, and indicates that the organic matter whence the latter are derived is not wholly, or, indeed, chiefly, a sewage material, although sewage may be present in it.

The free ammonia in the water measured .014 part per 100,000. This is a larger quantity than is usual in percolated waters known to be of good quality, and indicates, with the strong trace of nitrous acid which was found by Griess's delicate test, that the organic matter from which the nitrates are formed is not distant from the reservoir in which the water is collected, or that the filtering material or soil through which percolation is effected, is itself of such an impure character as to be incapable of effectually purifying the water in its transit.

A similarly small amount of recent organic matter is indicated by the quantity of oxygen required to oxidize it, to-wit: .110 part per 100,000 of the water.

From the rapid manner in which the albuminoid ammonia was eliminated in the laboratory experiment, from the relatively small proportion of carbon present, as indicated by the small quantity of oxygen required, and from the large amount of nitrates and small amount of carbonates in the residue, it is inferred that the small quantity of organic matter present in the water and the very large quantity which has recently been reduced to the inorganic form of a nitric acid salt, are of animal derivation. No undecomposed sewage is present in the water, but the quantity of chlorine renders it probable that decomposed sewage is not absent.

In the absence of all knowledge of the surroundings or natural history of this water, the analyst cannot speak with decision upon its probable unwholesomeness. The microscopic appearances of its sediment are against it, as well as the greater part of the analytical results. It is true that there is in the water only a small quantity of unreduced organic matter, but there was a much larger quantity present in it a short time before it reached the reservoir whence it was drawn. This water, indeed, appears to be an example of the class which led the writer to generalize as follows in his report on the waters of Memphis and other Southern municipalities (Annual Report Nat. Board of Health, 1880, page 485): "On the other hand, when a well which is liable to an impure inflow, as evidenced by the co-existence of nitrates and nitrites, furnishes a sample which is free from albuminoids, and from oxidizable organic matter, the microscopic characters may give direct assurance that the water has not always been as pure as the sample submitted for analysis."

Although there is not much recent organic matter in the water submitted, the surroundings of the reservoir from which the water was collected are evidently such that at any time an increased inflow might carry undecomposed organic matter into it. As it is, the last traces of the organic matter are in progress of change. The nitrogen of the nitrates in a water may be as much dissociated from the organic matter which it at one time constituted, as the chlorine of the chlorides in the water of the ocean, but in this instance the nitrates are undoubtedly a recent

formation, for the process of reduction is in progress in the water as submitted for examination. Nitrates alone are viewed by most sanitary authorities as indicating dangerous probabilities in a water. Frankland says that large quantities of nitrates convict water of previous pollution by organic matters of animal origin, and calls them an indication of the "previous sewage contamination" of the water. Some, as Ekin, of London, condemn as dangerously polluted waters which contain so small a quantity of nitrates as .5 or .6 part per 100,000, and Reuben Haines has met with cases which sustain Dr. Ekin's position. Without subscribing to the dangerous qualities of waters which contain so small a proportion of nitrates, the experience of the writer leads him to believe that, excluding the presence of existing organic matter, a water is to be regarded with suspicion in proportion to the amount of nitrates present, and that assuredly the water-supply of a city should not contain the very large quantity of nitrogen as nitrates which was found in the sample marked "No. 1, Island Crib," from the city of Wheeling, West Virginia.

More particularly dangerous are the waters which show a connecting link between the nitrates and their organic derivation in the form of traces of existing nitrites. In a recent investigation into the processes of water analysis, Professor Mallet, of the University of Virginia (now of Jefferson Medical College, Phila.), under whose direction the experiments were conducted, concluded that the danger was associated with the presence of nitrates and nitrites. In his report (page 203, Annual Report Nat. Board of Health, 1882) he says: "Looking at the results from the natural waters of classes 1 and 11, and bearing in mind the conclusions reached by Müller, Schlæsing and Muntz, Storer, Warrington, and others as to the process of nitrification being due to the presence of an organized ferment or ferments of bacterial character, the idea suggests itself whether the noxious character of waters containing largely nitrates and nitrites—themselves presumed to be harmless—and but very little organic matter—which ought to be present of some sort, to support the previous contamination view—*may not be in reality due to the presence of a specially nitrifying ferment, itself to be classed among the lower organisms capable of propagating disease.*"

Nitrates and nitrites are harmless in themselves so far as we know. So, also, are the ordinary organic matters, animal and vegetable, from which these salts are formed, at least where existing in quantities which do not render the water containing them repugnant to the senses. It is not the ordinary organic matters of the world, decaying garbage, animal fragments, and even sewage, nor the nitrogen salts formed from them, that are dangerous when taken into the system with the water-supply, but certain morbid micro-organisms which may accompany them. These micro-organisms, which are the probable cause of cholera, typhoid fever and other specific diseases, are associated in particular with waters which contain nitrates and nitrites, and, indeed, it is not unlikely that the living ferment which effects the nitrification of organic matter may itself be morbid.

NO. 2, CITY RESERVOIR. This water was clear,

transparent and free from color and odor. It contained a slight pulverulent sediment of an olive color, which consisted of disintegrated organic matter and some mineral particles, swarming with infusorial life, but without any algaoid forms and with few bacteria.

The water yielded a residue amounting to 14 parts in the 100,000; of these, 10 parts were mineral matter and 4 organic and volatile. The organic matter was not present in such quantity as to give a dark coloration on ignition of the residue, nor were any fumes or odors evolved during the process. Chlorine was present to the amount of 2.1 parts, equivalent to 3.5 parts of chloride of sodium in every 100,000 parts of the water. No nitrates were present other than the minute quantity—less than Dr. Ekin's limit—usually found in river water. A trace of nitrous acid was present, indicating that the organic matter of the water was undergoing change to the inorganic condition. The free ammonia amounted to .013 part and the albuminoid to .017 part per 100,000 of the water, while the oxygen required to oxidize this weighed .160 part.

River waters are very variable in their constitution. During the periods of spring snow-meltings, and autumnal rainfalls, when the stream is swollen and turbid, its waters usually attain their maximum of impurity. The organic matter on the surface of the area of drainage is washed into the bed of the stream, and the rapidity of flow prevents sedimentation, which is an important purifying agent. In seasons of drouth, on the other hand, when the water-level is low and the current fed less by surface-shed rain showers than by tributary springs, the water is usually less impregnated with organic matter. From the transparency of the sample furnished and its minute quantity of pulverulent sediment, the analyst infers a low water-level at the time the specimen was collected. The specimen therefore represents the river-water in its best condition. The albuminoid ammonia distilled from the sample is not above the average of that obtainable from good river-waters; but the free ammonia and chlorine are in excess, and suggest a sewage inflow into the stream. If the sewage were suspected to enter in mass at one particular point, its influence on the quality of the water might be ascertained chemically by determining the free ammonia and chlorine in specimens collected above and below the point of supposed entry; but usually such determinations are unnecessary, as the point at issue may be better determined by a sanitary inspection of the area of drainage.

Sewage is decomposed by the influences acting in running water, and leaves only its skeleton in the form of the inorganic chlorides. The presence of the evanescent ammonia indicates a more recent contamination and a less perfect decomposition. But whether decomposed or undecomposed, sewage contamination is dangerous, not in itself; for waters polluted with sewage have been used for ages with impunity, but in that it may be accompanied by and be the means of spreading the infection of typhoid fever and cholera. The former has long been known to be preventable by the use of water which is free from sewage contamination, and the recent researches

of Koch into the etiology of the latter indicate that a sewage-contaminated drinking-water supply is the most active agent in its propagation.

Respectfully submitted,

CHARLES SMART,
Surgeon U. S. Army.

The following supplemental report is not less interesting and instructive:

SURGEON GENERAL'S OFFICE, }
WASHINGTON, D. C., }
September 29, 1884. }

DR. JAMES E. REEVES:

Dear Sir:—Your letter of the 26th instant informing me of the history and surroundings of the water sent to me for examination, and marked respectively "No. 1, Island Crib," and "No. 2, City Reservoir," has been received and carefully considered in connection with the analytical results obtained from the waters in question. In my report on "No. 2, City Reservoir," I stated the probability of sewage inflow, and suggested a sanitary inspection of the drainage area as a more trustworthy means of determining a contamination of this character than is the laboratory work of the sanitary chemist. If the sewage is present in large quantity, and is not decomposed by natural causes, the urea present may be detected and estimated by the chemist. But urea is speedily broken up and leaves only the chlorides which accompanied it, with or without a trace of free ammonia, to evidence its recent existence. The sanitary inspector is therefore better qualified in many instances than the sanitary chemist to detect the presence of sewage in a water. Especially is this the case in surface waters where the water-shed and all its possible polluting influences are more or less known.

The germ or poison of typhoid fever may or may not be present in sewage. If it be not present the sewage is harmless as far as concerns the propagation of that disease; if it be present the water will convey the infection of typhoid fever whether the sewage is decomposed or not. In fact there is no evidence that the agencies which destroy ordinary organic or sewage matter in its course down stream have the slightest influence in destroying or removing the cause of this fever. On the contrary, all the evidence that has accumulated of late years shows the persistence of the germ or poison after the destruction of the sewage material which originally accompanied it. In the Lausen epidemic, for instance, there was not only a flow of several miles, but a filtration through the soil which sufficed to remove the minute cells of wheat-starch; yet the fever was undoubtedly disseminated by the infected water of the springs.

Instances of typhoid fever caused by well-water from which all trace of the sewage has disappeared, are of common occurrence in the recent records of medical progress. Before a city which uses a sewage-polluted water-supply can claim that the use of such water is not injurious or unwholesome, its health reports should show that typhoid fever is a rare disease among its citizens, although existing in the cities which cast their sewage into its water-supply.

The detection by chemical means of sewage in a water is therefore a matter of no moment. The point of interest is the contamination of the water-supply. If this is proved, the water is dangerous, and is undoubtedly the cause of much preventable sickness, which is accepted by force of habit as a normal condition.

It is not always in the power of an individual to prevent the sewage pollution of his water-supply by others who live above him on the water-shed; but it is always in his power to prevent his water-supply from being defiled by his own excreta. The sanitary laws which apply to individuals apply to their aggregation as communities. The city may not be able to prevent all defilement of the stream, but it is surely competent to preserve its citizens from swallowing their own filth, diluted but not rendered innocuous thereby, in its organized system of water-supply.

The water marked "Island Crib, No. 1," which I reported to you as a surface water that received a large amount of nitrates and nitrites during its percolation through some filtering material, I now understand to be the river water which has percolated through a sand-bar into a well or other reservoir. When the river is flooded and turbid, the filtration, of course, will remove the turbidity and give a clear water. But clearness and purity are not synonymous terms when applied to water-supplies. A water which contains strychnia might be perfectly clear. The Lausen water, in Switzerland, above referred to as having caused a deadly epidemic, was perfectly clear. At the present time the river water is as clear as the filtered water. They are, however, by no means the same waters. The one contains only 14 parts of solid matter per 100,000, the other 49 parts. The increase is the result of the filtration. It consists of nitrates and nitrites recently formed from organic matter. The organic matter which yielded them did not exist in the river water. It was therefore derived from the filtering medium, and freedom from turbidity is purchased at the expense of a dangerous change in the character of the water. I need not repeat what I have already said in my report as to the quality of this water. It is wholly unsuited for a potable water-supply, especially for a large community where the well-being of so many are at stake.

Sincerely yours,

CHARLES SMART,
Surgeon U. S. Army.

It is thus seen how narrowly the people of Wheeling escaped a positively dangerous water-supply, and it is to be hoped other communities may profit by the example. When Dr. Smart's report is read by the light of the history I have given of the surroundings, especially by the light of that unerring indicator of the character of the water-supply—the frequency of typhoid fever—it leaves no doubt on the subject.

An interrogation of the death-returns on file at the City Health Office shows that in the last 10 years there have been 460 deaths from typhoid fever, and 225 deaths from diphtheria within the same period. Indeed, typhoid fever is present at all seasons; some years showing a much larger mortality than in others. For example, in the year 1879 there were 90 deaths

in Wheeling from typhoid fever, while in 1880 there were but 52 deaths from the same cause. The same is true of the prevalence and fatality of diphtheria.

There is an easy remedy for the present impure water-supply in the city of Wheeling, namely, the extension of the receiving pipes three miles up the river, or to a point above the town of Martin's Ferry. When this improvement shall have been made, Wheeling may justly boast of having an abundant supply of the purest water the Ohio River can furnish, and fewer cases of typhoid fever.

The next and last city to be named in this record is Bellaire, Ohio, the northern limit of which is but a half mile below the southern boundary of Wheeling. It has a population of 10,000, and is supplied with water pumped from the Ohio at a point within a half mile below the place used by the city of Wheeling for dumping night-soil and other corrupting refuse. In other words, the citizens of Bellaire swallow with the water they drink all manner of abominable filth from the city of Wheeling, and they pay a fearful penalty for their utter disregard of sanitary laws. Typhoid fever and diphtheria prevail in malignant form at all seasons, and the death-rate from these diseases exceeds that from all other causes combined.

Finally, it were well if the boasted civilization and refinements of the age in which we live could be presented in fitting contrast with the sanitary works of the ancient Greeks and Romans, who well understood the value of pure water. Vitruvius informs us that as an evidence of the practical wisdom of the ancient Romans, who were often regulated in their conduct and opinions—especially in military matters—by the Augurs and Soothsayers, they frequently consulted the appearances presented in the livers and spleens of animals with a view of ascertaining the state of the air and the waters of a country, the healthfulness of its food-productions, its pasturage, etc., and to regulate their choice of sites for the building of cities.

Even to this day, though so far fallen from her high estate, Rome is supplied with good water conveyed from a great distance by aqueducts which were built in the days of her splendor and renown.

MEDICAL PROGRESS.

MATERIA MEDICA AND THERAPEUTICS.

ON THE USE OF SAND-BATHS AS A BALNEO-THERAPEUTIC AGENT.—Dr Suchard, in charge of the hospital and baths at Lavey (Switzerland), has prepared an apparatus which allows of the heating of a large quantity of sand for bathing purposes. His description of its use is very interesting (*Jour. de Med. et de Chir. Pratiques*). His first case was that of an ankylosis of the knee-joint caused by an arthritis of two years' standing. He placed the leg and articulation in a box made for the purpose and filled with heated sand. After a few days of this treatment, the oedema and doughy feel of the tissues disappeared,

and a very marked increase in the temperature, circulation and sensibility was noted. Experiments have shown Dr. Suchard that the temperature of these baths can be much higher than with water. A temperature of 112° to 122° F. is very agreeable to stout patients or elderly rheumatics. Scrofulous swellings with torpid circulation and cold extremities, are not satisfied with less than 131° F. In cases of sciatica, localized rheumatism, and ankylosed or atrophied limbs, the temperature should be as great as 140° F. to give the parts a proper degree of warmth.

The first impression of the patient when placed in the bath is that of comfort; in about five minutes comes a feeling of discomfort and oppression, then relief comes when transpiration is established. From this fact the temperature of the body is not elevated and maintains its equilibrium in a medium of much higher temperature than its own. Finally, after a time varying from twenty-five minutes to three-quarters of an hour, the heart is accelerated in its action, and the respiration becomes more frequent; and these symptoms indicate that it is time to leave the bath.

One peculiarity of the bath is that it permits of the application to the affected part of sand of a higher temperature than to the rest of the body. In some cases this can be restricted entirely to the affected part. Rheumatic cases particularly enjoy them and are tempted to remain in them for a long time. They can so remain for upwards of an hour and repeat the bath daily; the fatigue is much less than with a complete bath, which is so energetic as not to bear repetition oftener than every two or three days.

To get rid of the sand which adheres with the perspiration, the bath is supplemented by friction with towels, or with brandy, or by water bathing or douches.

The characteristic of these baths is to determine a marked afflux of blood to the skin, which can be prolonged for a long time without inconvenience; so that in a general way it may be said that they are useful when it is desirable to stimulate strongly the circulatory system and thus to increase molecular change with the view of restoring the functions of the skin, and maintaining there the afflux of blood somewhat permanently (as in atrophies, paralyses, chronic rheumatism, articular rigidity, old white swellings, and the resolution of effusions).

OBSTETRICS AND GYNÆCOLOGY.

CREDE'S METHOD OF EXPRESSION OF THE PLACENTA.—In a paper which is a reply to certain objections to his method by Ahlfeld, Créde (*Abender gegen Ahlfeld's Berichte und Arbeiten, etc.*) gives a very clear description of the mode in which his method is to be carried out (Edin. Clin. J.). "Immediately after the birth of the child, the uterus must be controlled by the hand laid on it, and the third stage shortened in this way, that the natural contractions of the uterus are increased by gentle, soft friction by the hand, and the contractions which would otherwise be delayed are excited. As soon as the hand resting on the uterus feels a more powerful con-

traction, with which some blood escapes, and the uterus becomes distinctly smaller in the hand, the uterus must be grasped on all sides with the fingers of one or both hands, and with the fundus directed forwards and upwards, gently pressed downwards toward the hollow of the sacrum, rather towards the coccyx, *i. e.*, with the patient lying horizontal on her back—vertically downwards into the small pelvis. This pressure is only to be made during the acme of a pain." The placenta will, as a rule, be expelled with the third or fourth contraction, *i. e.*, five minutes or more after the expulsion of the child. If not expelled then we must delay expression till the contractions are renewed.

ON THE VALUE OF ALTERATIONS IN THE KIDNEY, CONSECUTIVE TO FIBROIDS OF THE UTERUS, IN THE INDICATIONS FOR AND THE PROGNOSIS OF HYSTERECTOMY. S. Pozzi, *Annales de Gynéc. (Medical Chronicle)* calls attention to the exceptional gravity which is sometimes given to diseases of the uterus, owing to the intimate relations of that organ with the bladder and lower end of the ureter. The uræmic affections which complicate cancer of the cervix have for a long time attracted the attention of pathologists. Serious lesions of the kidneys and ureters may be caused by simple prolapse of the uterus, owing to the interference it causes with the position and functions both of the bladder and of the lower end of the ureters. Other uterine displacements, such as retroversions and retroflexions, not infrequently occasion a certain degree of compression of the ureters, and it is easy to see that uterine myomata are quite capable of producing a still more injurious degree of pressure. The author inquires how far the kidney lesions, resulting from this pressure, affect the indications for, and prognosis of, the operation of hysterotomy. He sums up his conclusions as follows:

1. Compression of the bladder and ureters is a frequent complication of uterine fibroids, even when they are of moderate size, and is capable of inducing serious lesions of the kidneys (hydronephrosis, cysts, sclerosis, fatty degeneration).

2. When this compression affects the bladder it is readily recognized, but when it only affects the ureters it is scarcely possible to do more than arrive at a suspicion of the truth, until the appearance of albumin in the urine points to implication of the kidney.

3. Compression of the bladder or ureters ought to be regarded as a distinct indication of the need of operative interference, and may alone be sufficient to justify it.

4. In the case of hydronephrosis, the indication for operating is particularly pressing, on account of the danger which menaces the hitherto more or less sound kidney.

The treatment of these complicated cases will be rendered less formidable by dividing the operation into two parts, *i. e.*, by first performing hysterotomy, and attacking the cyst after the patient has recovered from the first operation.

5. The prognosis of hysterotomy is rendered con-

siderably more grave by the presence in the urine of albumin dependent on kidney lesion. The operation is indeed contraindicated if there be confirmed Bright's disease, but not if, as in a very interesting case detailed by the author, the quantity of albumen be only slight.

MEDICINE.

PROPHYLAXIS OF DIPHTHERIA.—The Council of Hygiene of France has voted the following instructions. (*Jour. de Med. et de Chir.*):

Instructions upon the precautions to be taken against diphtheria:

Preservative measures.—Diphtheria is a contagious affection. All association of children with persons affected by it should be interdicted. No medicine is known to-day that is protective against diphtheria. It is important, particularly during the prevalence of epidemics, to nourish children as carefully as possible, and to see that they are not subjected to the prolonged influence of moisture and cold. It is very important to attend to all throat affections at their onset.

Measures to be taken when a case of diphtheria appears in a family:

It is indispensable to remove the case at once from all communication with other persons, especially children, who are not concerned in the treatment of the disease. Those who wait upon the case should not embrace the patient, inhale the breath or stand in front of the mouth of the patient during attacks of coughing. If they have any cracks or sores on the hands or face, they should cover them carefully with collodion.

They should be well-nourished, and go out into the fresh air several time every day, taking the precaution of first washing the hands and face with water containing to the quart about three teaspoonsful of crystallized boracic acid, or fifteen grains of thymic acid. They should be careful not to remain night and day in the room with the patient.

Measures of disinfection in the course of the disease or in the case of death:

1. The matters discharged by coughing or vomiting should be destroyed with the aid of a solution containing 3jss of chloride of zinc or sulphate of copper to the quart of water. The soiled linen, clothes, etc., should be immediately washed in one of these solutions, and then plunged into water which is kept boiling for an hour at least. The spoons, glasses, etc., after being used by the patient, should be plunged into boiling water.

2. Whatever be the result of the disease, disinfection is indispensable. Fumigations with sulphur are to be conducted as follows: After closing all openings, an earthen pan containing hot coals is to be placed upon sand, and on it powdered sulphur to be placed proportional in amount to the size of the room (20 grammes, or 5v, to the cubic metre). The chamber must remain closed for 24 hours, and then to be freely aired. The clothes, linen and other cloths used by the patient are to be disinfected by the solutions mentioned before being sent to the wash.

The mattress should be opened and left in the chamber during the fumigation.

IDIOPATHIC CONVULSIONS OF THE TONGUE.—Dr. O. Berger (*Archives de Neurologie, Jour. de Med. et de Chir.*) describes a singular affection of the tongue in a woman 28 years of age, without any particular antecedents, who was taken suddenly without prodromata, and while in very good health, with a sensation of laryngeal tension, situated immediately below the chin; when the tongue, which seemed to the patient to be so swollen as to fill the whole mouth, was affected throughout its length by an undulation. These symptoms constituted an aura which lasted a minute and a half. The organ was then irresistibly projected forward violently; it struck against the dental arches with such force as to produce a perceptible noise, or forced the tip between the lips. These rhythmic convulsions succeeded each other at the rate of fifty or sixty times per minute. Speech and deglutition are impossible during the attack, which causes no other disturbance immediate or consecutive. The duration of the attack is from one to two minutes; it is followed by fibrillary contractions, which last for several minutes. A cure was effected by the aid of tonics.

Dr. Berger cites another case, in a man 42 years of age; the same phenomena were repeated in his case, with the exception of the aura. There were brisk, involuntary and forcible projections of the tongue from the mouth many times in succession, even during the night. The patient becoming frightened, closed the jaws involuntarily and wounded the tongue frequently. No other accident occurred, and there was an absence of etiology.

Dr. Berger considered that there was a central excitation, either cortical or bulbar, of the hypoglossal nerve; it is similar to the idiopathic convulsions of the cremaster, also so inexplicable, which cause an extremely painful sensation of contraction. A cure was effected by means of injections of atropia and galvanism.

TESTS FOR ALBUMIN IN THE URINE.—Dr. Wm. Roberts, the well known authority on urinary and renal diseases, has an article on this subject in the *Medical Chronicle*, in which he premises that the urine in health contains appreciable traces of albuminoid matter of some kind. All urines contain a diastatic ferment, as shown in their power, to a low degree, of converting starch into sugar. All urines also contain mucin, and generally in sufficient quantity to be detectable by direct testing; traces of peptone and probably of other proteids. Now in testing the urine for albumin our object is to distinguish in kind and quantity the albuminoid matter which is morbid. A reagent which, like tannin, throws down every kind of albuminoid matter, even in the minutest traces, is, *ipso facto*, condemned. The new test for albumin, such as *picric acid*, *tungstate of soda*, *mercuric iodide*, and the *acidulated brine test*; all fall under this condemnation.

The most common cause of embarrassment in testing for minimal quantities of albumin is the pres-

ence of mucin in the urine. The new tests give a reaction in the mucin which is identical with that produced by albumin. Nitric acid wholly avoids this difficulty, and the boiling test avoids it almost as completely. When a urine containing both albumin and mucin is tested, by the *contact method*, adding the reagent by means of a pipette with a tapering point, with nitric acid, the albumin is thrown down just above the line of junction of the two fluids, while the mucin is brought into view towards the upper part of the column of urine, where it gradually forms a diffused haze, quite distinct from the opalescent zone at the line of junction. Sometimes the mucin haze is seen collected into a more or less distinct zone or ring which hovers toward the middle or upper part of the column of urine. When this happens a curious distinction may be observed between the two zones. The mucin zone is broken up into a diffused haze by a slight agitation, as by twirling the test tube between the fingers; but the albumen zone is remarkably steadfast, and resists unbroken a considerable amount of agitation.

When an opalescence in a specimen of urine is produced by the other tests mentioned, the observer cannot (without further testing) tell what it means; but when an opalescence is produced by nitric acid at the time of junction of the two fluids—it means albumin and nothing but albumin. For this reason nitric acid must be regarded as the albumin test best adapted for clinical work. If the observer waits fifteen to thirty minutes at the most, so as to allow time for a possible reaction to develop itself, nitric acid becomes a very sensitive test, and falls very slightly behind the most sensitive of the less reliable tests.

If it be desired to push the testing beyond the utmost sensitiveness of nitric acid, or to arrive at conclusions more rapidly, the heat test supplies the deficiency. When the heat test is performed with certain precautions, it transcends in delicacy all other albumin tests. The chief point to be attended to is the due acidulation of the urine; too much acid or too little acid equally vitiates the delicacy of the reaction. A test tube is charged with about three drachms (10 c.c.) of urine, and to this is added a single drop of acetic acid (B. P.). The upper half of the column is then heated to boiling. If albumin is present, even in minimal quantity, the upper boiled portion of the column will show opalescence, in contrast with the lowest half, which remains unchanged. If the urine be alkaline, it should first be carefully neutralized by adding successive drops of acetic acid until the litmus paper shows a distinct but slight acidity, and then the final single drop of acid is added before boiling. Even if the urine possess its natural acidity, it is better to add a drop of acetic acid if you want to bring out the maximum sensitiveness of the boiling test. The mucin reaction is to a slight degree intensified by heat, but only interferes in the case of a urine containing much mucin with a trace of albumin. When the mucin haze is very pronounced and rapidly developed, the quantity of mucin present is sufficient to lower slightly the value of the boiling test. When this is the case, Dr. Roberts

adds to the urine a fourth of its bulk of a saturated solution of common salt. This addition prevents the development of a mucin reaction on boiling, but does not interfere in the least with the albumen reaction.

A mixture of one volume of strong nitric acid with five volumes of a saturated solution of sulphate of magnesia makes an admirable albumin test. It forms a water-clear solution, which does not fume, nor stain nor burn the fingers, or garments. Its specific gravity is 1.440, so that it sinks with rapidity through a column of urine in a test tube, and is suitable for testing by the contact method. It is distinctly more prompt and sensitive as a test than the pure acid, and its action in regard to albumin, mucin and peptone, is similar. It acts less strongly than the pure acid on the coloring matter of the urine, and is not prone to cause disengagement of gas from destruction of uric acid. One of its recommendations is that it can be carried about in a corked bottle with considerable less risk of a catastrophe to skin and garment than the strong acid.

THE DRY DIET TREATMENT OF ULCER OF THE STOMACH.—M. Debove in *Le Progres Medical* points out certain risks in the ordinary milk treatment of ulcer of the stomach: The ingestion of so much fluid, viz.: five to seven pints of milk in the twenty-four hours, into a stomach with atonic mucous membrane is apt to produce almost fatal dilatation, and the stretching of the ulcer to provoke hæmorrhage and perforation. Indeed, all excessive dilatation of the stomach is dangerous, while contraction is favorable. M. Bouchard for a long time in this disease has given a dry diet, consisting of finely divided nutritious food—such as meat powders—with not more than three-quarters of a part of pure water during the twenty-four hours, and under this regimen he has seen the morbid dilatation of the stomach diminish or disappear. M. Debove's plan is as follows: The stomach is first carefully washed out, but the operation is to be instantly stopped if the returning liquid is tinged with blood. Then the patient is to take three meals daily, each consisting of meat powder twenty-five grammes, bicarb. of soda ten grammes, and, as the mixture is not very palatable, it is well to introduce it into the stomach by a siphon. To this dry food which represents 300 grammes (about ten ounces) and 30 grammes (about one ounce) of sod. bicarb. per diem, one litre (nearly a quart) of milk is added, which is to be drunk in small quantities at a time. M. Debove's object is to annul the action of the gastric juice, and thus stop digestion and favor the healing of the ulcer.

The albuminoids are not converted into peptones in the stomach, and their alkaline reaction is very favorable to their digestion in the intestine. Perhaps, too, the soda is *directly* beneficial to the ulcer. Two severe cases of gastric ulcer, accompanied with very painful crises, by hæmorrhage, and by great emaciation, which had resisted all treatment, were quickly cured by the above treatment of Dr. Debove.—*Medical Chronicle*.

CHICAGO, ILLINOIS.

SATURDAY, NOVEMBER 8, 1884.

MICROBES AND SUPPURATION.—In a previous editorial we called attention to the experiments of Mr. Cheyne on the production of suppuration by bacteria.

Since that time he has made two further reports upon the same subject. Incidentally he has elicited several interesting facts.

In order to test the degree of virulence when grown away from oxygen; in addition to the experiments described in our former editorial upon the growth of micrococci in eggs, Mr. Cheyne cultivated them in various gasses.

He found, contrary to the views of Dr. Ogston, that they grew best in oxygen gas, next in air, and feebly and slowly in hydrogen and carbonic acid gas.

The virulence of the micrococci did not seem to be materially modified by the atmosphere to which they were subjected.

Another point of interest elicited by one series of inoculation experiments, was the fact that the micrococci appeared to be eliminated from the blood through the kidneys. They were injected directly into the veins of the rabbit. When three-quarters of a cubic centimetre or less of the fluid in which the micrococci were growing was injected, death did not occur, but larger amounts were fatal.

In one series of experiments with micrococci obtained originally from pus taken from a case of incision of the knee joint, micrococci were found only in the kidney of the rabbits into which the cultivation fluid had been injected. The most careful search did not show them in the blood, or any other internal organ except the kidney.

The lesions in this organ consisted in masses of

micrococci, and of inflammatory infiltrate around them. These lesions were very numerous in the pyramids and less toward the junction of medullary and cortical substance, and rare in the cortex itself. The first effect of the mass of micrococci is the destruction of the tissue immediately around it. Therefore on staining these specimens the micrococci appear deeply stained; around them is a white ring, and outside of this a ring of inflammatory exudate.

After a time the micrococci spread from the centre into the clear ring, and the leucocytes from without inward. Finally the mass of organisms is completely broken up and is replaced by leucocytes. The micrococci by degrees disappear entirely; the white cells become absorbed or organize fibrous tissue.

It was difficult to determine whether the masses of micrococci formed in the uriniferous tubules or blood-vessels. Mr. Cheyne believes, however, that in the great majority of cases they formed in the tubules, although possibly some of earlier formation may have been in the blood-vessels.

In another series of experiments, made with micrococci taken from wound made in excision of the breast, after cultivation and injection into the veins they were found as plugs in the kidneys, walls of the heart, liver, lungs and spleen. The micrococci in the kidneys were in the blood-vessels, not in the uriniferous tubules.

Thus we see that when micrococci of pure cultivations are injected into the veins of animals different results follow, depending upon the source, or more probably the nature of the microbe.

Another conclusion which Mr. Cheyne draws from these experiments is, that "organisms not capable of growing in the blood may yet produce serious results by growing in the excretory canals."

Dr. Ogston has asserted that all suppuration is produced by microbes, except in cases of burns or blisters. Mr. Cheyne admits that micrococci are always found in acute abscesses, and are probably the cause of the suppuration, although perhaps not the primary cause of the inflammation. Still he shows that suppuration can be produced without the agency of these bodies.

The most conclusive experiments upon this point were made by placing within a thin glass tube a sterilized mixture of olive and croton oil. The tube was then sealed and inserted into the muscular tissues of an animal, under the strictest antiseptic precautions. The incision which was made was allowed to heal, when the tube was broken, thus permitting the irritating contents to escape into the tissues. Abscesses were formed containing pus, but no microbes.

At the time the oil-tube was inserted into the tissues, sterilized meat infusions were inoculated with the same sterilized oil mixture. In these, also, no micrococci developed.

These papers of Mr. Cheyne are interesting, both on account of the value of his own experiments, which we have briefly described, and for the conclusions which he adduces both from them and the work of others.

HYDROCHLORIDE OF COCAINE — A LOCAL ANÆSTHETIC FOR MUCOUS AND SUBMUCOUS SURFACES.—The news wafted across the water from the Ophthalmological Congress in September last by Dr. H. D. Noyes, of New York, of the remarkable powers of the hydrochloride of cocaine as an anæsthetic to the mucous and subjacent tissues of the eye, has excited the attention of physicians all through the country. The information sent to the *Medical Record* by Dr. Noyes was in substance as follows: Dr. Koller (Dr. Lucien Howe, in his letter to the *American Jour. of Ophthalmology*, calls him Dr. Carl Carson), of Vienna, gave to Dr. Brettauer, of Trieste, a 2 per cent. solution of hydrochloric of cocaine for exhibition as a local anæsthetic for the eye. He had only lately become acquainted with its properties relative to the eye, and began his observations from a knowledge of its anæsthetic influence on the vocal cords. The solution was used before the Ophthalmological Congress, and after the instillation of two drops of a 2 per cent. solution at an interval of ten minutes, the cornea, which was previous to the use of the solution of normal sensitiveness, could now be touched and even indented without any complaint of pain. Moreover, a speculum was introduced, the lids distended, the conjunctiva seized with the forceps, and the eye moved in any direction without any complaint whatever.

No sooner was this news received than active workers were eager to utilize its qualities, and with the exception of two reporters in the *British Medical Journal*, the record hitherto attributes to it such virtues that it promises to practically obliterate the use of ether from the ophthalmic surgeon's practice, except in cases in which the education has been so deficient that the patient screams at the sight of an instrument. To counterbalance the testimony of the two reporters in the *British Medical Journal* referred to above, it should be added that Mr. Nettleship, ophthalmologist at St. Thomas's Hospital, and of great experience, reports the most complete success with its use; and in New York, Drs. Agnew, Moore,

Minor and Knapp, as well as several others through the country, have all put it to the test by performing under its influence the various operations of extraction, tenotomy, removal of pterygium, etc., etc., with the most gratifying results. A 4 per cent. solution seems to be preferred to the 2 per cent.

With such a sudden revelation of remarkable and useful properties we naturally turn to literature and memory for some of the foreshadowings of its approach. We are told by Dr. E. R. Squibb that cocaine, although differing chemically from caffeine and theine, produces similar physiological effects, but that the cocaine is about six and a half times as strong,¹ but whether this new application of the properties of cocaine will modify his views or not will, we have no doubt, be revealed later. The common conviction among the laity of the value of tea as an application to the eye may lead us to suppose that even in this question of anæsthesia the similarity of the physiological effects may hold good. Stillé and Maisch say: Tea is applied in China as a wash to the eyes, ulcers and wounds of all kinds, and Lettsom is said to have shown that the volatile substance which may be distilled from an infusion of tea was capable of "paralyzing the hinder legs of the frog."

Robertson says, in his *Eléments de Thérapeutique et de Pharmacologie*, published in 1877, when a good quality of coca leaves are chewed one realizes a certain anæsthesia of the tongue and buccal surfaces. He further explains the well authenticated capacity of those who use the coca leaves habitually, to endure hunger, as arising from the anæsthetic condition of the mucous surfaces which unanæsthetized are the seat of the pain of unappeased hunger. His observations were made on a student of his in R's laboratory. The experiments of Mr. Dowdeswell in the physiological laboratory of University College, London, more or less contradict these statements, but the probability is that Mr. Dowdeswell worked upon very inferior samples of leaves. Indeed, Dr. Squibb has lately ceased to make the fluid extract simply because it was impossible to get a creditable article in the market. This is deplorable when we consider the large amount which is annually disposed of. In 1877 Rabuteau says that the annual amount of money exchanged for coca leaves was about 25,000,000 francs; and Dr. Squibb says that at present it amounts to \$10,000,000, the amount by weight being 40,000,000 pounds.

The average yield of cocaine from the leaves of good quality seems, from the observations collated and made by Dr. Squibb, to be about 0.25 per cent. All the reports hitherto seem to speak of the substance

¹Ephemeris, July, 1884, p. 605.

used as a definite hydrochloride or muriate of cocaine. It would seem, however, from the way in which it is used, to be questionable whether the salt is in solution as a definite hydrochloride or not.

Rabuteau says: The action of acids on the alkaloid cocaine is somewhat complicated; for according to Loessen hydrochloric acid decomposes it and develops from it benzoic acid and eczonine, and that with the latter base the hydrochloric acid forms a salt. Stillé and Maisch say cocaine when prime, is in colorless prisms of a strong alkaline reaction, has a bitterish taste, produces a transient numbness on the tongue, and dissolves in 704 parts of water and in much less alcohol and ether. They also say that strong hydrochloric acid decomposes it into methylic alcohol, benzoic acid and eczonine. Squibb in his investigations speaks of the cocaine as a greenish oily substance in which there was no appearance of a crystallized alkaloid. A sample of the solution in use which we have had the pleasure of seeing, gave on evaporation no sign of crystallization but presented the appearance rather of a gum.

The testimony in favor of its use as an anæsthetic for mucous surfaces is so great that its field of usefulness will certainly extend far beyond the domain of ophthalmic surgery, and the consequent demand will probably stimulate the producers to more care both in cultivation and transport.

AMERICAN PUBLIC HEALTH ASSOCIATION. — The third day of the recent annual meeting of this Association in St. Louis was occupied chiefly in listening to papers on Cattle Diseases, and especially on "Texas Cattle Fever," by Dr. W. B. Conery, of Missouri, and Dr. A. M. Partridge, of Indiana; on Malaria Protectives, by Dr. G. B. Thornton, of Tennessee; on The Importance of Water Analyses, both Chemical and Microscopical, by Dr. Charles Smart, of the U. S. Army, and Thad. M. Stevens, of Indiana; on The Pollution of the Waters of the Upper Ohio, by Dr. J. E. Reeves, of West Virginia (which may be found in full in this number of the JOURNAL); on The Relation of Depth of Water in Wells to the Causation of Typhoid Fever, by Dr. H. B. Baker, of Michigan; and The Use of Polluted Well Water in the Manufacture of Soda Water in St. Louis, by Dr. Frank R. Rye, of Missouri; on The Disposal of Sewage, by Dr. S. S. Herrick, of Louisiana, and Dr. W. J. Harris, of Missouri; on Disease Germs, by Dr. Geo. M. Sternberg, of the U. S. Army; and on The Bearing of the Discovery of the Tubercle Bacil-

lus on the Public Health, by Dr. L. Bremer, of Missouri.

All these papers contained some matter of value, and especially those of Drs. Thornton and Sternberg, yet we have been able to cull but little that is not already familiar to the readers of the JOURNAL. On the fourth and last day of the meeting the attendance of members was very small. Some time was devoted to the transaction of miscellaneous business, and some additional papers were read.

Officers Elected.—The Advisory Council recommended that the following gentlemen be elected officers of the Association for the year: Dr. James E. Reeves, of West Virginia, President; Hon. Erastus Brooks, of New York, and Dr. Henry B. Baker, of Michigan, Vice-Presidents; Dr. J. B. Lindsley, of Tennessee, Treasurer; Dr. H. P. Walcott, of Massachusetts, Dr. Charles Smart, of the United States Army, Dr. Geo. B. Thornton, of Tennessee, Dr. D. W. Hand, of Minnesota, Dr. Gustavus Derron, of Louisiana, and Dr. H. B. Holbeck, of South Carolina, Executive Committee. The Council further recommended that the next Conference of the Association be held at Washington in December, 1885, and that the thanks of the Association be tendered to the Government of the Dominion of Canada and the Ontario Board of Health for their kind invitation to hold the next meeting in Toronto, and that the Secretary be instructed to decline the invitation. The Conference unanimously approved of the recommendations of the Council.

An Advisory Council of one from each State was also appointed, and after adopting the usual complimentary resolutions the Association adjourned. Although the attendance of members during the annual meeting was not as large as we had anticipated, the papers read and all the discussions related more exclusively to the appropriate objects of the Association than at previous meetings, and the result will be a material advancement of the public health interests, and the promotion of greater harmony among the workers in that field throughout the whole country. The municipal authorities, citizens and profession of St. Louis deserve much credit for the liberal hospitalities extended by them to the members of the Association during the week of their sojourn in that city.

THE PULLMAN SYSTEM OF EPURATION OF SEWER-AGE.—Having received several inquiries in regard to the details of the system of sewerage and epuration in operation at Pullman in the vicinity of this city, we answer as follows: The population of the town is

about 8,000. The sewerage matter is received into a system of deep laid sewers through which it is conducted into a large cesspool, from which it is pumped through a large cast iron pipe to the farm, a distance of 15,500 feet (about three miles), where it is received into a tank, screened through $\frac{1}{2}$ inch screen to separate out the coarser matter contained in it. From the tank it is distributed over the farm through clay pipes laid four feet below the surface, with hydrants every 400 feet to carry it to the surface over which it is allowed to flow.

The farm has 140 acres capable of being irrigated through these pipes and hydrants, and takes care of the whole sewerage of the town with ease and profit.

CHOLERA INVESTIGATIONS.—A recent report of the French Commission for investigating the nature of cholera in Marseilles, shows an entire failure to produce cholera in rabbits or other animals by a great variety of experiments with the comma-bacilli, both as found in the intestines of cholera patients and by cultivation, and consequently it affirms the non-contagiousness of that disease.

The report describes a peculiar condition of many of the blood-copuscles, which the Commission regard as the essential pathological condition in epidemic cholera.

OVARIOTOMY WITH EXTIRPATION OF ONE KIDNEY.—We are informed that on Monday, Oct. 26, in presence of the medical class at Ann Arbor and a number of medical practitioners, Prof. Donald Maclean, of Detroit, extirpated the left kidney, both the ovaries and a large piece of the omentum from a married woman 27 years of age, who proved to be in an early stage of pregnancy.

So far, now one full week, the patient has done well, and the case promises to be a complete success. The kidney and both the ovaries were cystic, the former being very large.

MUNIFICENT BEQUEST.—The late Countess Bose, of Cassel, by her will made a legacy of \$190,000 to the University of Berlin, for the benefit of poor students of medicine.

DR. LOUIS A. DUGAS, one of the most learned and eminent physicians of Georgia, died at his home in Augusta, on the 19th ult., at the ripe age of 78 years.

STATE MEDICINE.

PRACTICAL RECOMMENDATIONS FOR THE EXCLUSION AND PREVENTION OF ASIATIC CHOLERA.

BY JOHN H. RAUCH, M.D.,
Secretary Illinois State Board of Health.

Presented to the Conference of State Boards of Health in St. Louis, Oct. 13, 1884.

MR. CHAIRMAN :

A grave responsibility rests upon those charged with the protection of the public health at the present time. For the past six years—ever since the memorable fever-summer of 1878—the country has been free from any serious and widespread epidemic disease. Small-pox, which prevailed from 1880 to 1883, has been successfully combated, and its ravages confined to proportions which are insignificant when compared with many other epidemics. Hundreds of thousands of unprotected immigrants were landed on our shores during those four years; but the Immigrant-Inspection Service, inaugurated in the spring of 1882, thenceforth rendered them comparatively harmless, by securing an improvement in their sanitary status through the effect of the Service upon the work of steamship surgeons during the voyage, and upon the methods at quarantine on arrival; as well as by its own sanitary surveillance of the immigrants from the port of arrival to the point of ultimate destination or distribution in the great interior—such surveillance consisting of repeated inspections, vaccination of the unprotected, systematic observation of suspicious sickness, prompt isolation of discovered small-pox or other contagious disease, and the enforcement of the measures necessary to prevent its further spread. Among our own people outbreaks of the disease were promptly suppressed wherever sanitary authority had control, and well-defined methods of dealing with the contagion were enforced. On the other hand, while we have fought small-pox and conquered it, we have been spared from any serious conflict with yellow fever. Nor have other diseases prevailed to an unusual extent, as they so often do in the absence of an epidemic. On the contrary, the average annual death-rate has been low, and during the past year remarkably so.

This very fact should be, in itself, a warning to the sanitarian. It means a survival of a large number of persons who would have been carried off had the non-epidemic diseases maintained their usual severity. It means the accumulation of susceptible material ready for the prey of epidemic contagion, whenever such contagion shall be introduced under conditions favoring its propagation and spread. It is one of the most important factors in determining the extent and severity of the next epidemic, whatever that may be and whenever it may visit us.

But, for a period of six years, sanitary effort and sanitary authority have had no unusual demand made upon them, or at least no demand which the public recognizes as unusual. And during these six years the interest in sanitary matters which was aroused by the epidemic of 1878, and which, among other causes,

led to the formation of many of the present State Boards of Health, and to the creation of the National Board, has gradually diminished as the memory of the epidemic faded away, or was displaced by other and newer topics and occurrences.

One of the chief reasons why sanitary work fails to receive continuous and adequate consideration and support from the public and from the legislator, is that, in its very essence, it is a work of prevention; and just in proportion to its own success and thoroughness does it destroy the obvious and palpable reasons for its continuance. When an epidemic actually exists, and industry and commerce are paralyzed in its presence, and the death-roll swells from day to day, there is then no question in the public mind about the desirability of sanitation, no hesitation as to making appropriations for its support, or enacting legislation to increase its efficiency.

But Rabelais told us, nearly four hundred years ago, what always happens whenever the devil gets well. And Congress adjourned its last session, not only without doing anything additional for the protection of the public health, but after substantially annulling and rendering inoperative the only national legislation of any real value which we possessed.

However, there is a revival of public interest in these matters within the past few months, due to the spread of Asiatic cholera in Southern Europe; and it is our present duty, as sanitary officials, to utilize and direct that interest to the securing of adequate legislation and intelligent action for the prevention of the introduction of the pestilence to our shores, and its limitation, should it unfortunately effect an entrance. Much has already been done in the latter direction, by the action of State and local health authorities in pushing the sanitary education of the people through circulars, memoranda and other modes of appeal. Since the second of July last such circulars from sixteen States and from the Dominion of Canada have already come under my notice. In many instances, sanitary inspections of municipalities, public institutions, jails, almshouses and kindred establishments, have been ordered and carried out, with the view of securing the abatement of nuisances and remedying defects in the sanitary conditions thence disclosed. An amount of sanitary work has been thus already accomplished which, aside from any consideration of cholera, will be of great value in reducing sickness and mortality from the entire list of diseases which are caused or favored by filth and other unsanitary conditions. As a recent number of the *New York Medical Record* says: "There is no doubt that the extra cleanliness produced by the cholera scare will effect a saving of life from other filth diseases far in excess of the mortality from the cholera itself; unless, indeed, it should spread beyond all expectation."

This work should be continued, and the measures which have already been inaugurated, looking to improvement in general and local sanitation, should be pushed with unabated vigor during the favorable weather we may yet have; and they should be resumed with redoubled energy whenever climatic conditions permit. It is not necessary to go into details as to this work; we are familiar with its requirements

and its necessity. It is a work of continuous interest and importance, whether cholera should come or not.

With theories and speculation as to the causation of cholera, or as to its mode of diffusion and epidemic spread in the countries of the old world, this conference is not concerned. It is enough for us to know, as the basis of our action, and the foundation for practical recommendations and advice, that the disease is not indigenous to this continent; that it is an exotic, and has never yet visited us except by importation, and that only after ample warning.

It may be entirely true that, if all our food supplies were wholesome, and our water-supplies not only unpolluted but unpollutable; if sewage and refuse disposal were prompt and complete; if our cities, towns and villages were all models of sanitary perfection, and their inhabitants free from predisposition or susceptibility, acquired or inherited—in short, that if there were no ignorance, nor poverty, nor filth, nor infirmity in the land, we might dispense with precautions against the introduction of disease.

But the sanitary millenium is not yet, and we are hardly likely to witness its advent before next spring or summer, no matter how earnestly we may labor for it. So, for the present, at least, as a practical sanitarian accustomed to deal with conditions as they actually exist, I think the wise thing to do in respect of cholera is to resist the first beginnings—*obsta principis*.

It is no doubt well to be prepared to expel the midnight burglar from one's dwelling; it is better to keep him out by locks and bolts and watchful patrols. If people must live among combustible material it is a prudent thing to forbid smoking on the premises, and to be careful about matches and other incendiary agencies, the contagion or contact of which may kindle a conflagration.

Until we can very materially change the conditions which cause considerably over one-half the annual mortality, it is our simple duty to adopt whatever measures promise a fair degree of success in excluding the foreign epidemics. Such typical filth-diseases as typhoid fever and diphtheria carry off sixty odd thousand people every year; and during the census year ten principal groups of more or less preventable diseases caused over 470,000 out of the total 756,000 deaths in the United States.

With such a showing it is simply nonsense to talk about relying upon sanitary measures alone to combat a disease like cholera. Let us push sanitation by every means in our power, and to the fullest extent. Not, however, with any hope that we can effect such a sanitary revolution in a few months as would prevent cholera, if once introduced, from spreading as an epidemic in hundreds of localities, but rather in the knowledge that every sanitary reform tells permanently and continuously on the whole body of preventable diseases; and that to the extent and measure of such reforms are the conditions made more favorable for the exclusion and prevention of all epidemics.

That cholera *will* come, it is our duty to assume. Mindful of the history of every previous cholera epidemic, we must accept as beyond a doubt—if ex-

perience is worth anything—the certainty that the disease will be brought to our shores. It always has come, sooner or later, whenever, since 1832, the contagion has obtained such a foothold in Europe as it now has.

Sooner or later, it is sure to come, and we cannot tell how soon. Cholera was brought to Marseilles in the early part of June, 1865, from Bombay via Mecca, by pilgrim-steamers conveying Algerine pilgrims returning home from the feast of sacrifices at the "holy city," and spread so rapidly that, during the month of October, it caused between four and five thousand deaths in Paris. On the 12th of that month the steamer *Atalanta* left Havre with over 600 cabin and steerage passengers, all of whom had been in Paris, and on her arrival in New York bay she had had 102 cases of cholera and 23 deaths. So that the disease was brought from its endemic home in India, by way of Mecca, Marseilles, Paris and Havre, to New York in less than nine months.

It is probable that we do not know how widely spread the disease is upon the continent, nor what places and ports are infected. The London *Lancet* recently stated that it has transpired that there were deaths from Asiatic cholera in Marseilles during 1883, and Dr. Albert Drysdale, health officer at Mentone, writes to that journal corroborating the statement from his own personal observation, having been taken to see a case in October, 1883, by a medical friend. Attendants, nurses, and all others cognizant of the facts were sworn to secrecy. Still more recently French naval officers have frankly stated that cholera existed on their vessels at Toulon long before the fact was made known last spring. In 1873 the existence of cholera was concealed in Austria on account of the great Vienna Exposition, and although the disease is now known to have been spreading from place to place from early in the spring, it was not until mid-summer that any warning was sounded of an epidemic which caused 240,000 deaths in the Austrian dominions alone.

I repeat that we may not know how widely spread the disease now is on the European continent, and that we do not know how soon its arrival on our own shores may be announced. It is not probable, however, that it will reach us before next spring, and we may pretty safely count on some months yet in which to push our preparations to meet it and to resist its advance.

I began my remarks with the statement that a grave responsibility rests upon the sanitarian at the present juncture; but there is an equally weighty obligation resting upon the public and upon our legislators. I undertake to say, as a sanitary official of nearly 25 years' experience in the practical administration of sanitary matters in city, State and nation, and after more than a third of a century of study and observation of the disease, beginning in 1850—that Asiatic cholera may be practically excluded from the United States: That it is preëminently a quarantinable disease. That, with a judicious employment of agencies which have already been tested, Asiatic cholera may be quite as successfully dealt with in this country as small-pox, and probably more so than yellow fever.

Whether cholera shall be excluded—whether the means and agencies necessary to deal with it shall be supplied—are questions which the public must answer through their representatives in Congress, in State legislatures, and in their municipal councils; and I propose in the remaining portion of these remarks to endeavor to point out what means and agencies are necessary to the end in view; premising that, in their consideration, it should be remembered that sanitary science is comparatively modern; that the sanitary organizations of the present day had no existence in the days of the great epidemic visitations of cholera in this country; that within the past few years there has been a rapid and wide-spread diffusion of sanitary knowledge among the people; and that, even so lately as the last cholera epidemic in the United States, that of 1873, no organized effort was made to prevent the importation of the disease, and practically little or nothing done to prevent its extension; certainly, no such measures have ever been employed, either to prevent its introduction or to limit its spread, as we have recently successfully employed against small-pox and yellow fever.

Asiatic cholera—so far as this country is concerned—is preëminently a quarantinable disease. Unlike the virus of small-pox, unlike the poison of yellow fever, the morbid potency of the cause of Asiatic cholera—whatever that cause may be—is sharply limited as to duration. Failing to find suitable conditions for its growth and reproduction it *dies out*. No single case, no single shipload of cases ever succeeded in establishing an epidemic in this country. I know this is contrary to the received opinion and popular belief; but I ask you to follow me in a brief resumé of the facts concerning each epidemic, beginning with 1832. That epidemic is attributed to the ship *Carrick*, which arrived at the Grosse Island quarantine station in the St. Lawrence river on the 3d day of June, 1832. But six days before that, the ship *Elizabeth* had arrived with 200 immigrants on board, and having had 20 cholera deaths during the voyage. Fourteen days before the *Elizabeth* the *Robert* had arrived, with 10 cholera deaths; and sixteen days before the *Robert*—that is on the 28th of April, 36 days before the arrival of the *Carrick*—the ship *Constantia* arrived, having had 29 cholera deaths during the voyage. These are all known to have been cholera-infected vessels, and their hundreds of passengers were known to be cholera-carriers; but these passengers are only a small fraction of the 30,000 immigrants who arrived in the St. Lawrence during the spring and early summer of 1832, from the same infected localities and sailing from the same infected ports as the passengers of the *Constantia*, the *Robert*, the *Elizabeth*, and the *Carrick*. And yet they failed to develop a single case in Canada or elsewhere until the 8th day of June. The introduction of the disease into New York is attributed to Canada; but the same class of immigrants from the same localities in Europe, were arriving in New York during the spring of 1832, as those in the St. Lawrence. And yet no case of the disease occurred in the city or vicinity until June 13.

In 1848, the noted cases of the New York and the

Swanton occurred—the former carrying cholera into New York, the latter into New Orleans; and to them is attributed the epidemic which, in the two succeeding years, spread from the Atlantic to the Pacific and from Canada to the gulf. But the importation by the New York, though causing fifty deaths at quarantine, resulted in only two cases in New York city, and it was not for months afterwards—not until the 11th day of May, 1849, and after the arrival of several other ships with cholera on board, that the first case appeared in the city, and the disease began to spread from that point. On the other hand, immigration from cholera-infected districts of Europe into New Orleans had been continuous for months before the arrival of the Swanton—the two vessels immediately preceding her, viz.: the Gutenberg and the Callao, having lost 25 passengers from cholera.

From this time until the close of what is generally known as the epidemic of 1854, but which was really only a continuation of the epidemic of 1848–49, there were continual importations of cholera-carriers, either in the persons of those who had been exposed, or in cholera-infected articles; in November, 1853, for example, no less than 28 vessels, on which 1,141 persons had died of cholera, arrived at the port of New York alone.

The case of the *Atalanta*, in 1865, has already been noted; but it should be further observed that there were three other arrivals from Havre soon after, and on the last two of these there were deaths from cholera during the voyage, but the disease got no nearer the city than Ward's island, and by the 20th of December had entirely ceased. In 1866, cholera was carried into Halifax by the steamer *England*, which vessel afterwards proceeded to New York, where, on the 20th of April, she landed 891 passengers and 116 officers and men, having lost 316 by cholera. There were eight cases and five deaths among those who had to do with the vessel at Halifax, but no other extension of the disease, and none in New York. Two days prior to the arrival of the *England*, the *Virginia* had arrived at New York quarantine, having had 116 deaths on the voyage; and before the first death of the epidemic of 1866 had occurred, namely, May 2, there had been nearly 3,000 arrivals in New York of individuals "who had been directly exposed to the infection of cholera at Liverpool, on shipboard, and at quarantine." Notwithstanding this, so slowly does cholera spread, except under favorable conditions, that there had been only 21 deaths from the disease up to July 8; and it was not until the first week in July that the disease appeared in Brooklyn, although there were frequent arrivals of cholera vessels during all this time.

The epidemic of 1873 was preceded—*fourteen months before the first case of the epidemic occurred*—by the arrival of the *Franklin* at Halifax, November 6, 1871, in distress, having lost 28 of her steerage passengers by cholera. Five cases, with three deaths, resulted from her on shore, but the disease did not spread, either in Halifax or vicinity. The vessel proceeded to New York, where she arrived November 12, 1871, having lost 11 more of her passengers, and having 72 cases then on board. But no epidemic

followed. During 1872 there were numerous arrivals from cholera-infected ports, and the disease appeared on the island of Cuba and in Jamaica in the autumn of that year. During December, 1872, and January, 1873, there arrived in New Orleans a total of nearly 2,000 immigrants from cholera-infected districts of Europe. And yet it was not until the 9th day of February, 1873, that the initial case of this epidemic occurred in the city of New Orleans.

No single case of cholera, no one shipload of cases has ever yet sufficed to establish an epidemic of Asiatic cholera on this continent. It has only been after repeated importations of the contagion in the persons of thousands of immigrants and in their infected baggage and household goods, that it has effected a lodgment, and has reproduced itself and multiplied into an active epidemic agency.

Hence my first proposition, that, for this country, the disease is essentially and preëminently a quarantinable disease, and may be practically excluded. If it were true of the cholera poison, as it is of the small-pox contagion, that favorable conditions for its spread exist wherever a susceptible individual is found, without reference to the sanitary surroundings, we should have no such history as I have just recited,—a history of repeated importations extending over months and months before it succeeded in establishing itself.

It will not do, however, to construe this tardy establishment of the contagion into an excuse for delaying measures of preparation—neither those for its exclusion, nor those for its limitation and suppression, should we fail to exclude it. Cholera is a capricious disease, and the history of its various pandemic extensions throughout the Old World affords occasional instances of a single introduction sufficing to inaugurate an epidemic. Fortunately, the same conditions do not, generally, obtain with us, except in a few localities. Populations are not so dense, nor are dwellings so saturated with crowd-poison, nor is the soil so thoroughly polluted by long occupancy. Where these evils exist they should be remedied forthwith to as great an extent as practicable, in order that, among other good results, the conditions favorable for the growth and multiplication of the cholera-poison may be destroyed or limited.

It is charged that quarantine is powerless to prevent the extension of epidemic diseases; that, in the language of John Simon, "a quarantine which is ineffective is a mere irrational derangement of commerce;" and that to be effective, it must be of such a nature as to absolutely prevent all intercourse with the infected country. All this may be true of Great Britain, owing to her geographical position, to her extensive commerce and its exigencies, to her dependence on other countries for her food supply, and to other conditions which do not obtain with us. It may also be true of Europe generally. There a narrow strait or sea, a river, a mountain chain, or merely a territorial boundary line, with its custom houses and passport system, defines the limits to be guarded, and forms the only physical barrier between the quarantiner and the quarantined. Here, the whole width of the Atlantic intervenes between us and the infected country. There, cordons and

quarantines mean privation, misery and suffering, and, ultimately, starvation. Here, the nation is self-supporting, and could exist unaffected in almost all her material interests. There, it may be true, as alleged, that a quarantine of exclusion is impossible of execution, and that the attempt to maintain it does more harm than good, in leading to numberless contraband practices by which the disease may be introduced in unsuspected ways.

None of this is true when applied to the exclusion of Asiatic cholera from this country; while to accept the statements unquestioned would cause vigilance to be relaxed, would invite contagion to our shores unimpeded, and would finally throw upon individual communities the burden and the responsibility of fighting the disease at an immense disadvantage—that is, of fighting it at home and from many quarters, instead of on the outer lines and from only one direction.

With the necessary agencies of an effective quarantine provided in due season, it would not require any very great degree of courage to promise the practical exclusion of the disease.

These necessary agencies may be thus stated in their natural order of sequence:

First.—Timely and trustworthy information of the existence of the disease in countries and at ports having commercial relations with our own, including telegraphic advices of the departure of vessels from such ports for ports in this country. Section 1752 of the Revised Statutes of the United States gives the President authority to use all diplomatic and consular officers for “the communication of information * * * conducive to the public interests;” and instructions have already been issued under this authority.

To properly utilize this information, in fact, in order to fully secure the information, there needs to be—

Second.—A national health organization, representing the natural sanitary divisions of the country; endowed with adequate authority; supplied with means commensurate with the duties imposed upon it; and with the power to call upon any other branch of the public service of the United States for legitimate assistance and coöperation. With some modifications the present National Board of Health would satisfactorily meet this indication. In my judgment its membership should be enlarged so as to more perfectly represent the natural sanitary areas, and its members should be familiar not alone with the sanitary features of their respective districts, but equally they should be identified with the commercial, business and industrial interests.

Under this national health organization there should be extended and perfected—

Third.—The system of Refuge Stations projected by the National Board of Health. With two or three exceptions, no port in the United States has adequate facilities for the proper administration of quarantine. Such a system as was inaugurated by the National Board of Health, and which is the only quarantine contemplated in these remarks, involves the removal of an infected or suspected vessel out of the track of

commerce; the segregation of her sick from the well; the proper care and shelter of both these classes; the necessary disinfection of infected cargo, and the purification of the vessel; and the release of vessel, cargo and persons so soon as they have been rendered safe and free from the danger of communicating disease.

This is very different from a mere quarantine of detention. It is the American quarantine of sanitation, a common-sense quarantine, which aims to prevent the introduction and extension of contagion, not by merely arresting it at a given point and then leaving sick and well at its mercy until, the susceptible material having become exhausted, no more cases of the given disease occur; but by removing the susceptible at once from its influence, and then destroying it and the conditions necessary for its existence by scientific methods of disinfection and purification.

To do this, however, requires a quarantine plant and facilities far beyond the means of any but the largest ports, supported either by abundant quarantine fees or by adequate appropriations from the State or municipality. But cholera may obtain access at a small port as well as at a large one, and hence the necessity for the Refuge Stations above indicated.

Under the system here outlined the departure of a vessel from a cholera-infected port would be at once cabled to the national health officer; the authority at the port of destination would be duly notified; pilots for such port would be ordered to take the vessel to the nearest Refuge Station; and at such station, under the charge of a national officer, and at the expense of the national government, she would be so treated as to make it impossible that she could land cholera-contagion in our midst.

So much for the measures which should be adopted for the exclusion of the disease—measures which have already been practically tested sufficiently to demonstrate their feasibility and value. But before dismissing this branch of the subject it will be well to consider the possibility that it may be necessary to absolutely prohibit immigration, for a time at least, from infected countries. Every one of our cholera epidemics has been directly and unmistakably traceable to the arrival of immigrants infected in person or in baggage and household goods. It was the crowded troop-ship and transport which brought the contagion into France from China and Egypt. It is the crowded pilgrim-steamer and passenger vessel which carries it from Bombay and Calcutta into Europe and elsewhere, as already instanced. It is the steerage of the immigrant vessel, with its crowded and other conditions favorable to the development of a specific contagion, which we have to fear. This contingency is one of the most important against which national legislation should be provided next winter.

I have said that I believe Asiatic cholera may be as successfully dealt with in this country as small-pox— notwithstanding that we have no such demonstrated prophylactic for the former, as vaccination is for the latter disease; that it may, probably, be more suc-

cessfully dealt with than yellow fever—notwithstanding that this is limited by climate and temperature, while cholera is independent of the one and only measurably affected by the other. I believe this to be the case as the result of my own official experience. In the last two epidemics of cholera, the disease was controlled wherever it appeared in the localities under my supervision, by the adoption and enforcement of the simplest measures. Surface wells were fouled with carbolic acid, so that their use for drinking and culinary purposes was necessarily abandoned, and a pure water supply was provided instead. Every house where a case of cholera appeared was promptly taken charge of by the sanitary authorities; the patient was isolated; discharges were disinfected and buried; all other sources of infection were carefully looked after, and the premises, generally, were put in the best attainable sanitary condition; and with marked results upon the extension and progress of the disease. Every community, for itself, may readily provide a similar mode of dealing with a cholera outbreak, should the disease, unfortunately, be introduced.

But something more than this is needed in order to perfect the sanitary defense of the whole country. For this we must have coöperation and concert of action. We must devise a plan whereby the limited and individual powers of communities and States may supplement each other and act harmoniously and efficiently for the common welfare. In the exercise of its police powers—upon which all its sanitary laws and ordinances are founded—the municipality is confined within its own limits, or, for certain purposes, to a short distance beyond. The power of the State is in like manner limited by its own boundary lines.

In the absence of a national health organization, with power to act without reference to State lines and with resources to meet every emergency, the best we can now do is to form an organization of all those clothed with sanitary power and authority, both State and municipal:—an organization which shall give effect to the principle that, in sanitary matters, the interests of one are the interests of all; that we are each our brother's keeper in whatever pertains to the prevention of the introduction and spread of epidemic contagion. Such an organization as the Sanitary Council of the Mississippi Valley, supervising—and if need be maintaining—a system of sanitary surveillance similar to the River and Rail Inspection Service in the Valley, and the Immigration-Inspection Service of the recent small-pox epidemic, will be of great value in a two-fold manner.

It will enable State and municipal authorities to aid each other and to make their rules and regulations substantially uniform, and thereby to secure the coöperation and assistance of transportation companies and other commercial interests, whose business success depend so largely on freedom from unnecessary interruption or conflicting and changing restrictions. It will be of positive sanitary value in the moral pressure exerted on the individual agents of travel and traffic.

Here in the Valley, a great improvement in the sanitary conditions of steamboats, barges and river craft, and, to a minor degree, in the care of railway cars, depots and out-buildings, followed the knowledge that the detention for inspection depended upon the experience of the inspector with regard to the particular boat or line. In the same way the conditions of immigrant travel were sensibly improved by the Immigrant-Inspection service, not only on our railroads, but on the ocean steamers themselves. Its effects were also manifested in the administration of the seaboard quarantines, to which the Service was a direct help in securing a prompter and more general compliance with the quarantine requirements of the different ports.

This latter point is one of supreme importance to the interior. Illinois, for example, is as much interested in maritime quarantines as are communities bordering upon the Atlantic and the Gulf of Mexico. During my own official experience the State has repeatedly suffered from the laches and inefficiency of their administration. Her sanitary interests are protected or endangered through them along the whole line from the mouth of the St. Lawrence to the mouth of the Mississippi, and even to the Rio Grande. Means of communication and intercourse are now so multiplied that time and space—in respect to contagious diseases—are practically annihilated; and the methods which secured protection for the interior twenty years ago are, to a great extent, valueless to-day. In 1873, for example, there were outbreaks of epidemic cholera at Carthage, Ohio, Kandiyohi county, Minn., and Yankton, Dak., caused by cholera poison packed up in the household effects of emigrants in Holland, Sweden and Russia, respectively; these emigrants sailed from healthy ports, in healthy vessels, and were subjected to the usual sanitary requirements of the period. They passed through New York and all the intermediate territory without injury to the public health. But when their infected goods were unpacked in the interior of the continent they liberated the poison which gave rise to the local outbreaks.

Sooner or later the national government will be compelled not only to assume supervision of exterior quarantines, but to provide for a permanent system of coöperation with State and local governments in the administration of inter-State sanitation, in order, on the one hand, to prevent the introduction of exotic epidemic diseases, and, on the other, to prevent their spread from State to State along the great intra-national highways of travel and commerce. This is a national duty. It is one that the national government only can adequately discharge, and its expense is, equitably, one which should be defrayed from the national treasury.

Such an organization as I suggest will be one agency for securing the assumption of this duty by the general government; and the present emergency offers a favorable time for pressing its consideration. Heretofore, legislation in the interest of public health has been obtained, as a rule, at the tail-end of an epidemic. It has too often been in the nature of a locking of the stable-door after the horse was stolen.

Let us now see if we cannot reverse the process, and, while there is yet time, induce not only Congress, but States and municipalities to take the necessary action for securing a better protection of the public health.

Just now this means more than the good to be found in the saving of human life and in avoiding the suffering and misery, the ruined homes and desolated families which an epidemic always leaves in its track. It means the prevention of panic; it means the prevention of the interruption of trade and commerce; it means the prevention of the loss of millions of dollars, all of which would inevitably result from an epidemic of Asiatic cholera in this country. Already the disease has cost Southern Europe not less than a hundred million dollars—six million dollars up to October 1st in trying to prevent its spread in Italy alone, with a loss of four million dollars even in the month of August, before the disease had effected a serious foothold; and now it is announced that the decrease of the national revenues of France has been materially aggravated by the reduction of receipts from railways, caused by the cessation of travel consequent upon the prevalence of the cholera epidemic. And yet Europe is only upon the threshold of this epidemic, if we may judge from the past.

Shall we be warned in time, or shall we wait until the pestilence has landed and obtained a foothold? A single outbreak—possibly a single case—of Asiatic cholera in New York, or Chicago, or St. Louis or New Orleans, in our present condition, would cost the country millions of dollars, even though no epidemic spread should result.¹ With a perfectly feasible quarantine system, whose entire cost would not be a tithe of this sum, the chances of that single case may be made exceedingly remote. With an adequate sanitary organization—embracing within its scope the national authority, the State and the municipal, each in its respective sphere—not one case, nor one hundred could establish an epidemic.

Such an organization of the sanitary defenses would inspire public confidence and prevent panic in the face of real danger—and panic is one of the worst complications of a cholera epidemic, as fear is one of the most potent predisposing causes of the disease.

Our duty, our responsibility, and our opportunity, seem to me plain and obvious. So far as pushing general and local sanitation go, I believe we are doing fairly well; and to this extent we are reducing the chances of the spread of cholera, should it effect a landing through defective or wanting quarantine provisions. The next work that lies close to our hands is to inform the public as to the necessity of securing adequate legislation—national, State and municipal.

Congress must be urged to reorganize and rehabilitate the National Board of Health, or to provide an efficient substitute—one clothed with increased power and supplied with ample funds to maintain an effective system of modern sanitary quarantine for the ex-

terior; to maintain an interior sanitary inspection service for the great highways of travel by land and water; and to give judicious coöperation and substantial assistance to States and municipalities in preventing the introduction of epidemic diseases into one State from another, and in preventing their spread within the States themselves.

Congress should give the President the power to issue a proclamation, upon the recommendation of the national health authority, forbidding immigration into the United States from infected districts of other countries, and it should provide some method of international sanitary coöperation between this country and the Dominion of Canada, whose interests are substantially the same as ours in these matters, and whose contiguity makes coöperation of vital importance.

In States which now have no boards of health, or whose boards are not vested with the necessary authority or provided with adequate resources, the people should be awakened to the necessities of the situation. Legislators should be thoroughly informed as to the facts, and urged to provide suitable legislation.

Information on sanitary matters should be widely diffused to this end, and also to the end that, if an epidemic should come, we may not have to encounter the obstacles which ignorance is always ready to put in the way of what it does not understand. Happily, in this country we are not likely to meet with the treatment that the superstitious peasantry of France and Italy have accorded their physicians and health officers. But sanitary education and knowledge cannot be too widely spread.

These are matters which may profitably occupy much of our time and attention for the next two months; and I would suggest that when this meeting of the Conference adjourn it be to meet again in Washington early in December, for the purpose of conferring with the President, the proper Cabinet officers and the committees of the Senate and House as to the legislation which should be asked for at the next session of Congress. To this meeting I think not only should representatives of State Boards of Health be invited, but also all quarantine officers and the health authorities of the large cities, as well as those of the Dominion of Canada. I would also suggest that quarantine officers and those who are responsible for the local sanitation of towns, cities and States should be requested to come prepared to give all necessary information concerning the quarantine and sanitary affairs of their respective ports and localities.

FOREIGN CORRESPONDENCE.

PARIS LETTER.

PARIS, October 17, 1884.

Dr. Magnan, physician to the "Hospice Sainte Anne" (asylum for lunatics), lately delivered a very interesting clinical lecture on the various forms or

¹In 1879 the report of a single case of yellow fever in the South caused a shrinkage in the provision market, in Chicago alone, which amounted to a million of dollars within twenty-four hours.

which he endeavored to show that anti-vivisectionists belonged to this interesting class of lunatics. He stated that the too ardent zeal displayed by anti-vivisectionists was a proof that their brains were weak and not properly balanced, that being of nervous temperaments, their conceptions, however just they may seem, are yet simply the precursory manifestations of incipient monomania. We have hitherto observed the insanity of financiers, speculators, and inventors, which consists of extravagant ideas of grandeur, of possessing large fortunes which did not in reality belong to them. In alcoholic subjects it is the delirium of persecution, whereas in anti-vivisectionists the monomania is quite of a different character, and may be considered a new type, as it is only within the last ten or fifteen years that it has been noticed, that is, since the question of vivisection was first agitated and protested against by would-be philanthropists. Dr. Magnan also brought the subject before the Biological Society of Paris, when he produced several examples of this new form of monomania, and among others he related the case of a lady of mature age whose solicitude for animals was such that whenever it rained she wept, because she was afraid of the animals out of doors getting wet. This morbid sensitiveness becomes exaggerated whenever she reads the reports of the anti-vivisectionists, when she gives herself up to the most delirious and eccentric acts. In the streets she is seen picking up pieces of broken glass lest they should hurt the horses' feet; she was also seen taking up her post at cab-stands with the view of preventing a horse that was feeding being disturbed. One morning, passing before a coal shop, this lady noticed that while the coal-man was harnessing his horse he ill-treated the animal, and begged of the man to let her do it herself. She then embraced the horse, fastened it to the shafts of the cart and let the man start on his business with the injunction that the horse should be no more maltreated, enquiring at the same time at what hour the animal was in the habit of getting its food. The next day she was seen at the shop at the hour mentioned, and went to the place at the same time for several days after. She would take up the ugliest and dirtiest dogs that she would find in the streets and carry them to her house, which was a regular menagerie. Dr. Magnan related the case of another woman who was a vegetarian, and whose eccentricity consisted in living exclusively on vegetables because, she said, every one who ate meat was guilty of murder, and she would go to the slaughter-houses and remonstrate with the butchers on their cruelty. This woman's weakness also consisted in bringing together stray animals in the streets, such as dogs, cats, etc., and feeding them with bread from a basket she carried about for the purpose.

Sciatica is certainly one of the most intractable diseases a medical man has to deal with, and after having tried the usual remedies both general and local with unsatisfactory results, Dr. Debove, a hospital physician, adopted the local application of intense cold which he produced with methyl-chloride, and with manifestations of monomania, or what is more properly termed "affective or impulsive insanity," in

which he obtained as low a temperature as 23° C., or 9.4° F. below freezing point. A spray of the fluid is directed to the whole of the painful region, and the skin becomes hard and pale. After a short time the tissues are allowed to thaw, and it is then often found that the pain has disappeared. Bullæ sometimes form on the skin as a consequence of the freezing, but they are of no importance, and the operation may be repeated if necessary. Dr. Debove states that he has had only a few relapses among the patients so treated.

The insolubility of the biniodide of mercury is well known, one litre of water dissolving only 4 centigrammes of the salt at the ordinary surrounding temperature, and at a slightly raised temperature it dissolves 5 centigrammes. M. Bourgoïn has found that by adding alcohol to the water in the proportion of one-tenth it would dissolve 8 centigrammes of the biniodide salt. In pure alcohol, that is in rectified spirits, 2 grammes 90 centigrammes of the salt per litre can be dissolved. A litre of absolute alcohol would dissolve 11 grammes 86 centigrammes of the biniodide of mercury, which is of some advantage to know, as the salt is frequently not prescribed owing to its feeble solubility.

The winter session of the Paris School of Medicine will begin on the 3rd of November, and the following is a list of the professors who are to officiate during the session:

Prof. Gavarret, on Medical Physics.
 Prof. Peter, on Medical Physiology.
 Prof. Sappey, on Anatomy.
 Prof. Gautier, on Medical Chemistry.
 Prof. Lannelongue, on Surgical Pathology.
 Prof. Robin, on Histology.
 Prof. Cornil, on Morbid Anatomy.
 Prof. Laboulbène, on History of Medicine and of Surgery.
 Prof. Brouardel, on Medical Jurisprudence.

CLINICIQUES.

Prof. Germain Sée, Clinical Medicine, at the Hotel-Dieu.
 Prof. Hardy, Clinical Medicine at the Hopital de la Charité.
 Prof. Potain, Clinical Medicine at the Hopital Necker.
 Prof. Jaccoud, Clinical Medicine at La Pitié.
 Prof. Ball, Mental Pathology at the Sainte-Anne Asylum.
 Deputy-Prof. Joffroy, Diseases of Children.
 Prof. Fournier, Syphilitic and Cutaneous Affections at the Hospital Saint-Louis.
 Prof. Charcot, Diseases of the Nervous System at the Salpêtrière Asylum.
 Prof. Richet, Clinical Surgery at the Hotel-Dieu.
 Prof. Verneuil, Clinical Surgery at La Pitié.
 Prof. Trélat, Clinical Surgery at La Charité.
 Prof. Le Fort, Clinical Surgery at the Hopital Necker.
 Prof. Panas, Ophthalmology at the Hotel-Dieu.
 Prof. Pajot, Clinical Obstetrics.

MISCELLANEOUS.

SANITARY CONVENTION AT EAST SAGINAW, MICH.,

Under the Auspices of the State Board of Health, Arrangements having been made by a Local Committee of Citizens of East Saginaw, acting with a Committee of the State Board of Health.

TIME AND PLACE.—You are cordially invited to be present at the sessions of a Sanitary Convention which will be held in East Saginaw, Mich., on Tuesday and Wednesday, December 2 and 3, 1884.

SESSIONS.—There will be sessions the first day at 2 P. M. and 7:30 P. M.; on the second day at 9 A. M., 2 P. M., and 7:30 P. M., standard time.

At each session of the Convention there will be addresses or papers on subjects of general interest pertaining to public health, each paper to be followed by a discussion of the subject treated.

OFFICERS OF THE CONVENTION.—President, Hon. Wm. L. Webber; Vice-Presidents, Hon. David H. Jerome, Saginaw City; Rev. Rowland Connor, East Saginaw; Hon. Benton Hanchett, Saginaw City; Dr. H. C. Potter, East Saginaw; Hon. N. B. Bradley, Bay City; Hon. John S. Estabrook, East Saginaw; Hon. John Moore, Saginaw City; Hon. John B. Atwood, Flint; B. B. Ross, M.D., East Saginaw; Hon. J. J. Wheeler, East Saginaw; John Barter, Esq., East Saginaw. Secretary, Dr. H. V. Brooks; Assistant Secretary, _____

ADMISSION.—The admission to all sessions of this Convention will be free, and the public are cordially invited. The invitation is especially extended to health officers to be present and take part in the discussions.

OBJECTS OF THE CONVENTION.—The objects of the Convention are the presentation of facts, the comparison of views, and the discussion of methods relating to the prevention of sickness and deaths, and the improvement of the conditions of living.

ADDRESSES AND SUBJECTS TO BE PRESENTED AND DISCUSSED.—Welcoming Address by Hon. John S. Estabrook, Mayor of East Saginaw; an address by the President of the Convention, Hon. William L. Webber.

Among the subjects which it is expected will be presented and discussed are the following:

1. The present and future water supply of East Saginaw.
2. Drainage and sewerage of East Saginaw.
3. The disposal of waste matter.
4. Coöperation of citizens in preventing the spread of diseases.
5. The sanitary condition and needs of school buildings and grounds.
6. The teaching of physiology and of the effects of alcohol, etc., in the public schools.
7. Ventilation
8. The preparation of food.
9. The adulteration of food.
10. Public health laws.

The papers are expected to be original contributions, which when read are to be considered the prop-

erty of the Convention, and to be left with the Secretary. Programmes will be issued before the Convention.

It is expected that reduced fare on railroads may be obtained by applying to the Secretary of the Convention for certificates.

For further information address,

HARRIET V. BROOKS, M.D.,
Secretary.

934 Genesee Avenue, East Saginaw, Mich.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM OCTOBER 25, 1884, TO OCTOBER 31, 1884.

Alden, Chas. H., Major and Surgeon, relieved from duty at Ft. Yates, D. T., and ordered for duty at Ft. Snelling, Minn. (S. O. 125, Dept. Dak., Oct. 20, 1884.)

Alden, C. H., Major and Surgeon, in addition to his duties at Ft. Snelling, Minn., to perform the duty of attending surgeon at Dept. Hdqrs. (S. O. 127, Hdqrs. Dept. Dak., Oct. 23, 1884.)

Wilson, W. J., Captain and Assistant-Surgeon, assigned to temporary duty at Fort Trumbull, Conn. (S. O. 220, Dept. East, Oct. 27, 1884.)

Corbusier, W. H., Captain and Assistant-Surgeon, assigned to duty at Fort Bowie, A.T. (S. O. 99, Dept. Ariz., Oct. 22, 1884.)

La Garde, L. A., Captain and Assistant-Surgeon, assigned to duty at Fort Ellis, M. T., relieving First Lieutenant G. E. Bushnell, Assistant-Surgeon U. S. A., who upon being relieved, will report for duty at Ft. Snelling, Minn. (S. O. 126, Dept. Dak., Oct. 22, 1884.)

Everts, Edward, First Lieutenant and Assistant-Surgeon, leave of absence extended one month. (S. O. 107, Hdqrs. Div. Pacific, Oct. 21, 1884.)

McCaw, Walter D., First-Lieutenant and Assistant-Surgeon, ordered from Ft. Craig, N. M., to Ft. Wingate, N. M., for duty. (S. O. 92, Hdqrs. Dist. of New Mexico, Oct. 21, 1884.)

OFFICIAL LIST OF CHANGES IN MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING NOVEMBER 1, 1884.

Beardsley, Grove S., Surgeon, to Washington, D. C., for examination preliminary to promotion and as to qualifications for sea duty, Oct. 31, 1884.

Craig, Thomas C., Passed Assistant-Surgeon, to the "Alliance" for temporary duty, Oct. 31, 1884.

Gardner, James E., Passed Assistant-Surgeon, to the Naval Hospital, Norfolk, Va., Oct. 28, 1884.

Hall, John H., Passed Assistant-Surgeon, from the Naval Hospital, New York, to the Navy Yard, Mare Island, Cal., Oct. 29, 1884.

Hord, William T., Medical Director, to continue duty as member of the Retiring Board, until Jan. 1, 1884, Oct. 27, 1884.

Lovering, P. A., Passed Assistant-Surgeon, to the Naval Dispensary, Washington, D. C., for temporary duty, Oct. 27, 1884.

Turner, Thomas J., Medical Director, to continue duty as member of the Retiring Board until Jan. 1, 1884, Oct. 27, 1884.

Steele, John M., Passed Assistant-Surgeon, to the Naval Hospital, New York, Oct. 29, 1884.

ORIGINAL ARTICLES.

ON THE ENTRANCE OF AIR INTO THE VEINS AS A CAUSE OF DEATH.

BY GEO. L. PORTER, M.D., BRIDGEPORT, CONN.

Read in the Section of Surgery and Anatomy of the American Medical Association, May, 1884.

While no welcome awaits the advent of a new danger in surgical practice, a cordial reception should be extended to the recognition of its existence.

Such knowledge is the beacon-light, which announces a threatening evil, and may prevent its occurrence. Forewarned is forearmed. The recognition, and not the danger, is new. Newton's discovery was only the new knowledge of a fact in the economy of nature as old as the universe. Dr. Bright, in 1827, published his recognition of diseased tissues, but albuminuria may have vexed the children of men since the flood. Many a victim, with a bronzed skin, and pearl-white sclerotic surrendered an enfeebled life, before the disease had received from Dr. Addison "a local habitation and a name." So who can tell how many deaths had followed the entrance of air into the veins, from the knife of the Druid priest, from "Rome's stout pilum in a stout Roman hand," from the spear of the Macedon, the Scythian arrow, and the scalpel of the surgeon, before Beauchesne in 1818—during that decade of discoveries, and classification of pathological conditions—while exsecting a tumor from the neck of a young man, ruptured the internal jugular vein, and witnessed the first death in surgical practice from the direct entrance of atmospheric air into the veins, which was prominently presented to the profession, and has ever since been a warning to surgeons while operating in the regions of the neck.

Once recognized, the reports of similar cases constantly accumulated, and before 1864 numbered sixty-seven (67).

This dreaded accident occurs without warning, announcing its own coming by the peculiar hissing sound at the opened vein, by the labored respiration, the expression of terror and suffering, the despairing cry, and by the consciousness of impending death. If the amount of air is considerable and suddenly introduced, life is immediately destroyed; if of small amount, and of gradual entrance, preventive means

may close the vein, and remedial measures may combat the danger and save the patient.

A number of cases where the bubbling sound and peculiar prostration were symptomatic of the entrance of air, did not result fatally, although followed, in the case of Cooper, by a countenance deadly pale, pupils fixed and inobedient to light, fluttering pulse, irregular respiration, a continual whining cry, and a constant motion of alternate flexion and extension of the right leg, the left remaining quiescent; in the case of Mott, by difficult breathing, violent and irregular action of heart, distortion of face, convulsions of the whole body, and after the convulsions complete hemiplegia. These cases well illustrate the severe, but not fatal, types of this dangerous surgical complication.

The early writers and experimenters reached these conclusions:

I. That the symptoms were:

(a) a gurgling, hissing, bubbling sound in the wound, noticed, says Dr. Green, in forty-eight (48) instances, comprising nearly all of which we have any details;

(b) fatal collapse, or if life is prolonged,

(c) anxious countenance;

(d) labored respiration;

(e) lividity of lips;

(f) dilated pupils;

(g) pulse feeble, or violent and irregular;

(h) convulsions;

(i) paralysis. In twenty-five (25) cases there were symptoms of syncope; in six (6) convulsions without syncope; in seven (7) syncope followed by convulsions; tetanic spasm in the case of Mirault; opisthotonos in the case of Asmus; temporary hemiplegia in the case of Mott.

II. That there is no uniformity as to the time of death; of the fatal cases analyzed twenty-four (24) died immediately; Mirault's lived three hours; Clemot's several hours; Willis's seven (7) hours; Girbal's thirteen (13) and died with symptoms of asphyxia; Roux's seven (7) days, and one of Wattman's twenty-eight (28) days, finally dying of pneumonia: in Girbal's and Wattman's cases no autopsy was made.

III. That the danger-zone was limited originally to the region of the venous pulse, but this was afterwards extended to the uterine sinuses. Of the sixty-seven (67) cases cited by Green the seat of injury was in thirteen (13) the external jugular, in ten (10) the internal jugu-

lar; in one (1) each the subclavian, axillary and facial, (11) eleven from uterine sinuses—and Dr. Lente adds seven (7) more—and in the others, with two doubtful cases, the vessels were not known.

IV. That post-mortem examinations revealed air in the circulatory system. Of the fatal cases eighteen were examined after death; in fifteen (15) air was found in the right cavities of the heart; in eight (8) air was found in the venous system; in six (6) in the arterial system; in the case of Dupuytren in the vessels of the brain; in Beauchesne's in all the vessels of the brain, in the inferior vena cava, iliac veins, aorta and crural arteries, (this examination was made eighteen (18) hours after death).

November 6, 1883, I made an official post-mortem examination in a case of suspected criminal abortion. The previous evening a spinster was alone in a room with a practitioner; within ten (10) minutes he came hurriedly out saying she had fainted. She never revived. The night temperature was 37° F.; examination made eighteen (18) hours after death.

No disease of vital organs.

No signs of decomposition.

Bloody stain on underclothes, but no blood in vagina.

In the uterus a five or six months' foetus; cervix uteri an inch long; mucus plug of a faint pink tinge, shoved up; a small puncture extending through right posterior border of internal os, and emerging in uterus; the decidua vera separated for a space the size of one's palm, the uterine wall throughout its whole extent crepitant and filled with air; no spumous froth in inferior vena cava, or in heart; a sound was heard that might have been the escape of air, as the pulmonary artery was inadvertently cut.

This case is a counterpart of those reported by Dr. Swinburn (*American Medical Monthly*, June, 1860), and by Dr. Hitchcock (*Transactions of the American Medical Association*, volume xv, p. 83).

The cause of death was thought to be shock from the puncture and the forcible introduction of air into the uterine sinuses.

Allow me, for a few moments, to invite your attention to a case, whose post-mortem appearances were those of death from air in the veins, but during life its presence had not been suspected, as no noise had been heard at its entrance, as the wound was outside of the danger-zone, as the vein was of small size and remote from the heart, as the entrance of air was ten (10) days after the original injury, and as general convulsions—death occurring in the second attack—and difficult respiration were the only symptoms that might be called characteristic.

The entrance of air into the veins as a dangerous secondary complication of surgical operations, and of injuries, has not been hitherto classified. This case is the first, in which its medico-legal aspect was considered.

Upon October 11, 1883, I made an official examination, twenty-seven (27) hours after death of a woman, who had been struck eleven (11) days before with a chair, inflicting an almost incised wound, one and a half (1½) inches long, extending upwards and outwards, its inner angle one (1) inch from median

line, and one (1) inch above right eyebrow, penetrating to and partially denuding the bone.

The temperature of the preceding night was 44° Fahrenheit. (Day, 10th, 43°; 67°).

Only slight discoloration around the cut; no union; pus had burrowed three-quarters (¾) of an inch below external angle. No other injury on surface of body.

Under scalp, ecchymosis at external angle of wound.

When sawing the skull, through an aperture near the left squamous suture there escaped bubbles of air mixed with blood; in the vessels of the brain a similar mass.

Abdominal organs healthy and normal.

Subinvolution of uterus—she had passed through a comfortable delivery two months before.

No appearance of decomposition.

Lungs, posteriorly congested—anteriorly normal.

Heart and pericardium carefully removed; walls relaxed; right auricle and ventricle filled with frothy blood; left ventricle contained semi-fluid blood un-mixed with air.

In both superior and inferior vena cava was found the same spumous fluid—a frothy mixture of air and blood.

The presence of air in the venous circulation was given as the immediate cause of death.

During the examination I obtained the following clinical history: After the injury there was considerable hæmorrhage for two days, finally controlled by domestic applications. Upon the fifth day she was seen by Dr. Donaldson, and found in a squalid room, suffering from well-marked trismus equally severe on each side of the face; the wound was unhealthy, inflamed, and gaped to the extent of one-half (½) inch. It was thoroughly cleaned, the edges brought together with plaster and covered with absorbent cotton. The jaws were separated by a soft pine stick; chloral and bromide—laxative medicines—and proper food administered.

Next morning there was only a little pain; jaws could be opened half an inch, and wound looked better.

Upon the ninth (9th) day the severity of the trismic spasms returned; wound looked well, but there was no union; at 3 o'clock A. M. on the tenth (10th) day she had a convulsion and was found gasping for breath, and coughing up a thick, tenacious mucus. Nitrite of amyl gave speedy relief. With the convulsion there had been great increase of the trismus; at 6 A. M. she had another convulsion, and the doctor arrived only in time to see her expire.

From the history and post-mortem examination it seemed reasonable and just to conclude that death was caused by the air in veins and heart, entering through divided or injured branches of the temporal or frontal veins, which had been stretched and held open by the traction of the muscles during the tonic spasm of the trismus; that the first general clonic spasm of the convulsion occurred when the air—gradually entering through a small opening—had overburdened the heart and lungs; that the atmospheric air had formed with part of the blood the spumous

fluid, which had been churned back into the veins, and the rest of the blood remaining fluid had passed on into the general circulation and sustained life, until the air constantly increasing in amount had vitiated so much of the remaining blood as to cause the second convulsion and destroyed life.

To this theory there are these objections :

I. The distance from the danger-zone, or limit of the venous pulse. The venous pulse is the wave or current of blood, in the cavæ and jugulars, transmitted by the systole of the heart. If air can enter an open vein and thence pass into the circulation, the distance from the heart is immaterial. Prof. Gross says:¹ "Air thrown into the veins in remote parts of the body will destroy life as promptly and effectually as when it enters in the localities above referred to," *i. e.*, the neck. Dr. Browning, in his admirable monograph on "Veins of the Head,"² refers to a report in Volkmann's clinic in 1878, where in attempting to remove a cancer of the dura mater, the longitudinal sinus was opened, and so much air was aspirated as to prove rapidly fatal.

Dr. Warren, in removing a tumor from the thigh, cut the internal saphena and heard the sucking sound of the entering air. The vein was closed, and patient recovered.

II. The long time after original wound before the entrance of air. The subsidence of the inflammatory swelling, the breaking down of coagula, the stretching of a partially divided wall, or its ulceration, would open a previously closed vein.

Dr. S. W. Gross, in *American Journal of the Medical Sciences*, January and April, 1867, mentions an instance where air was heard to enter the external jugular vein, opened by ulceration.

III. The small size of the vein; the tolerance of so large an amount of air in the circulation, and its distribution so generally in the veins, prove its gradual entrance in small quantities. The trismic spasms may not only have opened, but also have canalised the vessel. Wattman (*American Journal of the Medical Sciences*, N. S., vol. ix, p. 171), writes: "By the lateral dragging of the venous coats, and the consequent enlargement of the calibre of the vessel, even small veins may be rendered, under particular pathological conditions, capable, when wounded, of admitting air."

IV. The absence of noise of entering air. That it was not heard may be due to the small aperture or the gradual entrance; to the confusion caused by the spasms of the trismus, or to the ignorance and inattention of her friends.

V. The questionable liability of the spontaneous generation of air in the circulation, claimed as a fact by some, especially the older writers; held by others to be "not proven." After death gases may be formed in the blood by decomposition, but would not be confined to the left side of the heart and im-

mediate veins, and the tissues of the body would also exhibit putrefactive changes. To determine the frequency of air in the veins after death, Dr. Cless,¹ of Stuttgart, examined 1,200 bodies, in which death had resulted from various diseases, and found air in the veins in fourteen cases; in each of these the previous symptoms had led to the suspicion that air was present, as they were cases of blood-poisoning.

Jones and Sieveking (*Morbid Anatomy*, p. 412) think single bubbles have been heard to burst in the heart of a healthy person.

The most tangible cases are the six collected by Dr. May (*Transactions London Pathological Society*, vol. ix, p. 154-159), and I submit them to your judgment, respectfully claiming that some of them are not instances of spontaneous generation of air in the veins, but illustrations of the dangerous results following the introduction, into the venous system, of air, whether it be atmospheric, or intestinal, or gases evolved by degenerating tissues. In three there was a local lesion :

1st. Sudden death after opening the median vein, from which flowed immediately spumous fluid.

2nd. Ulceration of cœcum, air traced from ulcer to heart.

3rd. During a catamenial period; air traced from left lateral ligament to heart.

4th. Gangrene of great toe; air traced directly from it to the heart.

5th. Bronchitis; after two attacks of sudden cough, followed by insensibility, lividity, coldness of extremities, rapid pulse and respiration, ending with the expectoration of much frothy mucus tinged with blood, the patient died in the third attack. Frothy blood and air were found in the cavities and vessels of the heart.

6th. Case is inconclusive, as there were putrefactive changes in neck and upper portion of chest.

In the 5th and 6th cases there was also disease of the kidney.

As the final and VI. objection, that this case of secondary entrance of air as a surgical complication is without a recorded counterpart. In the Medical and Surgical History of the British Army in Turkey and the Crimea, vol. ii, p. 277, it is reported that a soldier died suddenly from entrance of air into the veins, three days and a half after amputation of the thigh. Twelve hours after death the right cavities of heart were filled with bright red froth, air mixed with blood, and the same fluid distended the ascending vena cava and two common iliac veins. The surfaces of the flaps were separated by gaseous products, and there had been no closure of the femoral vein, which lay quite open on the face of the stump.

A knowledge of this possible danger would prompt the surgeon to prevent its occurrence, and to carefully inspect open wounds when warned by the early recognition of the characteristic symptoms of the entrance of air.

ADDRESS ON ORAL AND DENTAL SURGERY.

BY TRUMAN W. BROPHY, M.D., CHICAGO.

Chairman of the Section on Oral and Dental Surgery of the American Medical Association, May, 1884.

MR. PRESIDENT AND GENTLEMEN:

A rule of this Association requires the chairman of each Section to prepare and read a paper in general session descriptive of what has been accomplished in his respective Section for its advancement during the past year. If I were to follow strictly the rule I should confine myself to a resumé of the *discoveries and advances made in oral and dental surgery during the last twelve months*. These have been sufficiently numerous and important to furnish material for a far more extended address than I contemplate, and the subjects are especially inviting; nevertheless, I shall venture, with your kind permission, upon rather a wide departure from established custom in this respect, and in place of these matters shall briefly recapitulate the struggles through which this department of medicine has passed since it assumed to antagonize pain and promote the health of man.

It is singular but true, that the healing art was not greatly honored for a long period after approximate civilization had in a measure dispelled the cloud of superstition which rested over the Middle Ages. The profession of arms was really the only one to which those who boasted of gentle blood could with propriety devote themselves, and the man whose occupation it was to make wounds had small respect for the one who in his rude way attempted to heal them. There was some reason for this sentiment. The disciples of Esculapius in those times were not models of learning, and for the most part were doubtless believers in the healing powers of magic rather than patient, thoughtful men, intelligently striving to find natural remedies for the various diseases that humanity is heir to, in the vegetable and mineral world.

But in those days superstition was not confined to the doctors, but it pervaded all ranks of society. The brightest intellects were employed in the laboratories of the alchemists, seeking for the philosopher's stone and the elixir of life. Divines believed in witchcraft as implicitly as in the decalogue ecclesiastics; performed or pretended to perform marvelous cures by the aid of locks of hair, finger-nails, relics of alleged departed saints, and the wisest took alarm or gained courage through spells and potents.

During all this benighted period the medical profession was never the avocation which a born gentleman could adopt without loss of caste, and it is only within the last century that practitioners of medicine as a class have attained real social position. Surgery as a distinctive art appears to have been hedged in by prejudice until a still later date, and its first devotees usually combined it with the calling of a barber. The dual avocation was announced to the world by the familiar striped pole which in these days denotes the apartments of a tonsorial artist, and

was intended to represent the manner in which the injured limb should be bandaged. The tonsorial was probably then regarded as the more honorable of the two callings, and it was unquestionably the most remunerative, at all events, gentlemen who let blood, bound up wounds and shaved beards were known as barber surgeons.

The general medical practitioners and surgeons had secured social recognition, were highly respected for their attainments, and had even begun to play the autocrat at times when fortune had been especially kind in making them the favorites in fashionable neighborhoods, before the specialty of dental surgery was ever heard of.

The old-time doctor who went about the country in his gig with a pair of saddle bags between his feet containing those old standard remedies, salts, senna, calomel, and quinine, was always provided with a single instrument with which all teeth were treated, known as a turnkey.

It never appeared to have occurred to the practitioner of this period that there were many and grave diseases which had their direct origin in the masticating organs, or that it was worth while to study them in detail. If a patient was afflicted with odontalgia, the turnkeys were brought into requisition and as for treating diseases of the teeth and parts immediately associated with them on scientific principles, it was indeed unknown. It is scarcely more than fifty years since dental surgery began to be known as a distinct profession.

It was most unmistakably and emphatically a department and an important one of medical science, but it was years before the medical fraternity chose to afford it the slightest recognition. The professional dentist occupied a curious position; the physicians considered him rather in the light of a harmless quack who was endeavoring to perform a certain work which in part they had previously performed, but as it was very disagreeable work and not especially remunerative moreover, they were quite willing that the dentist should have it, and smiled complacently when he answered to the title of doctor. But the public very soon discovered that these dental surgeons were indispensable; that they were provided with instruments adapted to their avocation, that hopelessly diseased teeth were extracted with comparatively little difficulty, and that those which were partially decayed could be preserved by various processes. The large degree of public favor that dental surgeons, as well as others who devote themselves to the treatment of special organs, have secured, demonstrates the necessity of medical specialists. The field of medical science is indeed so broad that it cannot be thoroughly traversed by any one in a lifetime. The human mind can not embrace all the far-reaching ramifications of this profession, hence men have found it expedient to devote their attention to the study of special organs of the body and to acquiring such a minute knowledge of them as the general practitioner can scarcely hope to attain. Incontrovertible facts bear witness that the highest degree of success which has been secured in the treatment of special diseases has been the reward of individuals who made those

diseases the subject of patient, continuous and special investigation.

All this came to be generally understood and in a way acknowledged by the medical fraternity for years before any medical college was brought to consider dental surgery worthy of recognition in its curriculum, and the dental fraternity during this period had no training school of its own.

An earnest appeal was made to a medical college of Philadelphia at an early day by leading practitioners of dental surgery for an opportunity to secure for their students a complete medical education together with their special training, but the appeal was in vain, and in 1839 the dental surgeons, after untold discouragements, succeeded in establishing a college devoted to their interests. Since then others have sprung up here and there until at the present time eighteen colleges of this description exist in the United States. Of course there are defects in the present system of educating oral and dental surgeons which we recognize. Practitioners of our specialty have frequent occasion to deplore their lack of thorough knowledge of the principles of medicine and surgery, but the progressive ones avail themselves of the best advantages attainable when students, and hope that those who come after them may be more fortunate in securing the highest degree of instruction. But while it is all-important that the dental surgeon should be well versed in medical lore, should indeed be a fully educated medical man, it is also of vital consequence to the general practitioner to be accurately instructed in certain branches of our specialty. The lesions incident to the masticating organs are too numerous and in some instances so grave in their results that it is an error in judgment to any longer disregard them in our medical institutions of learning. Dental pathology and surgery should be taught in all our schools of medicine, and so long as these schools fail to recognize its importance and to establish dental professorships they will fail to graduate physicians who possess all the learning it is important for them to possess while prescribing for human ills.

Among the reasons why each medical college should have a professor on oral and dental subjects are the following: First. A thorough knowledge of the origin and development of the teeth should be acquired by every student. Second. He should also understand the time and mode of their eruption. Third. He should be able to distinguish between deciduous and permanent teeth. Fourth. Students of medicine as a rule are deficient in knowledge of the anatomy and physiology of the teeth. Fifth. He should understand the etiology of dental diseases and the hygienic measures requisite to abate or eradicate them. Sixth. Alveolar dental abscesses not infrequently simulate nasal catarrh as well as parotitis, and these abscesses discharge in some instances upon the face, beneath the chin or on the neck as low as the clavicle. Seventh. Neuralgias of the eye and ear in many cases have their unsuspected origin in the teeth. Eighth. Facial deformities are often due to irregularities of the permanent teeth, and these irregularities are due chiefly to neglect of the deciduous ones, or lack of

proper advice pertaining to their care and treatment. These irregularities, indeed, not only cause the deformities mentioned but frequently the articulation is greatly impaired and the masticating organs are rendered almost useless. Ninth. Diseases of the maxillary sinus, caries and necrosis of the maxillary bones have their origin chiefly, also, from diseases of the teeth. Tenth. Pathological conditions of the teeth of children render perfect mastication impossible. "Without perfect mastication there can not be perfect digestion. Without perfect digestion there can not be perfect assimilation. Without perfect assimilation there can not be perfect nutrition. Without perfect nutrition there can not be health," and thus is it that injurious impressions are made upon the organism of a child which time can never efface.

These are grave facts and are worthy of the serious consideration of that great body to whom is entrusted the health and life of the community. The importance of this department of medical science you have frankly recognized in establishing the Section over which I have the honor to preside.

In the language of the great "Father of American Surgery," the illustrious member of our profession whose magnificent career has just terminated in death; the late Professor S. D. Gross, whose name we all love and venerate: "This is the most important of all the specialties of medicine; not because the diseases you treat are more important than others, but because of the enormous demand on the part of the community for skilled treatment in this department." But of this fact I doubt not you are already advised, and will agree with me that it cannot fail to contribute in the largest measure to the comfort of the laity and the relief of suffering humanity. I should not expect the medical student to familiarize himself with all the manipulations essential to dental art; but I do insist that our medical colleges should devote as much care to training in this department as is generally given to diseases of the skin, the eye and ear, etc., and that the general practitioner should be as capable of advising his patients in this department as in any other. Let the great tree of medical science foster and embrace every branch of the healing art. Let the student of medicine acquire a thorough knowledge of oral hygiene and dental pathology, and thus fortified, he can render a far better, because an infinitely more intelligent, service to his patients than he is now able to do.

To say what we have accomplished for the profession would consume too much time. In the treatment of compound fractures of the lower jaw marked improvements have been made of late in making and adjusting interdental splints.

If in our enthusiasm we eulogize the brilliant men who have adorned our ranks, we only echo the sentiments of each and every member of this distinguished body, as well as the entire educated world.

The greatest of all blessings, the anæsthetic agent, was presented to the world by a member of our specialty. And so long as humanity can remain unconscious in the swooning dream born of ether or chloroform while undergoing the most extensive surgical operations, the name of Horace Wells, the genius

who first dared to believe that all the sensibilities could be thus deadened, will be remembered and revered.

On examination of a report by the Illinois State Board of Health on Medical Education and the Regulation of the Practice of Medicine in the United States and Canada, I find the total number of medical colleges in these countries to be 135; in the United States 123, in Canada 12. And I am happy to state that in our own country there are now 20 medical colleges which sustain professorships of dental pathology and surgery. I hope the number may be greatly augmented during the next twelve months.

In conclusion, let me urge upon the directors of all schools of medical learning the importance of seeing that the curriculum embraces each and every specialty in which the student should be instructed before receiving a diploma authorizing him to deal with the health, not to say with the life, of those who entrust themselves to his professional care. It is a sacred trust the colleges confide to those whom they graduate as doctors of medicine. The great majority of gentlemen who receive this high honor are anxious to be deserving of it, and to be able in the future to give a good account of their stewardship. But with the best of intentions they will certainly fail, and perhaps ignobly, if their instruction is partial, not complete. Teach them all that can be taught; knowledge is like a good armor, and without it no professional man is prepared to enter the arena where his life contest is to be waged, and won or lost.

A CASE OF LIGATION OF THE VERTEBRAL ARTERY FOR AGGRAVATED EPILEPSY.

BY EDMUND ANDREWS, M.D., LL.D., CHICAGO,
PROF. OF CLINICAL SURGERY IN CHICAGO MEDICAL COLLEGE.

Read to Section of Surgery and Anatomy of the American Medical Association, May, 1884.

The proposition to ligate the vertebral artery for epilepsy has not met with great favor among surgeons, and the scanty literature upon the subject leaves its value a matter of uncertainty. I offer the following case, not as decisively proving the usefulness of the operation, but as a contribution toward the collection of facts necessary to the decision of the question. Mr. —, at the age of 17 received a very severe and afflicting mental shock, which was followed by epilepsy. The paroxysms increased in frequency until his mental powers were wrecked. He was in a state of thorough insanity, and from that cause added to the great frequency of the fits, had to be cared for in a state of virtual confinement. Five years later, at the age of twenty-two, he was brought to me in the mental condition above described, and suffering from twelve to fifteen paroxysms every twenty-four hours.

Seeing that he had nothing to lose, I determined to try the operation. Ligation of the vertebral is easiest done in front before the artery enters the ver-

tebral canal, and the high operation is condemned by some good authorities as too difficult, yet I have deemed it possible that the latter location, as being much nearer to the seat of disease, might have some advantages. Therefore I operated at the upper point, cutting down upon the vessel, and tying it between the right transverse processes of the atlas and the axis. The operation proved slow and difficult, notwithstanding previous practice upon the cadaver, but it was successfully accomplished. The paroxysms were not suddenly arrested, but they began at once to diminish in frequency and severity. At the end of three months he was having only about one in three weeks, and then only when provoked by mental excitement, or by indulgence in tobacco. At six and a half months the attacks had entirely ceased, and the mental powers were so much improved that the patient was comparatively sane and able to enjoy his liberty in walking about town. At this time I lost sight of the case and am unable to give any statement of the present condition.

No. 6 Sixteenth St., Chicago.

FRACTURE OF BASE OF SKULL WITH COMPLICATION OF VAGO-ACCESSORY NERVES.

BY JEFFERSON BETTMAN, M.D., CHICAGO.

(Read before the Chicago Society of Ophthalmology and Otology.)

Mr. C. W., grocer, aged 45, consulted me Oct. 1, 1883, for hoarseness and deafness. Three weeks prior he had fallen off a wagon and sustained severe injuries on the left side of head and face. The concussion almost deprived him of his senses; however remembers that persons hurried to his assistance and conveyed him home. Endeavors to communicate were futile, as his voice had sunken to a faint, hoarse whisper, rendering articulation inaudible. Simultaneously violent emesis set in and continued several hours, resisting all attempts to check it. Immediately upon the concussion he experienced a feeling expressed in his own vernacular "as if something had given way in his head," and he seemed to have lost all hearing power in his left ear. A sanguineous discharge, watery in consistency, set in from the same ear and continued oozing, drop by drop, for over two days. Vertigo was so intense that, although in a semi-conscious state, he lost all power of volition and could not exert the slightest control over muscular action. Attempts to swallow restoratives were useless, as he had lost all power of deglutition. Fluids were either rejected through the nostrils or passed into the larynx setting up violent spasm. High fever and a terrible headache, lancinating in character, set in and he lapsed into a stupor. A physician had in the meantime been called in and ordered ice applications to the head and neck. After five days the fever abated and he regained his consciousness. Vertigo was still so intense that he found it impossible to raise his head. The slightest movement of the lower jaw

called forth lancinating pains in the left ear, radiating over the entire left half of head and neck. The left side of neck and mastoid region were acutely sensitive to slightest pressure. All hæmorrhage had ceased, he was entirely deaf on the left ear, and a distressing tinnitus had in the mean time set in. His voice, which at first was gone, after a few days returned sufficiently to enable him to converse in a hoarse, monotone whisper. The power of deglutition was now restored to a limited extent and permitted him to be fed on thin soups and milk. The swallowing of these required visible efforts, and great care and deliberation had to be enforced to prevent suffocatory attacks. A fortnight after the injury he had recovered sufficiently to leave his bed. He experienced great difficulty in retaining his equilibrium and attempting locomotion. His gait was unsteady and staggering with a peculiar tendency to reel towards the left side. Vertigo was still intense, in brief, he experienced all the so-styled Menière symptoms. He also found difficulty in keeping his head erect and suffered from deep muscular pain over the back of his head and left side of his neck.

Status præsens. Mr. W. is robust in figure, well nourished in appearance, and on superficial survey presents but little trace of having undergone much physical suffering. The position of the head is peculiar, being bent to the right side and somewhat forward, the pose being similar to that in torticollis. Gait is unsteady with a perceptible reeling towards the left side. Voice is strikingly husky, weak, and is used with apparent exertion. Left side of head and neck somewhat discolored and bear faint traces of a contusion. Tissues over the left occiput, mastoid region and neck are somewhat tumefied and painful on deep pressure. He complains of a dull fixed pain, "muscular," as he himself states, radiating from the occipital protuberance over the left temporal-frontal region and affecting the muscles of the neck on the same side. The pains in the latter muscles are greatly aggravated by nodding motions of the head. Vertigo is still a prominent symptom, intensified by lowering the head or any sudden movement. Hearing power seems to be entirely obtunded on the left side. Tinnitus of a hissing, rushing nature, localized in the back of the head, is constant day and night, causing greatest discomfort. Disturbances of deglutition are still complained of, compelling him to restrict his diet to liquid food. The day previous on attempting to swallow some solid food, the bolus seemed to lodge in the upper part of the gullet, almost causing suffocation, ere it could be regurgitated.

Physical examination. Left auditory meatus filled with crusts and scales of dried blood, necessitating removal ere permitting detailed inspection of the parts. The upper and posterior walls of the osseous meatus are thickened, intensely congested, in places covered with adherent crusts of dried blood. These portions of canal are very sensitive to touch of the probe. Membrana tympani is lustreless, deeply injected, large interstitial clots of blood occupying the posterior and anterior inferior segments; manubrium mallei drawn inward and upward, posterior fold very prominent. Bone conduction is entirely suspended

on left side, hearing power (ærial) tested with acumeter O_1 —Eustachian tube patent. Insufflation of middle ear produced no apparent change in hearing power or tinnitus. The membrane responds freely to suction of Siegel's otoscope, being in no part adherent. Right ear is comparatively unaffected, with normal range of audition.

The fauces, the left strikingly so, are darkly congested and extremely relaxed. In the acts of retching, induced by depressing the base of the tongue, the mucous membrane of the post. pharyngeal wall is forcibly drawn to the right side. The left palatine arch is flaccid and non-responsive to titillation with probe. The right faucium, on contrast, is hyperæsthetic, the mere touch of the probe calling forth immediate reflex action. The loss of sensation also involves the entire left half of posterior pharynx. Motions of the tongue unaffected; sense of taste in no way involved. Laryngoscopic examination reveals a state of complete paralysis of left vocal cord. The latter is curved, relaxed and immovably fixed in the cadaveric position. There is an associated paralysis of the left depressor epiglottidis. The left ventricular band is somewhat congested and tumefied, the larynx in other respects appearing normal. Tested with laryngeal probe, there is a marked anæsthesia of entire left larynx and epiglottis. Sensation to touch is so reduced, that a prolonged application of the probe is tolerated without inducing reflex spasm or cough. The right cord functionates normally, and sensibility of parts is intact. The intelligence of the patient was of such a grade as not to enable me to determine precisely the state of the crico-thyroid muscle. Pressure over the left thyroid cartilage is still very painful. Auscultation over the left lateral region of œsophagus, at a level with the cricoid cartilage, yields a noisy rumbling sound (*deglutitio sonora*) during an act of deglutition. Fluids are swallowed slowly and with apparent effort. My brother, Dr. Boerne Bettman, kindly made an ophthalmoscopic examination, and found distinct congestion of left retinal veins. Appetite is good; pulse 80, full and regular. Prescribed a solution of iodide of potash, an anodyne embrocation to back of head and neck, advised absolute rest, both mentally and physically, and requested him to return in a few days. In the meantime, contrary to my directions, he engaged in business, and suddenly left the city to transact some mercantile affairs. I heard nothing of him, till he again consulted me in June last, some nine months later. His physical appearance is, if anything, more robust and florid. Voice is still very husky, intonation undecided and faulty. Firmness in gait has not yet returned, and the patient at times still experiences a dizzy, reeling sensation. Vertigo, although much diminished, has not entirely left him. The left side of head and region of trapezius and sternocleido mastoid muscles still painful and somewhat sensitive to touch. The patient has never lost the sensation of a foreign body lodged in the throat. Deglutition has improved very much; but for fear of any mishap, he is compelled to swallow slowly and deliberately. Hearing has in no way improved, and it is the annoyance and discomfort of the persisting

tinnitus, that induced him to consult me again. The membrane is depressed with radiiform thickening of the membrana propria. A small scar, flaccid and reflecting the light, occupies the anterior inferior segment of the membrane. Insufflation produces no alteration in hearing. Sensibility of faucium is entirely restored, but motor action is still very sluggish. The left cord is still fixed in a cadaveric position. Reflex irritability is everywhere reëstablished, palpation evoking prompt reaction. Repeated applications of Faradic and galvanic currents with administration of strychnia have as yet produced no perceptible improvement.

The total loss of hearing, the entire suspension of bone conduction on the same side, the long-continued oozing of blood, the various cerebral symptoms, all indicate a serious lesion of the internal ear. The concomitant laryngo-pharyngeal symptoms, both motor and sensory, necessarily include an involvement of the nerves supplying these functions. Bearing in mind the construction of the base of the skull, the relation of its component parts to each other and to the various nerve trunks passing through the foramina, it will not be difficult to trace and establish an intimate connection between the various complicated symptoms. A knowledge of the relations of these parts being requisite to associate the various pathological features in the case, it may not be superfluous to cursorily survey the leading anatomical landmarks of the region involved.

The jugular foramen (*foramen lacerum post.*), formed by the apposition of the jugular fossa of temporal bone (*pars petrosa*) with the articulating surface of the occipital bone, gives exit to the glosso-pharyngeal, vagus and spinal accessory nerves and internal jugular vein. In the passage through the foramen the vagus accompanies the spinal accessory, being contained in the same sheath of dura mater with it. The glosso-pharyngeal has its separate investment. The vagus at this point blending with fibres of spinal accessory, forms a well-marked ganglion, the jugular ganglion. Just inferior to its exit from the foramen, the fibres of the vagus blend with the accessory or inner ramus of the spinal accessory to form the plexus ganglioformis (*plexus nodosus*). It is this inner branch of the accessory that furnishes the motor filaments to the recurrent laryngeal, sup. laryngeal and pharyngeal nerves, offshoots of the vagus (Bischoff, Longet, Schech).¹ The spinal or outer ramus of the spinal accessory passes, in connection with the accessory branch, through the jugular foramen, and innervates the sterno-cleido mastoid and trapezius muscles. The superior laryngeal and pharyngeal nerves arise from the ganglioform plexus. The former is essentially a sensory nerve of vagus origin, the motor filament supplying the crico-thyroid muscle being, according to most physiologists, of accessory origin. The two pharyngeal branches, in conjunction with motor fibres of spinal accessory (Rüdinger, Luschka, Erb, Seeligmüller),² and possibly branches of the glosso-pharyngeal (Joh. Müller, Jolyet), innervate muscles of pharynx, soft palate and uvula. Pressure

or any lesion of the ganglioform plexus will call forth both sensory and motor disturbances in the larynx and pharynx. It is this part of the vagus nerve that Ziemssen¹ considers the first point exposed to injury outside of the cranial cavity. The complication of the muscles of the neck on left side, render it conclusive that the lesion in the case also involved the spinal or outer ramus of the spinal accessory nerve, locating the seat of injury above this point. Pressure on the vago-accessory in or at the jugular foramen will call forth a train of symptoms similar to those described in the clinical features of the case. The concurrence of aural and laryngo-pharyngeal symptoms render it extremely probable that the injury took place at this point. The direct concussion produced a fracture of the petrous portion of the temporal bone, the fissure extending through the entire bone to the border of the jugular foramen, involving the external osseous meatus, tegmen tympani and labyrinth. These immediately followed a disarticulation or displacement of the component bones at this part, with direct compression upon the structures passing through the foramen.

The absence of symptoms indicating an impaired function of the Glosso-pharyngeal nerve renders it probable that this nerve escaped injury. Although Joh. Müller² claims that the muscles of soft palate and uvula are in the main innervated by branches of the glosso-pharyngeal nerve, the more recent anatomical investigations of Burckhard³ and Bendz,⁴ confirmed by clinical observations of Erb⁵ and others, trace the principal supply to the vago-accessory nerves. There was absolutely no impairment of sense of taste in the case, a fact elicited by personal investigation, and this in itself is sufficient to warrant an exclusion of the glosso-pharyngeal in the lesion. What function the glosso-pharyngeal exerts in the sensory innervation of the pharynx, is still *sub judice* (Foster)⁶. The anatomical circumstance that the vago-accessory nerves have one fibrous sheath in common, separate and distinct from that of the glosso-pharyngeal, may possibly to some extent account for the escape of the latter nerve. According to Mackenzie⁷ "as the results of experiments of vivisection it would appear that when a pneumogastric nerve is injured, the opposite nerve, as a rule, suffices to discharge the more important functions previously supplied by both nerves. Hence, although in the first instance, the action of the heart and lungs is temporarily disturbed these organs generally soon recover, etc." The absence of cardiac disturbances so far as could be elicited at time of examination, render it presumable that, if any had taken place prior to this, they were merely transitory in nature. Cases of intracranial pressure or compression upon the nerves in their course through the jugular foramen are exceedingly rare. In the six instances recorded, all with but one exception were due to malignant tumors involving the base of the

skull. In a case recorded in a prelaryngoscopic period by Dufour¹, compression of spinal accessory nerve was induced by an intracranial echinococcus cyst. Chronologically allied to this, is an instance of pressure upon both spinal accessory nerves subsequent to cancerous infiltration of the bones of the basis cranii, observed by Türck². More recent observations have been made by Gerhard³, Fraenkel,⁴ Schech⁵, Mackenzie⁶. In all, as already mentioned, the compression was due to encroachment of malignant tumors. In Fraenkel's observation the vagus nerve was impinged upon at the left angle of the lower jaw by a lympho-sarcomatous growth. The publication of Schech, admirably thorough and exhaustive in its details, is highly valuable in assisting in the solution of many mooted points in the physiology of these nerves. Peripheric nerve lesions arising from pathological changes in the cerebral root centres, observed in tabes, bulbar paralysis, cerebro-spinal sclerosis, apoplexy and epilepsy, can not be included in the same category. Below the ganglioform plexus, the vagus, partly attributable to its more exposed position, has been injured in various ways.

From an otological standpoint, the fracture, excluding the nervous complication, offers but little of special interest. Judging from the clinical features alone, it is impossible to localize with any degree of certainty the exact extent of the fracture, and to detail the various parts of the structure involved. The acute localized tenderness of the superior posterior wall, the pains produced by movements of the lower maxilla, render it presumable that the fracture extended along the osseous meatus. The aural symptoms combined with the distinct cerebral disturbances, demonstrate beyond doubt an involvement of the labyrinth. According to Buck,⁷ fractures occur most readily at the lines of union of the tympanic, petrous and squamous portions of the temporal bone. Hartmann⁸ classifies these features into two divisions; one, in which solution of continuity involves the lines of union alluded to above, and a second, in which the fissure extends transversely through the int. audit. meatus and vestibule of the labyrinth. In the preponderating number of cases, fractures of the basis cranii end fatally, cerebritis or meningitis developing. Where great drainage of ear has ensued, Hutchinson⁹ states, that in fatal cases inflammation of subarachnoid spaces is more apt to occur. As exemplified by cases recorded by Eysell,¹⁰ Trautmann¹¹ and others, cases of complete recovery, *quoad vitam*, even in most complicated cases, are by no means isolated. Meningeal troubles need not of necessity supervene, healing of the fracture taking place by fibrous union (Schwartz).¹² In the most favorable cases, hearing power is almost always irrevocably lost. In those exceptional instances, where a gradual restoration of

hearing took place, (Schroter)¹ it is doubtful whether the structures of labyrinth were involved in the fracture. Tinnitus is an almost constant feature, and generally proves irremediable. The constant dull headache complained of and referred to the occipital region and nucha, render it probable that the structure at the base of the brain have not yet been fully restored to normal condition. The prognosis in such cases should be guarded, as instances have been recorded where patients, apparently recovered from the immediate effects of the injury, months later suddenly developed a fatal pachymeningitis.

Treatment can merely be of an expectant character in these cases. Strict precautions must be enforced to check or keep in obedience any meningeal symptoms that may develop. Tissue changes take place in the nerve structures involved, and it accordingly remains to be doubted whether any remedial agent can restore their functions. Even in those possible cases where the cause of the compression is but temporary in character, such as a hæmorrhagic exudation, the natural tendency would be to gradual restoration independent of medicinal aid. Physiologically the case is interesting in confirming experiments by vivisection, that the vagus nerve of the opposite side gradually performs the more important functions previously discharged by both nerves. Why this restoration should merely be restricted to the afferent fibres, as already mentioned essentially of vagus origin, and not include the efferent fibres, demonstrated conclusively to be filaments of spinal accessory, remains an open question for physiologists to solve.

HÆMORRHAGE OF THE VOCAL CORD.

E. FLETCHER INGALS, M.D., CHICAGO,

Professor of Laryngology Rush Medical College.

Hæmorrhage of the vocal cords is so rare that the following case will be of interest to many. The patient, H. B., æt. 45, merchant, came to me during the latter part of October complaining of hoarseness and discomfort in the larynx which had come on suddenly that morning.

On rising he had felt perfectly well, but while washing he was suddenly annoyed by a sensation as of some foreign body in the larynx that he described as a "lump in the throat" which troubled him particularly whenever he attempted to swallow.

Moderate hoarseness soon supervened.

When he called at my office about five hours afterward, the same sensations were still annoying him; he was quite hoarse and a small spot over the thyroid cartilage was tender to the touch. No constitutional symptoms were present.

I found the whole left vocal band of a brownish-red hue and thickened by sub-mucous infiltration of blood to about twice its normal size. Other portions of the larynx were normal.

I applied powdered iodoform to the larynx and di-

rected the patient to return to his home and apply cold compresses to the neck constantly for the next forty-eight hours. At the same time he was cautioned against the use of tobacco and directed to refrain from talking.

Two days later he returned to my office much improved. I found the vocal band much thinner than before, and its free edge lighter in color from partial absorption of the extravasated blood.

I applied a mild astringent spray to the larynx and as it was imperative for him to go about his business, I directed him to wear a silk handkerchief about the neck every day and apply a cold compress every night while soreness continued, or while the larynx should feel fatigued after talking. I also cautioned him not to smoke and not to use the voice when possible to avoid it.

No exciting cause for this extravasation could be detected, in which respect the case resembled a large percentage of the cases of hæmoptysis.

The patient first came under my care about two years ago, because of nasal polypi and anosmia. The polypi and all other causes of obstruction in the nares were completely removed, but the sense of smell was not restored; however, it would return temporarily at times, lasting for a few hours and then disappear without perceptible change in the physical condition of the nares.

This, together with a history of nervous prostration extending over two or three years before he first saw me, and not yet entirely recovered from, led me to attribute the hæmorrhage to disturbance of the vasomotor nerves.

65 State Street, Chicago.

MEDICAL PROGRESS.

PHYSIOLOGY AND PATHOLOGY.

SOME RECENT OBSERVATIONS UPON THE SUPRA-RENAL CAPSULE.—The *Lancet* gives a brief of the experiments performed by M. Tizzoni during the past year upon the supra-renal body. In order to avoid unnecessary sacrifice of life, the author studied the best methods of removing the supra-renal capsules without damage to the surrounding structures and with the infliction of the least possible injury to the system at large. After having made a small incision in the lumbar region at the level of the adrenal body, the parenchyma of the capsule was lacerated, and its ablation practised, strict antiseptic precautions being observed. On the right side the neighboring vena cava inferior rendered the operation of extirpation difficult. For his experiments Tizzoni generally made use of rabbits weighing only about a kilogramme each, because in this circumstance the muscular mass of the lumbar region was but little developed, and so the operation was facilitated. When the animals succumbed as the result of the operative procedure, death was not due to the nervous accidents signaled by Brown-Sequard, but was caused

by subcutaneous and intermuscular suppuration infiltrating the neighborhood of the wound. The majority of the animals which exhibited contracture of one or other of the front or hind limbs recovered, and it was only rarely that paralysis or death followed the appearance of the spastic contraction. The necropsy revealed in such cases the presence of an exudation about the meninges of the spinal cord and a softening of the spinal marrow without any demonstrable connection of the lesion of the supra-renal capsule with that of the nervous centres. Outside these complications—which may be regarded as quite exceptional—the operation was generally followed by no grave accidents; the animals, if the etherization were not too powerful, gave signs of pain only when the adrenal capsule was seized and lacerated. If this body, instead of being completely removed, were allowed to remain in the cavity of the abdomen (of course, after laceration of the capsule), the healing was much more rapidly effected; and if, some days later, the animal were killed, not a trace of the lacerated parenchyma of the supra-renal capsule could be detected; complete absorption of the essential elements appeared to have taken place. Thus, according to Tizzoni, the supra-renal body is absorbed without giving rise to any phenomena such as might be interpreted to be of the nature of blood-poisoning, so that the adrenal capsule contains no organic poison; and if by treating the organ with various chemical reagents a poison be obtained, one may affirm that it is not produced during life, and consequently the poison must be due to cadaveric decomposition. A certain time after the extirpation of the capsule there commences to appear a brownish discoloration of the nose, as if the animal had been plunged in charcoal powder after having drunk some liquid. Some small blackish linear markings also may be found scattered here and there over the mouth and nasal fossæ. The mucous membranes of these regions seem at first to be intact, but at the end of some days they become dotted with minute spots of the color of tobacco: the minute areas become circular as they enlarge, and by coalescence a bronzed surface of considerable extent and of a uniform tint is formed, and reaches its maximum intensity about the sixtieth day after the operation of removal or laceration of the supra-renal capsule.

A remarkable circumstance is mentioned by the Italian observer, which is to the effect that the destruction of one capsule only brings about unilateral pigmentation of that side of the body on which the operation was performed. If, however, the median line of the body were trespassed upon, the pigmentation extended to the whole of the surface of the body. [The text from which this report is taken leaves it doubtful by what the median line of the body was to be trespassed upon. We (the *Lancet*) take it that should the pigmentation proceed beyond the mesial line, then the discoloration would be universal.] White rabbits did not present any of the pigmentary phenomena.

From a histological point of view the following observations were made: When the coagulum of blood and the parenchyma of the lacerated organ had been resorbed, the fibrous envelope of the capsule

was found to be filled with a connective tissue of new formation, together with large granular cells like those which are found in white softening of the brain; giant-cells which had undergone caseous degeneration were also to be seen. The last fact would seem to negative Nothnagel's opinion that chronic caseous inflammation of the adrenal body was always of a tuberculous nature. These giant-cells were produced in the same way as those which develop as the result of irritation of serous membranes by a foreign body. Another observation was made by Tizzoni which appears to be extraordinary, to say the least of it. The various elements of the supra-renal capsule in the rabbit may be "reconstructed." This fact is alleged to have been observed 144 days after the almost total destruction of the supra-renal body in a rabbit. The size, color and structure of the organ were normal in another rabbit 26 days after the operation, presumably, of free laceration. At the autopsy a small nodule exhibiting active new formation of supra-renal parenchyma was also discovered. A fine interlacement of filaments of the great sympathetic cord with numerous ganglion cells and gangliform swellings had developed and covered the cortical substance of the adrenal gland of the animal last referred to. The Italian pathologist does not speculate on the mode of production of the bronzing which he observed. Many of the statements made by him require careful consideration at the hands of other experimental pathologists, but as opening up afresh the relations of the adrenal body to the system at large, the results of Tizzoni's experiments must be admitted to be of decided value.

MEDICINE.

PERIODICAL CHANGE OF COLOR OF HAIR.—The *Lancet* describes the case of a young girl aged thirteen, of an idiotic type, who was admitted into the asylum at Hamburg on April 1, 1880, and died there in 1882. At the age of three years she began to be affected with spontaneous movements like those of St. Vitus's dance, which were chiefly confined to the head and upper limbs. Between her fifth and sixth years she had become the subject of well-marked epilepsy. She was able when four years old to run round a table, but her powers of progression steadily diminished, and the lower limbs passed into a condition of chronic stiffness. When in the asylum of Dalldorf (Hamburg), she had epileptic fits about every eight or fourteen days; besides, it was observed that she experienced alternations of agitation and calmness, each of about a week's duration.

In the period of agitation the turgescence and redness of the face were most pronounced, the pulse was full, the skin warm, and actively transpiring, at the same time that the mental condition was one of extreme obstinacy. Further, it was often remarked that the color of the hair underwent decided changes; sometimes it was blonde and at others red, whilst the depth of these colors also varied. The alterations in color occurred in the brief space of two or three days; the first appearance of change was observed at

the free ends of the hairs; the same tint of hair persisted for seven or eight days. Each of these periods of changes of color of hair coincided with a phase of agitation or sedateness. During the state of excitement the hair always had a red color, whilst pending the phases of stupidity the blonde tint prevailed. The case appeared to be one of genuine pathological change. The paler hairs differed from the darker ones only in the presence of more numerous air spaces. The structure of the brain and spinal cord was much altered.

WILLING AND THOUGHT-READING.—The *British Medical Journal* has an article under this heading which shows that the mental exertion employed in such amusements is not without its perils and mischiefs, of which two cases, reported at the last meeting of the Cambridge Medical Society, afford characteristic examples. The one case was related by Mr. Deighton. In November, 1883, he was summoned in urgent haste to see an undergraduate. He found him surrounded by his friends, who said they had been playing the willing game, and that he had been blindfolded and willed; soon afterwards he became tottery on his legs, and went off into a state of convulsions. When seen, he was tossing about on a sofa, with face slightly flushed, the movements of the arms and legs being most irregular, almost equally exaggerated on both sides. The muscles of the face and neck were least affected, but he spoke in a jerky way, and, on putting out his tongue, it was protruded and withdrawn suddenly. He was quite conscious, clear and collected, and said that he tried to prevent himself from tossing about, but could not help it. The pupils acted to light, and were natural in size. He recovered after calming treatment and rest. It was an attack of induced chorea or hysteria brought on by mental strain.

Mr. Wherry also reported a case. He was sent for one evening to see an undergraduate who had become suddenly ill during the willing game. It appeared that his friends had blindfolded him in the same manner, and were willing him to do some simple action, when all of a sudden he became weak in the knees, and had to be helped to a seat. The handkerchief was removed at once, but the patient did not seem at all himself. Mr. Wherry found him leaning against the mantel-shelf, looking fixedly downwards in a dogged and morose attitude. He answered questions in monosyllables in a hesitating way, not stammering, but with a jerk and without expression. Usually, his friends said, his manners were natural and polite. The pupils were dilated, with no action to light, and his memory was a blank as to the details of the game. He was sent to bed, and when seen the next morning he was better; his pupils were normal and active to light, but his manner was still odd, and his speech was remarkable. When advised to leave Cambridge for a few days' change, he refused rudely, but was afterwards persuaded by his friends, and returned quite well. Mr. Wherry remarked upon the strange state induced by this willing game: the dogged and morose manner, slow replies, no action of the pupils to light, rapid recovery, and no recollection of the period during which he was being willed—altogether

a condition which, he was informed, corresponded with the hypnotic or mesmeric state, and one in which medical men were interested.

WINTER HÆMOGLOBINURIA.—Professor Nothnagel, of Vienna, has given a very interesting clinical lecture on this subject which is reported in the *Medical Times*. His patient complained of certain peculiar sensations, as the result of chilling the feet in the winter, a shivering throughout the whole of the body, afterwards feeling hot and perspiring profusely. He suffered from various acute infectious diseases during childhood and at the age of 18 contracted syphilis. Three years ago he had the first attack as following exposure to cold, and during the past winter the attacks have occurred so frequently that the patient is almost afraid of going out when it is cold. He further states that during the attack he suffers from great thirst as long as the shivering lasts. We cannot conclude that the main affection is of a malarious nature, for its occurrence is irregular and dependent upon the influence of cold. Moreover, he states that he has no attacks during the summer, but only in winter. The urine passed immediately after an attack is black, subsequently it is clear. A specimen of the black urine boiled with caustic potash, causes a precipitate of the phosphates of a brownish red color, no red corpuscles under the microscope. Albumen on boiling giving a flaky sediment. This sediment on boiling with alcohol which has been rendered acid with dilute sulphuric acid, gives up its blood-pigment to the alcohol. The blood-pigment therefore exists free in the liquid and not in combination with red blood-corpuscles. In hæmaturia we find red blood-corpuscles. Here we find blood-pigment which with the spectroscope gives the characteristic absorption lines of hæmoglobin, but not a sign of a red corpuscle, hence this is called hæmoglobinuria.

The conditions under which this disease occurs have been very much studied in the last fifteen years. First it has been observed in cases of poisoning, such as carbolic acid, sulphuric and phosphoric acids, and in cases of poisoning by arseniuretted hydrogen; secondly, in burns of the skin; thirdly, in certain acute infectious diseases, as for instance, scarlet fever and typhoid. In all these conditions the affection is *rare*. A large number of cases were observed about ten years ago, when the treatment of consumption and carcinoma by the transfusion of lamb's blood was in vogue. It was shown that when the blood of an animal of one species is transfused into the system of one of another species, it is injurious to the latter. If one transfuses blood from a lamb into a dog, it may prove fatal to the latter, just as it might to a man treated in a similar way. The serious symptoms observed in such a case are to be considered as a direct consequence of the transfusion, the blood corpuscles of one species having a pernicious effect on those of another. Landois has shown that marked hæmoglobinuria occurs in such cases, which he attributes to the fact that the red blood-corpuscles are dissolved; it is therefore an artificial hæmoglobinuria.

This special affection of paroxysmal or winter

hæmoglobinuria is a disease seldom met with. The majority of such cases have been recorded in English, American and German literature; very few have been recorded in French literature, and still fewer in Russian. The disease presents the following symptoms: "The patient is seized with it in paroxysms, hence the name paroxysmal. In the intervals he is perfectly well, though exhausted and weak owing to the loss of the blood-corpuscles which have been destroyed, but besides this general weakness he does not complain of anything. It is the effect of cold on hands and feet which especially produces the fa-fection. Sometimes one is able to bring on an attack artificially. Rosenbach gave one of his patients a cold bath in summer, and an attack resulted. The sensations of the patient during the attack are very unpleasant; he yawns constantly; he is then seized with shivering through the whole of the body which is followed by heat and perspiration (a temperature of 104° F. has been observed). The patient then passes urine which is of the color of blood; the same color may be noticed two or three times in the subsequent 24 hours and then it disappears. Sometimes casts are to be found in the urine, but this is an exception; there may, indeed, be blood casts, for the hæmoglobin may coagulate while still in the urinary passages. Sometimes hyaline casts are also to be found.

How does hæmoglobinuria arise? Probably by the influence of cold. If we make the blood freeze, the blood-corpuscles are destroyed, and we then have blood with a color like lac dye. During the attack there circulates in the vessels ruby-colored blood; that is to say, there is free hæmoglobin—this has been proved by the abstraction of blood by means of a cupping-glass during an attack; the hæmoglobin is said to have an influence on the vaso-motor centre, hence the shivering, followed by heat and perspiration. As to the prognosis, the disease lasts in some cases several years and then disappears suddenly. In some patients we obtain good results from anti-syphilitic treatment, even when the disease has not a syphilitic origin. Besides this the patient must have good nourishment; he must live on meat, milk, eggs and wine, and iron must be given to him. If we do not succeed in curing the patient in this way, we must order him to a milder climate during the winter.

SURGERY.

ON PREPUCE GRAFTING.—Under this heading R. Clement Lucas, B.S., advocates in the *Lancet*, the use of the prepuce, as removed from children in the operation of circumcision, for obtaining cuticle to apply to extensive burns, etc. There is seldom any danger of communicating disease in this way, as when balanitis is associated with phimosis it can, and should, always be cured before operating. The surplus skin of this part, from its suppleness, thinness and vascularity, appears to be peculiarly adapted for transplantation, so that Mr. Lucas has found grafts from this source adhere when those from other parts have

failed. These grafts may be readily obtained from childrens' hospitals where the number of children that are generally brought for the treatment of phimosis is so great that many days will never elapse without the surgeon being called upon to perform circumcision. The time which may be allowed to lapse between the removal of the skin and its application in the form of small grafts to a wound may probably be extended until signs of putrefaction begin to appear. Mr. Lucas has allowed from a half-hour to an hour sometimes to pass before the skin has been thus made use of. In no case has he placed them in hot water or made any provision for maintaining them at the temperature of the body. If the recipient of the grafts lived at a distance from the person yielding the skin, he believes the skin might be conveyed in a small glass bottle or wrapped in gutta-percha, without loss of vitality, for some hours.

It is possible that some surgeons may take a sentimental objection to this method of healing large granulating sores; but any such feeling should yield to the excellent practical results which may be obtained by it. The only reasonable argument against it is that disease might by careless grafting be introduced into the system of a healthy child; but this is so remote that with ordinary caution it would be impossible. On the other hand he believes the prepucce of a child possesses a germinal vitality which renders it peculiarly serviceable for grafting.

SUCCESSFUL NEPHRECTOMY FOR CALCULOUS PYELITIS.—*La Gazzetta degli Ospitali (Lancet)* contains a report by Dr. A. Salomoni of a case in which Professor E. Bottini successfully removed the kidney. The operation was performed at Milan, on the 8th of June last. The patient, Annibale M., aged 27, had had two calculi removed by lateral lithotomy fifteen years previously. Three years after that operation an abscess formed in the right iliac fossa. It opened spontaneously, and after a few months reappeared in the lumbar region, when it was opened with caustic potash. A permanent fistula resulted, and proved intractable to all local and constitutional treatment. The patient lying on the left side, under chloroform, Professor Bottini, under strict antiseptic precautions, made a vertical incision through the whole ileo-costal space, three inches outside the quadratus lumborum. The kidney having been isolated, the renal artery was secured in one ligature, the vein and ureter in another. The space having been well cleared and all bleeding stopped, a drainage tube about one-third of an inch in diameter was introduced. The walls of the fistula were excised, and the wound united by one deep metallic suture and eight superficial silk ones. The operation lasted a little over an hour. The antiseptic dressing was renewed daily, the metallic suture was removed on the third, and the silk ones on the fourth day, when the drainage-tube was shortened. It was withdrawn on the eighteenth day. Progress was uninterrupted. The highest temperature, 100° F., was reached the second day; urine in normal quantity, and without deposit, was passed without pain or trouble. The patient left his bed on the

sixth, and went home on the eighteenth day, when only a slight sinus remained, about an inch deep. The extirpated kidney weighed 48 grammes, and measured vertically 6 centimetres—4 across and 2 antero-posteriorly. Its consistence was greater than normal; color grayish. On section, the upper three-fourths consisted of fibro-cellular tissue; the lower fourth of renal parenchyma, altered, with the pyramids in process of disappearance. The fistula led into the pelvis of the kidney, which was dilated, with thickened and suppurating walls, and contained, besides some uric acid sand, two small calculi about the size and shape of grains of barley.

ON INFLAMMATION OF THE EYE AND ITS ANNEXES AS CAUSED BY ASTIGMATISM.—Dr. Georges-Martin (*Jour. de Med. de Paris*) considers that we do not appreciate sufficiently the serious conditions which may follow directly as caused by astigmatism. For a long time we have looked upon the astigmatic eye as a badly constructed optical instrument, producing only deformed images upon the retina; this idea does not conform to the other view that astigmatics are capable of excellent vision. A knowledge of the partial contractions of the ciliary muscle explains why the images are *not* deformed, and why vision is *not* defective. The optic defect of the astigmatic eye finds an intelligent corrective in these partial contractions. But the activity of this corrective cannot be indulged in without disturbing the perfect harmony of the nutrition of the eye and its surrounding tissues. Dr. Martin sees in these contractions the cause of certain inflammatory affections, such as blepharitis, conjunctivitis, phlyctenular keratitis, scrofulous keratitis, and hordeoli; and other ocular or peri-ocular affections, such as temporal neuralgias, blepharospasms, palpebral cysts, and muscæ volitantes. The relation of cause to effect as established between astigmatism and these affections is: (a) By the especial frequency of these affections in astigmatics; (b) by the fact, frequently established, of one or several of these affections being reproduced in successive attacks or relapses in the same cases, and always in the same eye—the one affected with astigmatism; (c) by the remarkable therapeutic effects produced by drugs which paralyze the ciliary muscle; (d) by the protective influence exerted by cylindrical glasses which are perfectly corrected; (e) by the fact that corneal astigmatism is replaced (when at fault) by the spasmodic astigmatism, *i. e.*, partial idiopathic ciliary contraction.

In the etiology of these affections astigmatism does not take the place of the general condition. Both exert their influences. The general condition, varying according to individuality, explains partly why the ciliary effect is revealed by these diverse morbid phenomena.

OPERATION UPON A CYST OF THE PANCREAS.—Gussenbauer (*Archiv für Klin. Chir.*) gives a case of a man 40 years of age who suffered for three months from an affection of the stomach, characterized by

pain, vomiting, and emaciation. On his entrance into the hospital, there was found a tumor in the epigastric region extending to the umbilicus, clearly defined, and diminishing in size transversely from the left costal border to the right lumbar region. The median horizontal diameter reached $18\frac{1}{2}$ centimetres, and the oblique diameter in its greatest length, 22 centimetres. On distending the stomach artificially, the greater curvature and the transverse colon were seen to cover the tumor transversely; these two organs, when the abdominal walls were relaxed, could be displaced from the tumor which followed the movements of respiration. The skin was of a greyish brown. Percussion was dull. Diagnosis: Cyst of the pancreas or left supra-renal capsule.

The operation consisted in fixing the cystic wall to the incised abdominal wall, after separating the colon and greater curvature of the stomach. Then the cyst, held firmly, was partly emptied by the trocar, and afterwards incised. The finger, when introduced into the resulting cavity, removed from the walls of the cyst adherent portions of a blackish-brown mass. In other respects, the walls were smooth; admitting of a penetration into the tissue of the pancreas and a pressing of the posterior cystic wall just over the aorta. The fluid discharged, about 1,900 grammes, contained altered blood, none of the biliary coloring matters, no metalbum, peptone or sugar, but simply ordinary albumen with a body analogous to mucine.

In the course of the second week, masses of a blackish substance, like that removed at the time of the operation, were spontaneously eliminated through the wound. Later the cavity contracted considerably, only secreting a colorless liquid. This liquid gave an alkaline reaction, digested albumen, formed leucine and tyrosine, transformed starch into sugar, and was no other than the pancreatic secretion. The cyst was a true hæmatoma of the pancreas. Twenty-eight days after the operation, the patient left the hospital; a small fistula led into the cavity 3 centimetres in depth; with but a slight secretion.

CONSIDERATIONS ON THE ABLATION OF THE ASTRAGALUS IN THE TREATMENT OF FUNGOUS OSTEO-ARTHRITIS OF THE INSTEP.—Dr. Robert (*Archives gén de Méd.*) in his article on this subject arrives at the following conclusions:

1. A sprain of the foot is frequently followed by chronic osseous lesions, having a great tendency to localize themselves in the astragalus or in the articular surface of the astragalus or calcaneum.

2. These lesions may remain for a long time limited to this region of the tarsus, nevertheless the simple means directed against this osteo-arthritis are often powerless, modifying injections and ignipuncture are equally inefficacious. Gouging, scraping and deep cauterization do not surely reach the full extent of the disease, and sometimes provoke an aggravation which makes amputation necessary.

3. The extraction of the astragalus is an operation which facilitates the exploration of the articular sur-

faces affected by caries, and permits of a sure removal of the diseased parts. Practiced according to Vogt's method, it is easy of execution, does not produce any serious results, the mortality being slight, gives permanent relief and functional results that are very good.

4. Like all other resections, the ablation of the astragalus should not be attempted in cases of pulmonary consumption, in aged persons, or when the lesions are too extensive.

VOGT'S METHOD OF RESECTION OF THE ASTRAGALUS.

—An anterior cutaneous incision is made from the tibio-tarsal articular line on the external border of the extensor communis, and directed longitudinally on the tibio-tarsal articulation and dorsum of the foot to Chopart's articulation. The subcutaneous cellular tissue, aponeurosis, and annular ligament are divided, the tendons of the extensor longus digitorum are separated carefully from the subjacent tissues and held firmly to one side, the extensor brevis d. is incised and drawn to one side upon the external lip of the wound, the external malleolar artery as well as the accompanying veins are divided between two ligatures.

The articular capsule being incised longitudinally as far as possible, the insertions of the capsule and its ligaments are detached on each side by the raspatorium, the head and neck of the astragalus are denuded, the astragalo-scaphoidean ligaments are divided transversely, so as to disengage the anterior part of the astragalus. Now an incision is made from the middle of the anterior longitudinal incision, which is laterally transverse, and in the adult about 10 centimetres long, terminating under the point of the external malleolus, and the soft parts are gradually divided down to the astragalus without interfering with the peroneal tendons.

The foot being forcibly supinated, the peroneo-calcanean ligaments are divided close to the malleolus, and a short-pointed bistoury cuts the ligamentous attachment of the sinus of the tarsus, using also if necessary a delicate pair of scissors.

The astragalus is brought forward in rotating outwards the supinated foot, by seizing the neck of the astragalus with a davier, or by the aid of an elevator placed beneath the bone. A fine pair of scissors introduced between the internal malleolus and the astragalus, cuts the large insertion of the internal lateral ligament to the astragalus; a new traction, effected by pressure, carries the astragalus so forcibly outward that its last attachments to the calcaneum at the posterior astragalo-calcanean articulation can be easily divided.

After the ablation of the astragalus, the whole of the articular cavity is exposed, the synovial membranes can be extirpated, and it is easy to remove all parts of the tibia and calcaneum that may be suspicious. After drainage and suture, the superior surface of the calcaneum adapts itself so exactly to the malleolar surfaces as to leave no cavity.

THE
Journal of the American Medical Association.

PUBLISHED WEEKLY.

THE EDITOR of this JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information, should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE..... \$5.00.
SINGLE COPIES..... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

CHICAGO, ILLINOIS.

SATURDAY, NOVEMBER 15, 1884.

CHOLERA, ITS INCREASE IN PARIS.—We have endeavored to keep the readers of the JOURNAL reasonably well advised concerning the progress of epidemic cholera in Europe, from the time of its outbreak in Toulon to the present time. For a few weeks past the prevalence of the scourge had been diminishing so rapidly, that it was hoped it would not reach the north of France or the more northern countries of Europe, at least, until another summer. But during the last few days it has developed a decided increase in Paris. We say increase because it has been known that some cases have been occurring from time to time in that city since June 20. True, they were called sporadic. But the early and more scattering cases that usher in all epidemics are called sporadic until the later stages of the progress of the disease. According to a Paris telegram of November 8, there had been 160 cases of cholera in that city since June 20, of which 60 had proved fatal. And during the twenty-four hours preceding midnight of the 7th inst. there had occurred 70 new cases and 8 deaths. This official acknowledgment of the existence of the disease and its rapid increase, has checked commerce and travel, and caused much alarm. It is still thought by many that the disease will develop only moderately during the winter, but will become sufficiently planted to cause a full epidemic at the commencement of another summer. This view also gives additional force to the probabilities of its development on this side of the Atlantic at the same time; and should prevent any relaxation of the efforts on the part of municipal authorities, Boards of Health, and citizens, to place every part of our country in

the best sanitary condition possible, and to continue it thus throughout the coming year. For the purpose of keeping the profession generally well informed in regard to the prevailing views of the leading sanitarians engaged in active sanitary work in this country, we published in full last week the report of Dr. John H. Rauch to the Conference of the State Boards of Health in St. Louis, and this week we give the recommendations of that Conference, which were also sanctioned by the American Public Health Association, in session at the same time. While we do not regard the "three essential factors" set forth by the Conference as the basis of their recommendations, so fully established as to justify their assertion in a manner so positive and unqualified, yet we think the recommendations are, for the most part, judicious and important. To do our utmost to prevent the importation of infectious diseases of all kinds; to secure pure air, pure water, wholesome food, and universal cleanliness; and to promptly disinfect or destroy the dejecta of cholera patients, whether they contain an infectious microbe or not, is not only calculated to protect the people against epidemics, but also to greatly lessen all the more common endemic and sporadic diseases to which they are ordinarily liable. Hence all the money and zeal expended, in an enlightened effort to accomplish these objects, are well spent; and will directly promote the health, happiness and wealth of the people.

AN IMPORTANT DEMONSTRATION IN MICROBIOLOGY.

—Whilst a good number of the profession require no word of caution in reference to the too hasty adoption of theories relative to bacteria as a causative element in the development of disease, yet from the recklessness with which the terms "septic" and "antiseptic," "germs" and "germicides" are used by some writers, the caution-signal is certainly not unnecessary; and experiments published by Dr. C. J. Salomonsen and J. Christmas Dirckinck-Holmfeld, from the Bacteriological Laboratory of Copenhagen, substantiate the value of the admonition. It will be remembered that after a series of experiments, Sattler, of Erlangen, published a statement to show that the active inflammation developed in the eye by the use of jequirity infusion was due to the presence of a bacillus. The exposure of this error as demonstrated by the two observers above mentioned, is detailed in the JOURNAL on p. 613, Ool. II, in the domestic correspondence. The position which they sustained has been so ably supported by others and ceded by Sattler, that it is now a settled, demonstrated fact that the inflammation is due to the presence of a ferment

which Messrs. Bruylants and Venneman have called "jequiratine"—which name bids fair to be adopted.

But whilst a certain unanimity relative to the active agent at work in the effects following the use of jequiratine prevailed, there remained unsettled the question of the bacilli, both as to their peculiarities and the part which they play, if any, in the peculiar pathological changes developed in connection with the use of the jequiratine. To make this question clear, it must be understood that two French observers, Messrs. Cornil and Berlioz, took up the experiments of Sattler, and after erroneously corroborating his work, continued their efforts by injecting the jequirity infusion into the subcutaneous tissues of the lower animals. In every well-conducted experiment the bacilli developed extensively in the blood and the animal died. Moreover, blood from frogs which died under these circumstances, injected into other frogs, also produced the development of the bacilli, and the development of the bacilli was followed by death, associated with the usual well-marked pathological changes, namely: subcutaneous œdema, bloody mucus in the alimentary canal, ecchymosed condition of the mucous membranes, and often a sero-sanguineous fluid in the peritoneal cavity. Moreover, it was claimed by Cornil and Berlioz that when the jequirity infusion was filtered with necessary precautions, the injection produced no effect. Hence it was claimed, and with apparent reason, that the bacilli were the active cause of death. To put this question to a crucial test, Salomonsen and Holmfeld continued their studies, the results of which demonstrated that the bacilli, in themselves, have nothing whatever to do with the cessation of life nor with the pathological changes which accompany it.

Several investigators have made observations which show that on the injection of the *jequirity infusion* into the tissues death follows, and that bacilli are present in the animals thus treated; and Bruylants and Vennemann have shown that when the ferment *jequiratine* is used with frogs death follows in a similar way, but no bacilli are found in the blood or tissues, and concluded therefrom that the frogs were killed by the poisonous ferment alone. S. and H., however, undertook to develop the question as to what the bacilli have to do with the subject, and consequently used in their observations not the jequiratine which B. and V. used, but the infusion which Cornil and Berlioz used. By following the same methods, namely, the injection into the dorsal lymph sac of two drops of a two per cent. infusion, or a very minute drop of a four per cent. infusion, after a gradual

muscular weakness, death followed with the characteristic pathological changes above described.

It was found, however, that the bacteria developed varied greatly both in quantity and kind, and, whilst the peculiar bacillus described by Sattler was almost always dominant, several other well-marked varieties were present. It is impossible to follow these experimenters through their whole investigation, which is published in B. 2. No. 19 of the *Fortschritte der Medicin*; we must not omit to say, however, that they cultivated these bacteria from the blood of the frog, and injected them in large quantities into the dorsal lymph sac, and kept watch of them for an indefinite time, and could not perceive that they suffered any inconvenience from the injection. Thinking it might be possible that by the culture on gelatine the bacteria might have lost their virulence, they injected the blood taken directly from the frogs affected. In these instances also, although a relatively large quantity was used, no result followed. In this respect their observations differed from those of the French observers; and they stated their position thus: That frogs subjected to an hypodermic injection of jequiratine die from the effects of the poison with a secondary development of non-virulent bacteria.

To test the question as to whether the bacteria were introduced with the poison, they took several samples of sterilized jequirity infusion and sowed in them different bacteria—the jequirity bacillus, micrococcus prodigiosus, bacillus cyanogenus, and a colorless micrococcus; and after, with due care, demonstrating their pure culture, injected the jequirity infusion thus infected into various frogs, and were rewarded by finding that what they had sown they could now reap in the blood of the various frogs upon which they had experimented.

But the curious and interesting fact is that, unless the frog is subjected to the jequirity poison, these bacteria will not thrive in the blood, and thus it is that the jequiratine in this instance supplies or develops the predisposition for the bacterial invasion. Bacteria injected without the jequiratine diminish and become extinct. After the injection of a large quantity, some few individual germs are found for some weeks, but they also soon disappear.

Contrary to the observations of Salomonsen, Cornil and Berlioz found that the blood of the frogs affected with the jequirity was poisonous to other frogs. Salomonsen has shown this to be the case only when a large quantity of the poison is used with the first frogs, so that the poison when diluted with the affected frog's blood is still strong enough to be

fatal to a second frog. The control experiments were made in this case by showing that when the blood in question was capable of developing the characteristic jequirity inflammation in the eye it was also capable of developing the characteristic poisoning, and when it was not capable of developing the inflammation of the eye it was not capable of poisoning. The explanation given by Dr. Salomonsen why C. and B. did not get any manifestation of poisoning after filtering the jequirity infusion by special precaution, is the possibility that in filtering out the bacteria they also filtered out the poison in question.

This infection of the organism with bacteria, which are in themselves innocuous, Dr. Salomonsen calls a pseudo-infection, which may readily be mistaken for a true infection. Such developments will certainly cultivate caution.

“AURAL THERMOMETRY.”—Under this title the *Medical Record*, of Nov. 1, 1884, makes mention of a series of experiments conducted by Dr. Flitner, and by him detailed in the *St. Petersburg Dissertation*. By means of a thermometer adapted to the purpose he measured the temperature of the external auditory meatus in health and acute and chronic diseases of the ear. The average temperature in health was discovered to be 98.4° F., while that of the rectum and axilla was about 99° F. Dr. Flitner has drawn the following conclusions: 1. That if the temperature of the meatus be measured daily in the course of acute inflammation of the ear, it will be found to bear a constant uniform relation to that of the system at large. 2. The same may be said when pneumonitis, erysipelas and other acute inflammatory affections complicate the aural disorder. 3. The temperature of the meatus is sometimes higher than that of the rectum, in cases where the affection of the ear is accompanied by morbid processes either of the interior or exterior of the cranium, phlebitis of the sinuses, caries, erysipelas, etc. Hence a more reliable indication as to the progress of the cranial affections may be received from the temperature of the auditory canal than from that of the axilla or rectum, and should be preferred to the latter.

This line of investigation is original, and appears to us to deserve further research. If Dr. Flitner's conclusions shall be substantiated, “Aural Thermometry” will prove a valuable addition to our means of diagnosis. Why may it not be found in future a reliable method of detecting, at their outset, obscure inflammatory processes within the cranial cavity.

DOMESTIC CORRESPONDENCE.—We cheerfully give place to the letter of Dr. Wilder, of San Francisco, although we fail to see wherein our reviewer was in any measure incorrect in his representation of the paper alluded to. His remark that “no examination can positively determine a man's fitness to be a practitioner,” was by no means intended to imply that all examinations are useless, but rather that it is only one of several tests that are necessary to determine a man's fitness for performing the responsible duties of professional life.

Our correspondent in West Virginia will receive proper attention next week.

NEW YORK STATE MEDICAL ASSOCIATION.—As we stated in a previous number, this important organization will hold its annual meeting in New York City, commencing on the 18th inst. and continuing four days. We have assurances that the meeting will be numerously attended and its proceedings full of interest.

THE LAW REGULATING THE PRACTICE OF MEDICINE IN WEST VIRGINIA has been decided by the Court of Appeals of that State to be “constitutional and valid.” The opinion of the court was delivered by Judge Green on the 1st inst., and is an able review of the questions involved.

A MEDICAL CENTENARIAN.—Dr. Christopher Columbus Graham, of Louisville, Kentucky, recently celebrated his *hundredth birthday* in the enjoyment of a banquet tendered to him by his neighbors.

THE eminent professor, Luigi Somma, of Naples, fell at his post of professional duty a victim to the cholera epidemic, on the 19th of September, 1884.

SOCIETY PROCEEDINGS.

AMERICAN ACADEMY OF MEDICINE—NINTH ANNUAL SESSION, HELD IN HOPKINS HALL, BALTIMORE, OCTOBER 28 AND 29, 1884.

The Academy convened at 3 o'clock in the afternoon with President Benjamin Lee, of Philadelphia, in the chair, and was opened with prayer by the Rev. Dr. Grammar, of Baltimore.

The minutes of the last meeting and the report of Council were read and approved.

The following gentlemen were recommended for election by the Council, and upon ballot were duly elected:

Drs. J. H. Baxter, Chief Medical Purveyor U. S. A., Washington, D. C.; Geo. W. Miles, Perryville, N. Y.; A. B. Tadlock, Knoxville, Tenn.; Eugene E. Barnum, Watport, N. Y.; C. W. Stevens, Boston, Mass.; John A. Robinson, Chicago, Ill.; J. L. Miner, Wilkesbarre, Pa.; H. A. Johnson, Chicago, Ill.; F. S. Johnson, Chicago, Ill.; J. W. Holland, Louisville, Ky.; H. J. C. Wilson, Baltimore, Md.; W. W. Jagard, Chicago, Ill.; Charles Warren, Washington, D. C.; J. N. Hyde, Chicago; Ira B. Reade, New York; L. S. McMurtry, Danville, Ky.; E. O. Shakespeare, Philadelphia; Douglas Morton, Louisville; M. P. Hatfield, Chicago; T. E. McArdle, Washington; S. M. Free, Dagus Mines, Pa.; F. R. Graham, Chester, Pa.; W. P. Watson, Jersey City, N. J.; J. G. Young, Philadelphia; Joseph Coblenz, Baltimore; J. S. Green, Elizabeth, N. J.; J. M. Stevenson, Pittsburgh, Pa.; David Bockes, New York; E. L. Keyes, New York; E. Andrews, Chicago; E. W. Andrews, Chicago; C. Kollock, Cheraw, S. C.; W. Murray Weidman, Reading, Pa.; T. C. Stellwagon, Philadelphia; M. E. Wordin, Bridgeport, Conn.; G. R. Morehouse, Philadelphia; E. Cowles, Somerville, Mass.; F. H. Davenport, Boston; E. O. Otis, Boston; T. J. Turner, Navy Dept., Washington; T. B. Brune, Baltimore.

Drs. Bulkley, Steiner and Bombaugh were appointed a Committee on Nomination.

The first paper of the afternoon was by Peter D. Keyser, M.D., of Philadelphia, entitled "The Relation of the Medical Colleges to Preliminary Education." This relationship was deduced from the statements made by the various colleges in their announcements, and examining these statements and the method of their execution, it appeared that but comparatively few of the 91 medical colleges made any pretence to any real educational requirement, and even among these few, many did not rigidly enforce their own requirements.

"The Examination of Applicants for License to Practice, a means of Raising the Standard of Medical Education," was the title of the next paper, presented by Edward Jackson, M.D., of Philadelphia. A medical college resembles very much a human being in that what it is, depends upon first, its inherent tendencies, and secondly, the surrounding influences. The attempts that of late have been made to raise the standard of medicine, have been to direct the former condition and develop from within. But a great aid would be given if the surrounding conditions were changed. Every college graduates students of all classes, so that a diploma does not possess an equal guarantee of the ability of its possessor to practice the healing art. The need is not to guard so much against colleges as it is to guard against individuals. This can only be accomplished by an independent Board of Examiners in each State. When this is brought about, and the certificate of this Board will be the only license to practice, another factor will be introduced, which will cause that medical Faculty to be most popular whose students more uniformly pass the Board examination, hence a need on the part of medical teachers imparting more thoroughly and examining more carefully before giving their diplomas.

Henry O. Marcy, M.D., of Boston, was the author of the third paper of the afternoon, entitled "The Role of Bacteria in Infectious Diseases," which paper will appear in full in our columns.

"The Trade Aspect of Medicine," by Albert L. Gihon, M.D., Medical Director U. S. N., was the next paper. The object of the paper was to show the great tendency of the times to belittle the profession of medicine to a trade in medicine, to show the meanness in so doing, and to suggest a better way. The author insisted that the men who look at the practice of medicine only as a means of collecting a fee, whose sole aim is to increase the size of one's practice and thereby one's income, who deal in the methods of the shops, ought not to be included among the profession, and if they desire to retain the methods of tradesmen should be so classified. The remedy for this condition rests solely with the profession themselves, who first ought to cast several beams out of their own eyes. Physicians should be ready to say, "I do not know what is the matter with you, and I will not prescribe until I do know;" to frankly say that there is nothing the matter, or that drugs will not cure, to prescribe freely hygienic methods and drugs less, even though it does involve a loss of fees, when it is for the best good of the patient. But the question was raised, how shall one live by the avocation of medicine? The essayist would largely increase the number of hospitals, dispensaries, etc., for the free treatment of all who were unable to pay the fees. But while the treatment should be free, the physicians in charge should receive a competent salary. Instead of, as at present, a young man putting out his sign and waiting for patients, he would be placed in a hospital with a salary sufficiently large to support him, where he would work under instruction.

By this means not only would better work be done, but an opportunity offered for the collection of statistics of disease, a thing now nearly impossible. Then in a short time there will be a demand for sanitary inspectors in every city in the land, where an opportunity will be given for the employment of many. Even now, if the fines were collected for the violation of the existing sanitary laws, they would suffice for an efficient sanitary service. Dr. Gihon thought the position of family physician would be a much more honorable one, if he were salaried as sanitary adviser of the family, and not to depend for fees upon the presence or not of sickness in the family, and thus have his income depend upon the size of his clientele, and not the amount of sickness.

This was the last paper for the afternoon, the Academy going into executive session, when a resolution was adopted that a committee of two should be appointed in each State where the Academy has Fellows, for the purpose of suggesting and furthering the appointment of State Examining Boards independent of the colleges.

EVENING SESSION.

The Academy assembled in the evening for the purpose of listening to the President's annual address—Vice-President Gihon presiding. Dr. Lee selected

for his subject "Differentiation the Test of Civilization: The Specialist and his Education." He alluded to the earlier medical history of Maryland, quoting from its annals "1805, June Medical and Chirurgical Faculty meeting, Faculty endorse vaccination, Faculty agree to license oculists if competent." From which is seen that Maryland early recognized specialists, and that they adopted competency as the qualification to practice. When a nation grows from barbarism towards civilization, there is a marked increase in the division of labor. There is a differentiation, and the many do in parts that which formerly the one did in entirety.

In the learned professions the same process has been going on but it has met opposition. In this country more than in Europe medicine is expansive, while law and theology are fixed sciences, so if anywhere differentiation should be working, it would be in medicine, but here it meets probably the greatest opposition. The arguments of both sides were presented—on the one hand those opposed to the practice of specialties urge: First, that a multiplication of specialties has a narrowing effect upon the doctor. Secondly, it degrades the profession, and third, it is not best for the patient. On the other hand the upholders of specialties say, that specialism is nothing new—indeed, medicine is in itself a specialty, theology and medicine having of old but a single exponent. Then if one recognizes the physician and surgeon, obstetrician or alienist, why not go further. Again, the field of medicine is too vast to be gone over by one man, and if all attempted so to do we should all sink to the dead level of mediocrity. If, on the other hand, one finds enough to employ his mind in a single branch, he then becomes a specialist. The complexity of modern life demands specialism, here as elsewhere differentiation is a test of civilization. The defense calls witnesses and asks if there have not been important contributions to medical knowledge by the specialists. So that with Gamaliel one feels like saying let them alone, for if they be of man, that is if the distinction is forced and unnatural, they will come to naught, but if they be of God, that is of a legitimate natural growth really required by the times, who can prevent them.

It seems clear that the specialist has come, and he has come to stay. Look at the catalogue of any of the great medical colleges twenty-five years ago, and compare it with that of to-day; and observe the great increase in the number of specialist teachers, in branches distinctively special; whether we think of him as the product of a degenerate race, or as the flower of the profession, we ought to make the best of it.

What shall he be—a physician and something more? or something less than a physician? He has need for a broad education in direct proportion to the narrowness of his work. The consciousness of the self-dwarfing is not a pleasant one, so that he should have that foundation that will prevent it. He should even have a higher standard of preliminary training, but as many do not begin to be specialists, can only say that there be no lowering. This Academy will not be willing to adopt the assertion of one of the

prominent medical colleges: "The student is presumed to have sufficient medical knowledge." A medical specialist should be first of all a man of culture. Having made up his mind to study medicine, should he stop without studying all of medicine? Assuredly not, for the part that he will treat is but a part of a whole, intimately associated with each other and a knowledge of all is necessary to a study of any. With one exception he ought to have all of the old seven, and that exception is obstetrics, because it is itself a specialty. Having the foundation, then comes the superstructure, whether in Alma Mater or polyclinic, a special degree or license. One thing is apt to be overlooked. Specialists are apt to see and treat disease in chronic forms, which are but the outcome of acute forms of disease, and the specialist should have an opportunity for the study of diseases in the acute form, hence an experience in a general hospital is greatly to be desired.

Such an one will not threaten the profession. He concluded with a brief tribute to Fellows who had died during the year—Dr. F. D. Lente, ex-President of the Academy; Elisha Harris, Secretary of the New York State Board of Health, and Surgeon General Crane, of the Army; and the honorary members Drs. S. D. Gross and J. Marion Sims.

After the address the Academy sat down to its annual collation in the Athenæum Club, having a very pleasant social time.

WEDNESDAY MORNING SESSION.

The Council recommended the election of Drs. George M. Sternberg, U. S. A., and Oliver Wendell Holmes, of Boston, to honorary membership, and the following additional gentlemen to fellowship:

Drs. R. J. Lewis, Philadelphia; J. W. Kerr, York, Pa.; Alex. Hadden, New York; J. D. Kelley, Utica, New York, making 45 in all.

They also presented a series of amendments to the constitution and by-laws looking toward another class of members, associates, who shall consist of those who have attained distinction in medicine and the collateral sciences and do not possess the degree in arts, the qualification of a Fellow. These lay over until the next session under the rules.

The following resolution was also adopted:

Resolved, That the American Academy of Medicine recognizes in the recent munificent gift of W. H. Vanderbilt to the College of Physicians and Surgeons of New York, a most important and valuable service to the science of medicine in America.

That in this spirit the Academy tenders to Mr. Vanderbilt its obligations with the assurance that in no better way could the higher education of our profession and the benefit of humanity be promoted.

The nominating committee reported the following suggestions for officers for the ensuing year:

President, Albert L. Gihon, M.D., U. S. Navy.

Vice-Presidents, R. Stansbury Sutton, M.D., of Pittsburg; Jas. A. Stewart, M.D., of Baltimore; William Elmer, M.D., of Bridgeton, N. J.; J. Cheston Morris, M.D., of Philadelphia.

Secretary and Treasurer, R. J. Dunglison, M.D., of Philadelphia.

Assistant Secretary, Charles McIntire, Jr., M.D., of Easton, Pa.

The report was received and the gentlemen elected.

The first paper of the morning was by R. D. Rockwell, M.D., of New York, on "The Induction Coil; Its Varieties and the Differential Indications for their Use."

Two kinds of electro-magnetic machines are in use by the medical profession, the separate coil and the continuous. By means of diagrams the construction and principle of each were explained. The essayist devoted the greater part of the paper to the therapeutical use of the second class or continuous coil machine. While it is possible to have no less than ten combinations of current, after much experience and careful observation he has concluded that three of these will do the work of the ten.

First, the current obtained from the primary coil, of large quantity and small tension. It is of considerable power, will burn iron and electroplate. It has but slight contractile power upon the muscles in health, but in some pathological conditions will produce muscular contractions far exceeding those brought about by the stronger induction coils. It is of benefit in true neuralgic pains about the head. In cases of asthenopia the tired eye is often relieved and by its continuous use strengthened, it will also frequently remove muscæ volitantes.

Second, a combination of the primary with the first and second induction coils. This gives a current both peculiar and unique. It will electroplate, but will not burn iron. It has the maximum power to contract muscles, each additional coil giving decreased contractility. The current is harsh, sharp and cutting in character, and is of use when a powerful impression is required; hence in not a few cases of paralysis where the response to the galvanic current is perfect, but where there is a diminution of the farado-muscular contractility, this current is better than any other. While in superficial forms of anæsthesia it may be in no way superior to other forms, it is to be preferred in certain persistent forms of lost or perverted sensibility.

Third, the primary in connection with all three induction coils. A very interesting and important combination is made, tonic and sedative in character. The range is wider than the others, and is of use in general faradization. The best constitutional effects are brought about by this form, and it aids in relieving that host of symptoms gathered together in general neurasthenia. The action on the motor and sentient nerves is less severe, and its general effects are more agreeable.

"Some Comparative Results of Treatment of Chronic Articular Osteitis of the Hips," by Dr. P. Gibney, M.D., of New York, was read by title and referred to Council.

L. C. Bombaugh, M.D., of Baltimore, read the next paper, entitled "The Place of the Physician in Literature." This place is a two-fold one—an active and passive condition; the physician may write or be written about. The passive state was the only one to be treated of in the paper. He quoted freely from authors of all ages and climes, showing the

esteem or lack of it in which the profession was held. He analyzed the motives of the writers, and traced out the real drift and relative worth of their criticism and irony. The attack upon quacks was upon those in high places, and if the profession had but more carefully examined into many of these attacks, and found that they were but mirrors held up to nature, have laughed with the people, but profited by the caricature, they would have more quickly pruned many of the excrescences; and to-day as well as for the future, if to-morrow is to be as to-day, there is ample opportunity for other Molieres if "machine-made doctors who have no aspirations beyond the trade aspect are to be assigned a share in the work of filling the gaps in preventive medicine and sanitary science, of making nearer approaches to infallibility in our etiology, of developing knowledge of micro-organisms, of probing the depths of hereditary and constitutional taint, of strengthening expert testimony in medical jurisprudence, of inquiring into new types of disease occasioned by new forms of manufacturing industry, of introducing improved remedial measures and demonstrating their efficiency, of learning more of climatology and the geographical distribution of disease, of hastening the removal of the *opprobria medicorum*, and so on to the end of the long, long chapter."

"Observations in One Hundred and Thirty-seven Abdominal Sections," was the title of a paper by R. S. Sutton, M.D., of Pittsburg. The cases upon which these observations were founded were operated on by various operators in America and Europe, twenty-nine of them being by myself, comprising the various forms of abdominal section. Cases for McDowel's operation are, as a rule, a comparatively poor class of patients, and in the United States the rule has been to operate after the health of the patient has been broken and at her home. In England, Scotland and Germany, early ovariectomy in a special hospital is recommended, while in Austria the cases are farther advanced, and the operation made in the general hospital, and the results obtained are not so good. There is a time in every ovarian tumor when there are no adhesions and the operation almost without danger. If by neglect of the patient or bad medical practice, she is treated with the trocar and persuaded to wait until death stares her in the face before operating, the risks are greatly increased. He has been gradually approaching the following conclusions:

First. Nearly all cases of ovarian cystomata recover if operated on early and under proper precautions.

Second. A very large number of cases of ovarian cystomata die if operated on in their own homes under ordinary precautions.

Third. That simple cases and a well regulated special institution for the work will always be the mainspring of success in McDowel's operation.

An ovariectomy done early may be considered one of the easiest of surgical operations, but a neglected case is a very different affair. After the completion of the operation it is most important to leave the cavity of the peritonæum dry. As a rule, the younger subjects do best, but the elder subjects bear the oper-

ation well. Climatic influence has very little effect. The details of antiseptic precautions need not be taken, but thorough cleanliness must be insisted upon. The methods of operating differ very much; the simpler methods are preferable. The prevention of the loss of blood is of the greatest importance. In supra-vaginal hysterectomy the question of the disposition of the pedicle is still *sub judice*. Where a cyst is multilocular a trocar should be used, and as the cysts are emptied the abdomen should be filled with warm sponges that the intestines may be protected from chill. Adhesions are best treated by ligation and division with Paquelin's cautery. The best super-dressing after hysterectomy with the stump outside is iodoform gauze. Drainage in intra-abdominal operations should only be resorted to in cases when it is not certain that the bleeding is all arrested; where many adhesions were divided without the cautery, and when the peritonæum is so irritated that it is almost certain to throw off much serum.

At the conclusion of Dr. Sutton's paper the Academy took a recess and visited the very handsomely equipped chemical and biological laboratory of Johns Hopkins University.

Upon reconvening there was a spirited discussion upon Dr. Sutton's paper, participated in by Drs. J. Tabor Johnson, of Washington; E. H. M. Sell, of New York; H. O. Marcy, of Boston; and H. J. C. Wilson, of Baltimore. The views of the essayist were generally agreed to, the chief exception being that an operator should never refuse to operate no matter how desperate the case. The discussion was closed by Dr. Sutton.

The last paper of the session was by L. Duncan Bulkley, of New York, entitled, "Specialties and their Relation to the Medical Profession. The following conclusions were reached:

1. The science and practice of medicine is so vast that it is beyond the power of one mind to grapple with it all.
2. Divisions of study and of practice have unconsciously been made.
3. Specialists are those who devote excessive attention to their branches.
4. By the development of these they have increased the scope of medical knowledge.
5. Everyone should be more or less a specialist, in that he should know or do some one thing better than another.
6. Specialists should have a thorough training in general medicine in addition to their special preparation.
7. Specialties will limit themselves by the law of supply and demand, and by the increase of the teaching of special branches in the medical schools, thereby giving the general practitioner greater knowledge in these departments.

Drs. Herman Knapp, and F. M. L. Chrystie, of New York, were prevented from attending the meeting. Dr. Nathan Allan's paper on "Physiology in Its more Public Relations," was read by title and referred to Council.

The report of the standing committee on "Laws Regulating the Practice of Medicine," showed such

regulation in one State, Virginia, since the last meeting.

Dr. Lee, the retiring President, made a short valedictory address, and introduced the President-elect, Medical Director A. L. Gihon, who made a short salutatory.

The President appointed Drs. L. Duncan Bulkley and E. H. M. Sell additional members of Council.

Votes of thanks were tendered to the retiring President for his efficiency and the authorities of Johns Hopkins University for their courtesy. The Academy then adjourned to meet in New York in 1885.

After adjournment many of the Fellows visited the Johns Hopkins Hospital under the guidance of Dr. J. S. Billings.

CHICAGO SOCIETY OF OPHTHALMOLOGY AND OTOTOLOGY.

JUNE 9, 1884.

The society convened as usual in the parlors of the Illinois Charitable Eye and Ear Infirmary. The following gentlemen were proposed for membership: Dr. Ira Marshall, Dr. Casselberry, Dr. W. H. Fitch.

Dr. Holmes made a verbal report of an interesting case in which, two months after a very successful extraction of cataract, he divided extremely delicate capsular remains with a Knapp's needle knife. The patient was much elated at the great improvement of her sight.

After a few days the patient complained of irritation, although she had been confined to her room constantly and to her bed four days. The eye had been under the influence of atropine and boracic acid. The conjunctiva especially of the lids was red. A small mass of mucus (?) was found on the edge of the lower lid and adherent to the globe. On the removal of this collection it was observed that a minute filament extended from the needle puncture down over the cornea. There had been no pain. On the eighth day vision had not suffered. More or less pain soon followed with slight increase of tension. Eserine was substituted for the atropine.

It was observed that a very fine thread-like opacity extended into the vitreous. In a few days the vitreous became more and more cloudy, the conjunctiva red and œdematous and the eye painful. In a week more the patient was unable to count fingers.

The reporter was inclined to believe that the inflammation was not caused primarily by the injury of the intra-ocular tissue, but secondarily by the entrance of germs through the puncture from the *minute prolapse of vitreous*.¹

After the conclusion of these remarks, Dr. Holmes invited the members to repair to the patient's room and examine the case at their leisure. The case was discussed at length. Owing to the great interest attached to it, Dr. Holmes was requested by a vote of the society to prepare a paper on his experience in secondary operations for cataract.

¹ We have since learned that the patient has greatly improved in all respects. Her sight especially is now quite good.

Dr. E. J. Gardiner read an exhaustive paper on "Boracic Acid in Ocular Therapeutics." No further mention is made of it here as it will soon appear at length.

AUGUST 12, 1884.

Drs. Marshall, Casselberry and W. H. Fitch were elected to membership.

Dr. Hotz presented a pathological specimen, with the following history: Mary S., aged 4, was first examined August 1, 1884. About ten days previously, without injury or any other manifest cause, the left eyeball became violently inflamed. She slept well, and never complained of pain. One or two days before her visit to the doctor's office the patient was apparently sick; she had no appetite, and no desire to play as usual.

Before this inflammation set in, the left eye had the same appearance as the right. The following changes were noted by Dr. Hotz, August 1: Intense episcleral injection, interstitial haziness of cornea, retraction of iris in consequence of which the anterior chamber was abnormally deep. Pupil invisible, three-quarters of the anterior chamber being filled with a grayish white substance.

Aug. 11, upper anterior portion of sclerotic discolored and distended (staphylomatous); injection of eyeball more intense; condition of cornea the same; anterior chamber filled entirely with the grayish white substance. The eyeball was enucleated and at once opened by a meridional section. Vitreous appeared wine-colored and cloudy in its anterior half, the cloudiness being most dense near the region of the ciliary processes and anterior limitans, which appeared densely white. Lens intact; pupil contracted; anterior chamber filled with a whitish red vascular substance 2 mm. thick; it cannot be separated and distinguished from the iris tissue, and is firmly coherent with the posterior surface of the cornea. At the corneo-scleral margin the anatomical boundaries of the various tissues are lost; all blend with the mass, which has invaded cornea, sclera and ciliary body.

There is no trace of ciliary processes. The surface from ora serrata to pupil is perfectly flat and smooth. The posterior part of the eye has a normal appearance. The doctor expressed the opinion that the growth might prove to be a so-called granuloma on microscopic examination.

Dr. Boerne Bettman then read a paper on Amaurosis following Hæmorrhage. The two cases cited offered certain symptoms which, according to the doctor's opinion, pointed to a common cause, namely, to intracranial hæmorrhage with subsequent alterations of the optic nerves. The first case, Margaret Feth, æt. 24, was admitted into the Eye clinic of Heidelberg in 1879. She is of healthy parentage. Patient had repeated attacks of convulsions up to her fifth year. Several brothers and sisters, seven in all, died a few months after birth from the effects of convulsions. Miss F. was a healthy, well-nourished child. Menstruation set in at the age of 16. On the 17th of May, 1879, while at home, she suddenly experienced severe pain on the left side of her head,

accompanied by dizziness and severe spells of vomiting. The pain increased during the night. A physician was hastily summoned; he prescribed powders which apparently intensified the nausea and emesis. On the 21st, a second attack of sudden dizziness came on while in bed. She became unconscious, and remained in this condition 24 hours. While in this state, a large quantity of dark-colored blood was seen to well from her mouth by her parents. On coming to her senses, everything appeared dark about her. Investigation showed her to be perfectly blind. Sight returned to the right eye during the course of the day. A third attack of unconsciousness followed a few days afterward, leaving the sight of the right eye very much impaired. On the day of admission into the clinic there was complete amaurosis. Both pupils were dilated *ad maximum*. Irides did not respond to light. The ophthalmoscope revealed pronounced atrophy of both discs. Treatment of all varieties proved of no avail.

The second case was that of a boy, George Dohl, æt. 3. The child fell against a chair, striking the upper teeth. The gums bled for three days, followed by severe convulsions which lasted fully 48 hours. After the first 24 hours, during an interval of consciousness, the parents noticed that the child had lost sight in both eyes.

Ten days after the injury the child presented the following appearance: Pale, weak-looking boy; pupils dilated *ad maximum*; reaction to light prompt; media both eyes clear; papillæ very anæmic, almost perfectly white; caliber of arteries somewhat diminished; veins perhaps somewhat dilated; amaurosis. The prognosis was unfavorable. Particular pains were taken to call the attention of the parents to one favorable feature of the case, the prompt reaction of the irides, which was interpreted as a sign of partial restoration of vision. Sight gradually returned sufficiently to enable the child to roam about the house. Eight weeks after the accident a second attack of convulsions ended fatally. The various theories of Graefe, Sammelsohn and Leber were then discussed.

The next paper was by Dr. Jefferson Bettman, entitled "Fracture of Base of Skull with Complication of Vago-Accessory Nerves."

Dr. Holmes made a verbal report of an unusual case of upward strabismus. A boy, 13 years of age, had suffered from very early childhood from a peculiar turn of the right eye upward, which occurred about every half minute. There was not a quick spasmodic motion as in chorea, but a slow movement as in certain cases of convergent strabismus. During the contraction of the levator superioris more than three-quarters of the cornea was concealed under the upper lid; the vision with $-1\frac{1}{48}$ cyl. 90° was normal. Neither by the use of prisms or any other means could diplopia be induced. A division of the superior rectus almost absolutely relieved the annoying action of the muscle. At the end of three months the patient reported no return of the anomaly.

BOERNE BETTMAN,
Secretary.

¹This case will be found in full in the department for Original Articles.

REGULAR MEETING OF THE CHICAGO GYNÆCOLOGICAL SOCIETY, OCT. 31, 1884.

In conformity with an ancient custom, the members of the Society met at the residence (271 Michigan Ave.) of the retiring President, Dr. A. Reeves Jackson, and were entertained by an elegant and elaborate banquet. After the banquet, the President called the meeting to order. The following officers for the ensuing year were elected :

President, Dr. H. P. Merriman ; 1st Vice-President, Dr. E. C. Dudley ; 2d Vice-President, Dr. Charles Warrington Earle ; Secretary and Treasurer, Dr. Edward Warren Sawyer ; Editor, Dr. W. W. Jaggard.

After an appropriate address by the retiring President, the Society adjourned to meet Friday, Nov. 21, at the residence of Dr. C. W. Earle, 535 Washington Boulevard, Dr. Edward Warren Sawyer to open the discussion of "The Premature Expulsion of the Ovum."

W. W. J., Editor.

2330 Indiana Ave., Chicago, Ill.

STATE MEDICINE.

HEALTH IN MICHIGAN, OCT., 1884.

Reports to the State Board of Health, Lansing, by observers in different parts of the State, show the diseases which caused most sickness in Michigan during the month of October (5 weeks ending Nov. 1), 1884, as follows :

Number of Weekly Reports Received, 225.		For Preceding Month.	
Diseases Arranged in Order of Greatest Prevalence.		Per Cent. of Reports Stating Presence of Disease.	Per Cent. of Reports Stating Presence of Disease.
Diarrhœa.....	75	88	
Intermittent fever.....	72	84	
Rheumatism.....	67	61	
Neuralgia.....	64	57	
Consumption of lungs.....	60	62	
Bronchitis.....	56	44	
Remittent fever.....	52	59	
Dysentery.....	44	56	
Tonsillitis.....	44	31	
Influenza.....	37	24	
Typho-malarial fever.....	36	27	
Cholera morbus.....	31	62	
Erysipelas.....	28	22	
Cholera infantum.....	28	51	
Typhoid fever (Enteric).....	25	15	
Pneumonia.....	22	13	
Diphtheria.....	22	19	
Inflammation of bowels.....	22	21	
Inflammation of kidney.....	22	18	
Whooping-cough.....	16	22	
Scarlet fever.....	9	11	
Inflammation of brain.....	8	8	
Membranous croup.....	8	3	
Cerebro-spinal meningitis.....	7	5	
Measles.....	6	10	
Puerperal fever.....	5	6	

For the month of October, 1884, compared with preceding month, the reports indicate that influenza, tonsilitis, bronchitis, typhoid (enteric) fever, pneumonia, typho-malarial fever, and neuralgia increased, and that cholera morbus, cholera infantum, diarrhœa,

dysentery, intermittent fever, and remittent fever decreased in prevalence.

Compared with the average for the month of October in the six years, 1879-1884, dysentery, diarrhœa, cholera infantum, and cholera morbus were more prevalent, and intermittent fever and typho-malarial fever were less prevalent in the month of October, 1884.

For the month of October, 1884, compared with the average of corresponding months for the six years, 1879-1884, the temperature was slightly higher, the absolute humidity and the night ozone were slightly more, and the relative humidity and the day ozone were slightly less.

Including reports by regular observers and others, diphtheria was reported in Michigan in the month of October, 1884, at 40 places, namely—Armada, Ann Arbor, Adrian, Albion, Big Rapids, Coldwater, Charlevoix, Detroit, Douglas, Edmore, East Saginaw, Fowlerville, Garfield, Grand Haven, Grand Rapids, Handy, Houghton, Hastings, Hartford, Howard City, Kalamazoo, Lyons, Port Austin, Lansing, Leelanaw, Marcellus, Muskegon, Meredith, Mendon, Manistee, Northport, New Buffalo, New Haven, Port Huron, Reynolds, Romeo, Sand Lake, Springwells, Wyandotte, Whitehall ; scarlet fever at 19 places—Burr Oak, Coldwater, Columbiaville, Cadillac, Detroit, East Saginaw, Grand Rapids, Ishpeming, Jasper, Kalamazoo, Leelanaw, Manistee, Muskegon, Portland, Vicksburg, Wyandotte, Albion, Cedar Plains, Roxand ; and measies at 6 places—Detroit, Cadillac, Ithaca, Marcellus, Whitehall and Wyandotte.

HENRY B. BAKER, Sec.

Lansing, Nov. 7, 1884.

REPORT ON THE PREVENTION OF EPIDEMIC CHOLERA IN AMERICA.

[Adopted by the American Public Health Association and the Conference of the State Boards of Health.]

TO THE CONFERENCE OF STATE BOARDS OF HEALTH :
Mr. President and Members :—Your committee, to whom was referred papers relating to the practical work required for the prevention of epidemic cholera in this country, respectfully report as follows :

ORIGIN AND DISSEMINATION.

There are three essential factors to the prevalence of cholera in this country as an epidemic,—(1) the importation of the disease by means of ships more or less directly from its only place of origin in India ; (2) local unsanitary conditions favorable to the reception and development of the disease ; (3) persons sick with the disease in some of its stages, or things infected by such sick persons, to carry it from place to place. These three factors naturally suggest the methods of combating the disease, for which there is needed practical work,—international, national, and inter-state, state, and local. So far as relates to state and local boards of health, their organization and activities are greater than ever before ; but it must be admitted, that after cholera has been introduced into a country, inland quarantines are not easily

and successfully maintained, although efforts in this direction are then advisable.

In view of the threatened introduction of cholera into this country during the coming year, and the consequent immense waste of life and property values through derangements of commerce, trade, and productive industries, it is the sense of this conference that the general government should maintain such a national health service as shall, by rigid inspection at the port of embarkation, question the freedom from disease and infection of all persons and things from infected districts, and shall secure the surveillance of such persons and things while on shipboard, and, when necessary, detention at quarantine stations on this side for treatment and disinfection.

OFFICIAL INSPECTION.

In view of the present threatening aspect of Asiatic cholera, and the constant danger from other communicable diseases occurring at foreign ports having commercial relations with the United States, we urge upon congress to provide for the appointment and maintenance at all such foreign ports where cholera, yellow fever, plague, small-pox, or scarlet fever exists, or are liable to exist, of medical officers of health, the same being either accredited consuls, or attached to the consulates. The duties of these officers shall be to give notice, by telegraph when practicable, of the existence or appearance of any of the above named diseases to some constituted authority in this country; to give notice of the departure of any vessel known or suspected to be infected for any port in the United States; and, whenever requested by the master of any vessel about to load or leave for this country, to inspect thoroughly such vessel in all her parts, and also her cargo, her crew and passengers, to use such cleansing and disinfection as he may deem necessary, and to satisfy himself that all persons about to sail are free from dangerous communicable diseases, are not recently from infected places, and are properly protected from small-pox, giving to her commander a certificate of the inspection, and of all precautionary measures taken. And it shall be the duty of the central authority in this country promptly to transmit intelligence of the existence of the above mentioned diseases at foreign ports and places, and of the departure of dangerous vessels for the United States and Canada, to all state and local health authorities in the country which may be interested in the same.

We further recommend, in case of those foreign ports which have no consular agents of this country or no telegraphic communication with this country, and which are liable to transmit pestilence through commercial intercourse, that one or more medical officers be chosen to visit such ports as often as may be deemed necessary by the central health authority in this country, so as to give trustworthy information of the health and sanitary condition of those places.

CANADIAN HEALTH ALLIANCE.

Inasmuch as the Dominion of Canada is equally interested with the United States in protecting itself

and the United States from the importation of dangerous diseases, we suggest that congress take such measures as will bring about concerted action with the Dominion and the British government, by which the consuls of this country or of England at foreign ports shall examine and take such action as they may deem effective, and notify the authorities of such government as has authority over any port to which any ship may sail in the United States or Canada, in order that such government may be in a position to take effective measures against the importation of these diseases.

We are gratified that the authorities of the Dominion of Canada and of the Province of Ontario have taken active steps toward protecting the people of Canada, and indirectly those of the United States, by the adoption of extensive quarantine regulations. We feel, however, that with respect to those regulations regarding the landing of passengers from the mail steamers along the St. Lawrence, etc., further special regulations for the thorough disinfection of the baggage and effects of all passengers, cabin or steerage, as come from infected ports or places, should be carried out in a manner similar to that recommended by the National Board of Health. Believing that the importation of cholera into this country has usually attended the presence of immigrants from infected countries, we therefore recommend that all such immigrants be prevented from landing at our ports until such time as the danger of the introduction of cholera by them shall have passed.

The inspection and quarantine service inaugurated by the National Board of Health, and set forth in the paper by Dr. Smart before this conference, but which system is now inoperative for want of an appropriation by congress, meets with our cordial approval. To enable these protective measures to be carried out, we recommend that congress be urged in the strongest terms to legislate on this subject at an early date in its coming session, and to appropriate such funds as may be needful. The expenses incident to the work which has to be performed at foreign ports, and the establishment of refuge stations at points on our own coast for the detention and treatment of infected vessels arriving from foreign ports, should undoubtedly be borne by the national government, and not by individual States or municipalities; for the benefits accruing therefrom are general, and not restricted to localities, although some ports and cities on the coast may have a more immediate interest in the matter than others in the interior. It is probable, however, that this national protective work may not be sufficient.

LOCAL SAFEGUARDS.

It will undoubtedly delay and lessen the chances of invasion, but it may not prevent invasion. The poison of the disease is subtle, and may effect an entrance into the country at some unguarded point. The funds necessary to the stamping out of the disease in a particular locality, and to the prevention of its spread to other localities, might in some instances be borne by the municipality or state affected; but should the disease occur in a locality which has failed or is

unable to make provision for the occurrence, its spread to other cities and states would be imminent. The want of means at the infected point would be disastrous to many others. Congress has recognized the necessity for aid to state and local boards of health under similar conditions in the case of yellow fever. In 1879 the sum of \$500,000 was appropriated, and placed at the disposal of the National Board of Health; and the records show that of this sum \$160,000 was employed in combating the epidemic of that year. We therefore recommend that the influence of this conference be used with the view of having appropriated by the national legislature the sum of \$500,000, to be used, or as much thereof as may be needful, in case of a cholera invasion, in stamping out the disease from the infected localities, and in preventing its spread from state to state.

The removal of local unsanitary conditions favorable to the development of cholera is the special work of state and local boards of health. Much has been done already in some states, but much remains which should receive immediate attention. Where it can be done, state sanitary inspectors should be appointed to visit all towns and cities specially liable to the disease, to counsel with the local authorities as to the best methods of prevention. This work should be vigorously prosecuted before the disease reaches our shores.

ADVICE TO CITIZENS.

The cause of cholera is contained in the discharges from persons affected by the disease, or in things infected by such discharges. Should the disease reach our shores, the first case, and after this the first case which reaches any given community, should be strictly isolated. All infective material from these and from any subsequent cases should be destroyed in such manner as to stamp out the disease. Intelligent sanitary precautions beforehand, and scientific disinfection and treatment in the presence of the disease, should take the place of the necessary cruelties of a panic. In case any city or town is infected, the same principles of isolation should in general be applied to the city as to the infected individual. Intercourse with other cities and places should be under sanitary supervision, substantially as set forth in the rules and regulations of the National Board of Health respecting the inspection of travellers, disinfection of effects, vehicles, etc.

Health officers and inspectors appointed by state or provincial boards of health should, in addition to other sanitary work, see that the localities have set apart, erected, or planned to be so set apart or erected, structures which shall possess the sanitary requirements of an isolation hospital. But as regards all necessary work by local boards of health, most state and provincial boards of health have printed and issued documents which give ample instruction.

Your committee recommends that when this conference adjourns it be to meet in Washington, D. C., the second Wednesday in December next, and that the secretary of this conference be directed to invite the attendance at that time of the quarantine officers and the health officers of the principal cities in the United States and Canada; and that all delegates to

that meeting be prepared to report the sanitary status of their state or locality, and what steps have been taken to improve the same, and to prevent the introduction of disease.

All of which is respectfully submitted.

HENRY B. BAKER,

Secretary State Board of Health of Michigan,

DOMESTIC CORRESPONDENCE.

215 GEARY ST., SAN FRANCISCO, CA., }
Oct. 27, 1884.

EDITOR OF JOURNAL OF AMERICAN MEDICAL ASSOCIATION:

Dear Sir:—In your issue of the 11th inst. you were pleased to notice at some length my paper on "Old and New Codes," read at the meeting of the California State Medical Society in April last. I think you have drawn some erroneous conclusions from my proposed plan for the establishment of a "caste" in the profession, and I venture to explain more at length my ideas in this direction. It was far from my thoughts to attempt the formation of an aggressive organization; that partakes too much of legislation methods, which have always proven utter failures in the past and will most certainly continue to do so in the future. There is no doubt of the truth of your statement that "no examination can positively determine a man's fitness to be a practitioner," and "his success in the actual conflict with disease is the only true criterion by which his merit can be judged;" but allow me to ask whether you would hesitate for one instant as to which class of men you would select a doctor from, provided you had no personal acquaintance with the individual. From among those whom you knew had passed a thorough and critical examination in all the tenets of the profession, or from the great mass of so-called medical men who come from nobody knows where? You who have had such good opportunity of knowing, through the earnest work of your State Board of

Health, the perfect ease with which a diploma can be obtained from many of the medical schools of the country, and who, at the same time, stand at the head of the accredited organ of the American Medical Association, can illy afford—so it would seem to me—to make use of the veritable arguments of the “Sweet Family,” “natural bone-setters,” and others of like ilk.

Will you kindly inform me why, when our Government in the early days of 1861 found a great necessity existing for reliable medical men, it established through Congressional enactment a special corps of surgeons and assistant-surgeons under the name and title of Surgeons and Assistant-Surgeons U. S. Vols. General Staff, and designated their duties as being confined to such positions as Medical Directors of Army Corps, Division and Brigade Surgeons, Surgeons in charge of General Hospitals, and Medical Inspectors of Armies and Departments? And also, why all applicants for these positions were obliged to submit to a rigid examination before an Army Board appointed for that special purpose? And also, why, as a further criterion, no person successfully passing said examination should receive the appointment of Surgeon unless he was at least 30 years of age?

Has not Dr. Gihon set forth in most striking terms the utter absurdity of many of the examinations made before the Army Medical Boards of to-day, and shown the shameful ignorance manifested by many of the applicants for positions?

The facts are as I have stated. In our country, under the existing form of government, there can never be any limit placed *by law* upon the number of medical schools that shall graduate students. Neither can there be any uniform standard of requirements for such graduation enforced. We must face these facts; no logic, no reasoning, no anything will change them. The consequence is that our entire country is flooded with graduated doctors, good, bad and indifferent, but in swarms and multitudes. I am not taking into account the armies of quacks and irregulars, only those supposed to be regulars.

How is it possible for the people to select from these masses with judgment? It is in this extremity that I ask relief in the establishment of higher grades in the profession—not in the spirit of *aggression*, but in the spirit of *progress*.

As in our civil war the surgeons and assistant-surgeons, U. S. Vols. Gen. Staff, were on a par with the medical officers of the regular army, by reason of the increased demands in the way of examinations, etc., made upon them by the government, and which were not made upon the great bulk of surgeons and assistant-surgeons appointed from the different states; and as a commission in this special corps placed its possessor at once and without hesitation, on a certain established basis, so I would have in the great professional field higher organizations, entrance to which can only be had except by the attainment to certain standards, then a diploma, or certificate, or whatever might be used to signify that the possessor had complied with the requirements, the fact of such possession would give him recognition at once.

I would not have you or any one else infer that I for one moment could or would convey the impression that there were not just as eminent medical men, just as able surgeons on duty with the regiments from the different states during the war as could be found in the regular Army Corps or that of the U. S. Vols. Gen. Staff. Nor would I dare to say that in the rank and file of the profession there might not remain men infinitely superior to those entering the higher grades. What I do mean to say, is that the possession of a higher title would give a man recognition at once wherever he might be, or wherever he might go. Neither the laity or the profession could make any very serious mistakes in demanding his services, either for advice or consultation. At the same time it would be a direct stimulant to a higher education, and those schools that did not bring their matriculants up to the required standard on final examinations, would find themselves dropping out of the race for want of material.

I send you this as a letter, and ask you to publish it as correspondence. You may criticize as severely as you will, only give me opportunity for reply.

Very truly yours,

A. M. WILDER, M.D.,
Late Surgeon and Brev. Lieut.-Col. U. S. Vols. Prof. Ophthalmology and Otology Med. Dept. University of California;

PHILADELPHIA LETTER.

PHILADELPHIA, OCT. 31, 1884.

Dear Doctor:—Our schools are fairly at work, and it would seem as though with the array of talent offered in our city that we ought to educate *medically* to a certain extent. What we do turn out, may seem good enough for the outside world, but it would seem as though for home use it were of no value. We are led to this view by the recent selections by two of our schools. The Jefferson has always preferred to import her professors, and perhaps she knew so well the calibre of her graduates that she had reason to look elsewhere. But now comes the University whose trustees are compelled to look to a foreign land for the occupant of a chair. As if to confirm the view as above, our almshouse has been compelled to import its head nurse from England. We have had for many years her Nurse Training Schools actively at work, but neither seems capable of producing results fit to carry on the work required in the great hospital connected with the almshouse.

The old plan is reversed. In place of going abroad to study, we import teachers, and perhaps at some distant day we may educate men and women fit to take their places.

Our city is dirty, but healthy. Dirt alone does not seem to produce disease. Thanks to the wretched paving, it is difficult to clean the streets, and thanks equally to official inefficiency they are not cleaned. Our daily papers almost constantly growl over this state of things, but it is of no consequence. Should the cholera approach, we may expect a spasmodic effort when too late. But after all, it reminds one of a paper on Cholera Infantum read some years ago before

our local medical society in which the author announced that the disease was the result of filth and heat. When he had concluded, a member asked, if that were true, how was it possible that any of the children in a certain locality escaped, inasmuch as said neighborhood was remarkable for its filth, and yet during the summer just passed, cholera infantum, in fact all forms of disease had failed to occur, and the whole region was as remarkable for its health.

Speaking of medical societies brings up the fact that our County Medical Society now numbers its members up to about 500. This is the union of all specialists and general practitioners; while the Pathological, the Obstetrical, the Neurological, the Medico-Legal, etc., devote their evenings to the subjects after which they are named. Judging by the volumes put forth, each body seems to succeed in evolving from its members a goodly share of work.

Our clinics under the name of dispensaries and hospitals are numerous, and show that not only the younger members of the profession but many of the older ones devote a goodly portion of their time to free prescribing. We had nearly said "for the poor," but this would have been a great error. Fully half of those who apply at such places are abundantly able to pay for both medicine and advice. We have just been told of a case now receiving first-class advice at a public clinic, yet the patient is the daughter of a man owning four horses, several houses, and who is doing an excellent business. Knowing these things, is it any wonder that our profession is crowded here? or that the members must resort to a variety of plans to keep the wolf from the door? Yours,

PHILADELPHIA.

OVARIOTOMY.

TO THE EDITOR:

Dear Sir.—In your issue of October 25, you publish a letter from Prof. Donald McLean, of Detroit. In this he corrects his statement of statistics, *made in Washington last May*. At that meeting he said that from Oct. 1, 1883, to May, 1884, he had done *five* ovariectomies, and that all the cases had recovered. He now says that *one* of these cases died. That leaves him then with *five* ovariectomies from Oct. 1, 1883, to May, 1884, with *one* death and *four* recoveries. Now, I have in my possession a copy of the death certificate of *another*. She died on the 30th day of January, 1884, at Lansing, Mich. Will Prof. McLean recall this case also?

Very respectfully yours,

R. S. SUTTON.

419 Pennsylvania Avenue, Pittsburgh, Pa.

BOOK REVIEWS.

ON TUMORS OF THE BLADDER, their Nature, Symptoms and Surgical Treatment, Preceded by a Consideration of the best Methods of Diagnosing all forms of Vesical Disease, including Digital Exploration and its Results, by SIR HENRY THOMPSON,

F.R.C.S., M.B., etc. Phila.: Blakiston, Son & Co. 1884 Pp. 110 (with six plates).

We believe this monograph is the first important contribution to the new and important question of digital exploration of the bladder.

Although the work is entitled "Tumors of the Bladder," yet the vital part of it is contained in the discussion of cystotomy as a justifiable resource in obscure cases of bladder disease, as a step toward diagnosis by digital exploration of the interior of that organ.

This is true first, because no case of tumor can be diagnosed or treated without cystotomy as a preliminary step, and, secondly, because the operation, which is not a serious one, gives marked relief in a large number of cases, even where no tumor is found which can be removed. The relief thus seen to follow, is due to the perfect *rest* from distension, tenesmus and catheterization which the perineal opening allows to the inflamed organ.

Primarily, therefore, this little book sets out to approve and justify the opening of the bladder for exploration in a large number of cases which heretofore have baffled surgical skill. As this is a question which has for some years been pretty frequently in the minds of surgeons on theoretical grounds, the present contribution will be regarded as settling a vexed question, so far as one man's authority can decide.

In speaking of a tumor found at the autopsy on a case of fatal bladder disease, Sir Henry says:

"It was clear to me from this case that the ordinary sound, 'a lengthened finger' in practised hands, had proved incapable of giving me sufficient information relative to the presence of a considerable growth within the bladder. Supposing that I could but once have put my real finger there, instantly discovering, as I should have done, that easily removable tumor, how different would have been the issue of that unhappy case! He might have been enjoying life and health to-day. What, then, was to prevent me in future, under circumstances of equal gravity and like obscurity, from determining the presence or absence of such a growth by the direct sense of touch, as I could easily have done had the necessity for applying it ever occurred to me? The questions, therefore, naturally presented were: Might it not be possible to examine with my finger the whole interior surface of the bladder; and, if so, from what region could such exploration be most easily and safely accomplished—from the perinæum or from the pubes?"—Pp. 10-11.

Here we find stated at once the *rationale* and the justification of the operation for digital exploration of the bladder.

Histories in detail are given of forty-three cases where it was performed. In twenty of these tumors of the interior of the bladder were actually found present and removed. In most of the remainder marked relief followed the operation. Six admirable colored plates and a number of engravings add to the clearness of the work.

AN AID TO MATERIA MEDICA. ROBERT H. M. DAWBAIN, M.D., New York. J. H. Vail & Co. Cloth, 86 pp.

Contains Drugs, Official Preparations, their strength, dosage, etc. Table of the solubility of chemicals in water and alcohol. Simple methods of metric prescription writing. The author's rule for

teaspoonful doses is this: For a two ounce mixture order 60 c.c. to contain 1 gm of the drug to each grain in the dose.

C. E. W.

ELEMENTS OF PHARMACY, MATERIA MEDICA, AND THERAPEUTICS. By WILLIAM WHITLA, M.D.(Q.U.I.), Physician to the Belfast Royal Hospital; Consulting Physician to the Ulster Hospital for Diseases of Women and Children; Vice-President of the Ulster Medical Society, etc. With Lithographs and Woodcuts. Second Edition. London: Henry Renshaw, 356 Strand. 1884.

This is a book of 602 small and rather closely printed pages, in the less expensive English style of publication.

The first 100 pages are devoted to Pharmacy; the next 124 to Materia Medica; then 189 to Therapeutics; 59 to New Remedies; and the remainder to the Administration of Remedies, Prescription Writing, Chemical Reactions, Weights and Measures, and a copious Index. The subjects in each division of the work are treated of in alphabetical order.

Of course, when so much is included in so small a compass, everything must be treated in the briefest manner; yet for quick and brief references this work will be found both convenient and useful. From Jansen, McClurg & Co., Chicago.

NECROLOGY.

SOUTHWORTH, CHARLES T., M.D., of Monroe, Michigan, was born in Chenango County, New York, May 19, 1827, and died August 12, 1884, in the 57th year of his age.

In 1835, his father, who was also a physician, removed to Monroe, Mich., where he practiced medicine until his death, which occurred in 1843. The son was then placed in a select school where he prepared for college. He afterward went through the Freshman class at Oberlin, Ohio, and the Sophomore and Junior years at the University of Michigan. His father's death called him home during his Junior year, and he did not return to the University. He commenced the study of medicine immediately, and entered the College of Physicians and Surgeons in New York City. In the spring of 1846 he sailed for Europe. He took a six months' course of lectures under Ricord and Trousseau, in Paris; and then went to Madrid and studied under Saavedra. Here he graduated in 1849. After this thorough preparation, he practiced in Havanna, Cuba, until 1851. He then removed to Matamoras, Mexico, remaining there through the cholera epidemic of the summer of 1851. He went from Matamoras to Vera Cruz, where he was commissioned Division Surgeon of Cavalry. He marched with the army to the city of Mexico, and remained there until the abdication of Santa Anna, in August, 1855. During the next three years he was engaged in private practice in the City of Mexico; but, owing to the entire overthrow of the Church party—the result of the revolution—he left the country in 1858. He returned to Monroe in the same

year, where he remained the rest of his days, leaving only for a term of service in the Civil War. In February, 1863, he was commissioned Surgeon of the 18th Michigan Volunteer Infantry. He was soon after ordered to establish and take charge of the Post Hospital at Nashville, Tenn., and remained in the service until mustered out in June, 1864.

Dr. Southworth was a member of the Masonic Fraternity, a Royal Arch Mason, and High Priest of River Raisin Chapter No. 22. He was a permanent member of the Michigan State Medical Association, also of the American Medical Association; and was President of the Southern Michigan Medical Society.

He was always opposed to the State's control over medical education. In his political views he was a Democrat, but never took an active part. Dr. Southworth's study under the ablest European physicians, his wide practice, and extensive experience, enabled him to enjoy in his later years a lucrative business. His death was the result of an injury which happened on the 26th day of February last; never having recovered, the disease was pronounced to be "valvular disease of the heart, arising from injury."

Dr. Southworth leaves a family of a wife and five children, two sons and three daughters. The older son is now in his Junior year in the Michigan College of Medicine, Detroit, Michigan.

MISCELLANEOUS.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY DURING THE WEEK ENDING NOVEMBER 8, 1884.

Craig, Thomas C., Passed Assistant Surgeon, to the "Alliance," for temporary duty, Nov. 1, 1884.

Swan, Robert, Passed Assistant Surgeon, detached from the Naval Hospital, Norfolk, Va., and placed on sick leave, November 3, 1884.

Wieber, F. W. F., Appointed Assistant Surgeon, Nov. 3, 1884.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, UNITED STATES ARMY, FROM NOVEMBER 1, 1884, TO NOVEMBER 7, 1884.

Spencer, W. C., Major and Surgeon, ordered to Fort Trumbull, Conn., for duty as Post Surgeon, relieving Assistant Surgeon Wm. J. Wilson, U. S. A., who will report at Department Headquarters and await further orders. (S. O. 227, Department of the East, Nov. 5, 1884.)

Town, F. L., Major and Surgeon, assigned to temporary duty as Post Surgeon, Ft. Clark, Texas. (S. O. 145, Department of Texas, Oct. 27, 1884.)

Bentley, Edwin, Major and Surgeon, to be relieved from duty at Ft. Clark, Texas. (S. O. 145, Department of Texas, October 27, 1884.)

Corhisier, W. H., Captain and Assistant Surgeon, ordered to Ft. Grant, A. T., for duty as Post Surgeon. (S. O. 102, Department of Arizona, Oct. 30, 1884.)

Hopkins, Wm. E., First Lieutenant and Assistant Surgeon, ordered to Ft. Lowell, A. T., for duty as Post Surgeon. (S. O. 102, Department of Arizona, Oct. 30, 1884.)

Egan, Peter R., First Lieutenant and Assistant Surgeon, relieved from duty at Ft. Lowell, A. T., and ordered to Ft. Bowie, A. T., for duty as Post Surgeon. (S. O. 102, Department of Arizona, Oct. 30, 1884.)

PRACTICAL REMARKS ON THE TREATMENT OF THE MORE GRAVE AND MALIGNANT FORMS OF SCARLATINA.

BY BEDFORD BROWN, M.D., ALEXANDRIA, VIRGINIA.

Read in the Section of Diseases of Children of American Medical Association, May, 1884.

Whether the type of malignancy in scarlatina is imparted by the intensity of the infectious poison, by excess in quantity, or because of the extreme susceptibility of the system to its peculiar action, are questions which remain yet unsolved. But that there are certain prominent and important morbid elements or conditions entering into combination, in more or less degree, which give character to the type in all cases having a malignant tendency, there can be no doubt.

Preliminary to the consideration of the treatment of this form of disease, it is proper and necessary that these various morbid factors which unite for the development of the type of malignancy should be carefully investigated and analysed, with a view of ascertaining and comprehending their full meaning and bearing on the progress of the case, and as a guide for treatment.

During a personal observation of scarlatina extending over a period of more than thirty years, no case presenting malignant tendencies or characteristics has ever presented itself without the following peculiar features, viz.: a very high grade of corporeal temperature; excessive frequency of cardiac action, as manifested by the pulse rate; great debility of the heart, as indicated by the impulse of the organ and the feebleness of the pulse; excessive vital prostration of the muscular and nervous systems; suspension in great part of cutaneous action; a notably defective action of the renal organs, as indicated by the very scanty and albuminous urine, showing from a very early stage of these cases the presence of either functional or organic disease of these important depurative organs.

Frequent, and often intense, vomiting, manifesting the very serious impression made by the infectious poison on the great ganglionic system of nerves, and

the functions of organic life. We also observe in these cases usually a partial or entire suspension of the functions of digestion or assimilation.

Another, and one of the most characteristic, of these morbid elements is the lymph-adenitis, which forms so often a conspicuous part in the history of the severe forms of scarlatina.

While these simple facts do not explain the peculiar nature of the infection, whether it is germinal or chemical in character, nor its action in disturbing the vital operations of the economy, they are nevertheless facts always associated with the development and progress of all severe or malignant cases, and claim our attention individually as objects of treatment in the most earnest degree.

From time to time various methods or systems of treatment for this affection have been introduced, and practiced by our profession. Very recently the antiseptic method has been proposed to be used exclusively as an all-sufficient antidote to the action of scarlatinous infection.

Others regard the pure and simple antipyretic plan in which cold constitutes the chief element as superior to all others. The sedative plan, composed of those agents as digitalis, aconite, and veratrum, which reduce cardiac action, and slow the pulse, has many and able advocates. Then there is the eliminative method which I think has not been duly appreciated; by which the portals of the skin and kidneys are opened and these organs are at once made the sewers of the system for the removal of the pent-up poisonous material which has accumulated from the toxic state of the blood and disintegration of tissue, and which is dangerous to life.

Can the Type of Grave or Malignant Cases of Scarlatina be Modified by the Action of Therapeutic Agents?—In my treatment of the severe forms of this disease for the last twelve years, I have acted upon the principle that if the features peculiar to this disease could be modified by treatment, the type of disease could also be modified to a certain extent and the case be converted from a dangerous to a benign form.

A very considerable experience during this period has only tended to confirm this opinion.

I am convinced that many cases of so-called malignant scarlet fever are lost because the disease is regarded as incurable.

Treatment of the more Violent Forms of Scarlatinous Lymph-adenitis.—One of the most frequent forms of the more severe and malignant types of scarlatina met with, is that which is accompanied with very

violent and extensive adenitis of the cervical glands and cellulitis. In these cases the fauces and tonsils are usually extensively involved. The infiltration and swelling of the neighboring cellular structures are usually so great as to impede the function of deglutition, and the muscular movements of the neck.

The temperature always rises to 106° or 107° . The pulse is characterized by great feebleness and frequency, often reaching the rate of two hundred per minute.

The functions of digestion and assimilation are for the time being partially paralyzed. All the indications point to the fact that the blood-making powers are seriously impaired, and the vital condition of the blood is greatly deteriorated.

These cases are exceedingly alarming in character, and if the morbid processes are permitted to proceed unmodified, usually terminate fatally. Can anything be done to modify the type of this class of cases, and avert the tendency to death?

If we reflect for a moment on the two important facts that an over-excited heart is pumping poisoned blood into the inflamed and enormously infiltrated structures of the throat and neck, at the rate of from 160 to 200 pulsations per minute, thereby constantly aggravating the local lesions, while the organ itself is being rapidly exhausted, and that the high temperature indicates a degree of combustion in the vital organism which will inevitably destroy life if not arrested, we are enabled to appreciate the necessity of reducing the action of the heart and the temperature to degrees safe to life. In accomplishing this object two of the leading factors, high temperature and a frequent pulse, in the process of malignancy, are removed, and if the vital condition of the blood can subsequently be maintained at a standard compatible with life, the chances for recovery will be greatly improved. In my experience, to temporize in these cases is to endanger the life of the patient. Success can only result from prompt and energetic treatment. The high temperature and frequent pulse must be reduced speedily to a point near the normal standard. I have seen the accomplishment of this object in repeated instances convert cases with decided malignant features into the benign type. There are two safe and efficient means always at hand to control high temperature. One is the warm bath, either by the immersion of the body in water at the temperature of 80° , or the wet pack at the same degree, repeated every three or four hours until copious perspiration follows:

The patient is permitted to repose in the wet sheet, enveloped in blankets, the entire body being for hours subjected to free perspiration, and of course undergoing the combined antipyretic and eliminative processes. In connection with those measures the sedative treatment is also practiced. For this purpose I have found the following formula well adapted.

R Infus. digitalis. $\text{f}\overline{\text{3}}\text{ij}$.
 Tinct. aconit. Rad. $\text{gtt}\overline{\text{xvi}}$.
 Spts ammon. arom. $\text{f}\overline{\text{3}}\text{ij}$.
 Spts. nit. eth. $\text{f}\overline{\text{3}}\text{i}$.
m S. A teaspoonful in water every 2
 hours to a child of 5 years.

This method of treatment in my experience rarely fails to induce a marked change for the better in the temperature and pulse.

In this manner we accomplish two leading objects simultaneously. My rule has been, in those cases attended with excessive inflammation and swelling of the structures of the throat and neck, a very high grade of temperature, and frequent pulse, to reduce the pulse rate and temperature by the combined agency of digitalis and aconite, as rapidly and steadily as is consistent with safety, down to a standard perfectly compatible with life. This peculiar combination I regard as particularly effective in this class of cases, and whatever dangerous or ill effect the one may exert is counteracted by the other.

In this way many cases of the severe form of what is termed the anginose variety with decided malignant tendencies may be robbed in great measure of malignancy of type, and converted into more simple and manageable forms. With a slow, strong pulse, and a moderately low temperature, the chances for life become at once greatly improved. The combined influence of the sedative and eliminative treatment over the extensive and dangerous swelling of the structures of the throat, usually diminishes the effusion and inflammation permanently, and in proportion to the abatement of fever. Long and continued experience in the use of eliminative measures through the skin and kidneys, principally the former, only tends to increase my high estimation of the great value of this means of treatment in all the more severe forms of scarlatina.

In all grave forms of the affection the skin is particularly dry, and devoid of perspiration. My custom has been, in all of this class of cases, to maintain a free and continuous action of the skin by means of the tepid bath and the wet pack, throughout the course of the attack.

For the purpose of illustrating what may be accomplished in the conversion of a very grave and malignant type of this disease into a very simple and benign form, I will cite the following case: A little boy of six years, in very robust health, in 24 hours after the first indications of scarlatina, became alarmingly ill with malignant symptoms. The eruption was imperfect in development; the pulse so frequent that it could not be estimated. There was great stupor. The temperature ranged at about 106° ; the general prostration was correspondingly great. The child was first given a general bath at 80° , then enveloped in a wet sheet at the same temperature, and over this a dry blanket; then put to bed and permitted to luxuriate in a free and delightful perspiration for many hours. When the temperature increased, the same process was resumed. Then he was given a drachm of infusion of digitalis, one drop of the tincture of aconite root and ten drops of sweet spirits of nitre, every two hours, until the pulse and temperature were reduced to near the normal standard. Then the consciousness and vital powers of the little patient returned, and the type of the case in another 24 hours was changed from a very dangerous to a very simple one.

Treatment of the True Adynamic Type of Scar-

latina.—We occasionally meet with a class of cases presenting from the incipency symptoms of adynamia. The eruption is always of a dark or mahogany color, and not abundant; the pulse is exceedingly frequent and feeble. The urine is dark, very scanty, and often albuminous. There is excessive stupor and prostration of the vital powers, the tongue a dark red and very dry. We all appreciate the gravity of these cases. The treatment which I have found most efficient in this type of disease, consists of the wet pack saturated in water at 80°, with a considerable proportion of alcohol combined, used sufficiently often to maintain a moderate perspiration. The following formula I have found the most useful of all of which I have made trial:

R Sodæ sulph.-carbolat..... $\bar{5}$ iss.
 Sodæ hyposulphite..... $\bar{5}$ i.
 Aqua..... $\bar{5}$ iss.
 Infus. digitalis..... $\bar{5}$ iss.
 Tinct. nux vom.....xii gtt.

Of this 2 teaspoonfuls are to be given to a child of 5 years every two hours. Alternately with this a teaspoonful of brandy and elix. of calisaya are to be administered.

In these cases the temperature rarely reaches a very high grade. The temperature and circulation are both unequally distributed. The extremities are usually cool and livid, the body hot. The action of the heart is excessively feeble and frequent, often reaching a rate of 200 per minute in very young children. The poisoned condition of the blood renders the dangers of thrombosis of the heart, lungs and brain imminent. This condition is particularly encouraged because of the inability of the heart to maintain an equable circulation. Hence in these cases we need especially a remedy which will both slow and strengthen the action of the organ.

The Treatment of the Malignant Type Due to Early Renal Complications.—In a certain proportion of cases the malignancy of type seems to be due to early renal complications. We observe in these cases the early development of malignant features very similar to those manifested in cases of serious nephritis from more simple causes. Thus there is always tendency to coma. The urine is very scanty, high colored, acid in reaction, and albuminous. The temperature is high, and the pulse rate very frequent. There may be but moderate adenitis, yet the case presents all the indications of gravity and danger.

In all cases of importance I believe it to be our duty to examine the state of the urine throughout the course daily.

Doubtless many cases have assumed the malignant type and ended fatally, solely because of the development of nephritis. In the treatment of these cases all of our appliances, consisting of the warm bath, the wet pack, and if necessary, the hot air bath, for the purpose of inducing copious elimination through the skin should be brought to bear on the patient frequently.

Prolonged observation of scarlatina convinces me that our attention is directed usually to renal complication at too late a period of the case, and that treat-

ment is often delayed too long. In cases of nephritic complication with high grade of fever and frequent pulse, I have found a combination of alkaline diuretics with sedatives of infinite service. The alkaline diuretics can not only be given freely in these cases without harm, but with benefit. In my experience it is best to maintain the urine in a perfectly neutral and bland state, so that its acids cannot act as irritants and thereby aggravate the existing inflammation. I have found the following formula a valuable one under these circumstances:

R Liq. potass. citratis..... \bar{f} 3iss.
 Potass. bicarb..... $\bar{5}$ ij.
 Spts. nit. ether..... $\bar{5}$ ij.
 Tinct. aconit. Rad.....xiijgtt.
 Infus. digitalis..... \bar{f} 3i.
m A dessertspoonful every 2 or 3
 hours to a child of 5 years.

This combination of therapeutic agents usually exerts a most favorable influence over the engorged and inflamed kidneys. Their functions are always improved and generally restored. At the same time the action of the heart is slowed and strengthened; the abnormal temperature is reduced to a point of safety and the nervous centers relieved.

In connection with this method the patient is fed liberally on skimmed milk.

I do not remember ever to have seen a case of organic renal disease or dropsy following scarlatina in an exclusively nursing infant. Whether this is due to the exclusive milk diet, to the exclusion of animal food, or to the better care or protection from cold is not known.

The Treatment of Protracted Adenitis, followed by Abscesses and Symptoms of Pyæmia.—In the severe anginose form of the disease, protracted adenitis, followed by a long line of abscesses in different portions of the system and symptoms of pyæmia, occasionally occurs. The fever is usually hectic in character. The temperature rises and remits at certain periods of the day, followed occasionally, but not always, by exhausting perspirations. The tongue is usually red and dry. There is complete anorexia; symptoms of adynamia are always present. The process of emaciation is progressive. These morbid processes may continue in operation for many weeks, and either end in death or restoration.

I have found in this particular affection no combination of remedies so effective as the tinct. of the chloride of iron, arsenic and digitalis. I usually give to a child of five years, five drops of the iron, one-third of a drop of Fowler's solution of arsenic and three drops of the tinct. of digitalis every four hours. This method of therapeutics should be maintained until the pyæmic tendency has been arrested. In this place I regard the arsenic as an important ingredient.

When the tendency to exhausting perspiration is decided, I usually combine the tinct. of belladonna.

Treatment of the Convulsions of Malignant Scarlatina.—A history of the treatment of scarlatina would be very incomplete without allusion to the subject of convulsions. Usually in these cases renal complica-

tions are present, and must receive a share of our treatment. The pulse in these cases is usually very frequent and the temperature high. The entire voluntary, reflex, and ganglionic nervous centres are all profoundly affected by the infectious poison. To relieve the circulation of uræmic poisoning, which is generally present, and to prevent that irreparable damage to the brain which results from the capillary thrombosis and extravasation of blood that may arise from the violent and unequal action of the heart, our remedial agents should be addressed to the eliminative organs, the reflex nervous system, and the general circulation. Elimination through the skin and kidneys, as heretofore advised, should be assiduously practised. Chloral hydrate, to control the over-excited reflex centres, and veratrum viride combined, have been more efficient in my experience as a means of reducing cardiac action and regulating the unbalanced circulation than any other agents. Five grains of the chloral and one or two drops of the tinct. veratrum act well after the functions of the skin have been restored. These remedies should be repeated every two hours to a child of five or six years until the object has been attained. In dangerous cases of this kind I regard the use of the veratrum as an important addition to the treatment. In my own hands, when combined with chloral, it has been more prompt, energetic, and decided in repressing the convulsive tendency than any other therapeutic agent.

Treatment of Scarlatinous Pharyngitis.—After a trial of the various local remedies devised by myself and recommended by others, I have reached the conclusion that a combination of astringent and antiseptic agents, composed of bromo-chloralum $\mathfrak{z}\text{i}$, the antiseptic vegetable compound known as listerine $\mathfrak{z}\text{ij}$, pulverized alum $\mathfrak{z}\text{ij}$, carbolic acid xgtt , diluted with rose water $\mathfrak{z}\text{iv}$, either used by means of gargling, the atomizer, or brush to the inflamed surface, constitutes the most valuable of all the local applications. I feel sure that the absorption of the antiseptic properties through the mucous surface is in such quantities as to exert decided effect. Two or three drops of carbolic acid, when applied to the cervix of the uterus, will be tasted by the patient almost instantaneously.

I have faith, also, in the value of antiseptic agents applied to the cutaneous surface. When carbolic acid, salicylic acid and ointment of rose water in combination are applied to the skin, they act not only as an emollient, allaying inflammation and irritation, but the antiseptic agents being spread over a vast extent of surface, are largely absorbed, and exert their peculiar influence in correcting the septic processes going on within the system, thus saving the digestive organs the ill effects of their influence.

In the selection of nourishment we should be influenced both by the condition of the digestive organs and the renal functions. In cases of seriously impaired digestion, irritable stomach, scanty, albuminous and acid urine, the best method of administering nourishment, in my experience, is in the form of skimmed milk, containing a small amount of bicarbonate of soda in solution, and combined with

one-third lithia water. This may be continued so long as these symptoms exist.

In all serious cases preference is given to the alkaline lithiated milk as a constant diet. The milk is evidently better digested and assimilated than any other form of nourishment. It is in this form exceedingly bland and unirritating to the renal passages, and affords relief to the engorged and inflamed kidneys. It is given abundantly, and almost exclusively. This form of diet not only serves a good purpose during the acute stages of the disease, but acts well as a prevention of renal sequelæ.

THE RELATION OF BACTERIA TO INFECTIOUS DISEASES.

BY HENRY O. MARCY, A.M. M.D., BOSTON, MASS.

Read before the American Academy of Medicine, Baltimore, Oct. 28, 1884.

No subject in medicine either in relation to its theory or practice holds at present in any considerable degree an interest equal to that of the rôle of micro-organisms to disease. Although in a strict sense not new, it is only within a very recent period that systematic study and scientific research have invested the theme with an interest by any means general, or elevated it from the domain of speculative philosophy and pseudo-science. Recent as have been the investigations, it is marvellous to find the flood of literature already contributed.

Notwithstanding the interest and importance of the subject, this contribution might not have been added to the list had I not listened to a series of six semi-popular lectures delivered in Boston within the year, in which course the entire subject was carefully reviewed and in a most labored argument it was deduced that the fundamental basis is wanting upon which the entire system of the germ-theory of disease is founded; that there is no real proof that fermentation even, is caused by the development of a low order of vegetable organisms. This sweeping assertion was based upon the statement that the various classes of micro-organisms in any of the series of experiments had never been separated from the "ambient, organic, living matter" which must be considered to have a low degree of inherent vitality, and that, as a consequence, it can not be determined what, in the subsequent changes, is due to the germ development and what the rôle of the ambient living matter may be. This, in the mind of the objector, would pertain as distinctly and definitely to the so-called pure cultures, or many removes from the primary infection, where, it is obvious, that only an infinitesimal quantity of the original material could remain, since the ambient living matter might have been reproduced indefinitely as well as the mingled germs. With an emphatic pointing of the argument it was declared "that not until it had been demonstrated, what would ensue, after a well-washed micrococcus or bacillus had been isolated upon the point of

a needle and then introduced into a sterilized, nutrient solution would the real conditions of the problem be fulfilled."

Anything may be doubted. There are many who would not accept the demonstration of any historic fact; and even mathematical formulation, or axiomatic truth would by some be questioned. However, it is well to have even the old, established creeds and codes occasionally reexamined and reviewed by the keen criticisms of opponents, for "Science is only pure and simple truth," and never suffers by test.

Negative proof may assume a value not less than positive demonstration, and yet, when we come to accept the gauntlet thus thrown down, we shall find the defenders of the germ-theory are not reduced even to this exigency. Let us separate the problem as formulated by Dr. Longstreth into its component parts, the ambient, living matter and the germ. We grant that the former has, under certain conditions, an inherent vital power, which is indeed no new discovery, but has been accepted by many of the best investigators. It has been known under different names, but, perhaps, most widely under the excellent definition given by Dr. Lionel Beale as bioplasm. In the differentiation of the organic material which serves as food, there must evidently be somewhere along the series a point where the protoplasmic masses are imbued with a certain vital power. Let us admit that this hypothetical point be accepted as bioplastic, that the material in a considerable share is particulate, and that it has its highest expression of effect when in the greatest degree "ambient." I think we may safely assume that in the blood of a healthy animal we should find this ambient living matter in its highest potency. In order to determine the bioplastic powers of the liquid, ambient, or protoplasmic matter, I decided upon a series of careful laboratory studies, in the execution of which I am greatly indebted to my assistant, Dr. Samuel N. Nelson. The blood of healthy animals, sheep and oxen, was taken with careful precaution at the abattoir in flasks, sterilized by heat and immediately protected by carbolized gauze. As soon as the blood clot had separated by standing, sterilized glass bulbs were filled and sealed in the flame, and others charged with sterilized, culture fluids were inoculated in varying proportions, following the method which I have adopted in the study of germicides and micro-organisms. These were kept for different periods of time subject to the same conditions as in the growth and testing of various bacterial organisms. Careful microscopic examinations were made at different data with a Zeiss fourteenth objective, giving an amplification of about a thousand diameters. In only one of more than twenty bulbs did any change take place, and this upon its first opening, the third day, remained sterilized. Albumen from the egg yet warm from the nest, milk aseptically milked and put up at once, and the aqueous humor were also tested. In a series of forty-five bulbs, only two contained bacteria—termo and micrococci, which evidently were accidentally introduced, since one was a sterilized bulb inoculated with serum, and the other was fertilized when opened a second time the seventeenth day, which

was sterile upon the ninth day when first examined. In the rest of the series no changes ensued, and no micro-organisms developed. See table.

RESULTS OF TESTS WITH "AMBIENT ORGANIC MATTER."

SUBSTANCES.	TOTAL.	NO.	DAYS.	RESULTS (F. 3.)
Serum from sheep's blood.	7..	4	6	Some protoplasmic masses as in fresh serum
		1	9	ditto.
		1	11	ditto.
		1	16	ditto.
Bulbs inoculated with sheep's serum.	18..	5	6	Five unchanged, one contained micrococci and bacteria termo active.
		2	9	Unchanged protoplasmic masses.
		1	11	ditto.
		1	16	ditto.
		8	17	ditto. Also one opened at 9th day contain micrococci and bacteria termo active.
Serum from ox's blood.	2	2	6	Same protoplasmic masses this one inoculated after nine days.
				ditto.
Bulbs inoculated with ox's serum.	4	2	6	ditto.
		2	17	ditto.
Aqueous humor sheep's eye.	2	2	6	ditto.
Inoc. aqueous humor sheep's eye.	3	3	6	ditto.
Inoc. milk.	4	3	4	ditto with same.
		1	5	ditto "
Albumen of egg.	2	2	5	ditto.
Inoc. ditto.	3	3	5	ditto.
Total,	45			

It seems from the above experiments a clear deduction that the ambient living matter, upon the germinal qualities of which so much emphasis has been placed, possesses no power of reproduction, and that, at the most, it is an organic nutrient fluid serving the highest purpose for bioplastic uses, but having in itself absolutely no independent, inherent power of growth,

This, indeed, is what has been assumed *a priori* to be true by most investigators and, so far as I know, had never before been questioned. Blood serum has been selected by many of the most distinguished observers as the best possible culture fluid for the growth of micro-organisms, never suspecting that in the fluid itself there could be a source of error.

Numerous experiments familiar to all students of the subject have conclusively shown that when blood has been taken under proper precautions from a healthy animal, it undergoes no decomposition and is absolutely free from all bacterial organisms. The only objection to blood as a culture medium has been found in the presence of the corpuscles, which, after a time, may break up and present a granular debris, thus rendering the recognition of micrococci more difficult.

This is not the occasion to enter upon the character or the classification of micro-organisms. At the present, no one denies their vegetable nature. That they are organic and have an inherent, independent vitality is proven by their distinctive shape elements, spontaneous, independent movement and powers of reproduction. The rôle or relationship of these

minute organisms to disease is a question the importance of which cannot be over-estimated, and, if the relationship of cause and effect in the class of zymotic diseases be demonstrated, medicine will at last have for its foundation a scientific basis.

Although we may accept the formulation that, "Science is pure and simple truth," no question probably ever presented, the solution of which is involved in greater difficulty. It is very doubtful if the time has arrived when generalization may be made or formulation adopted.

In the rapidly accumulating evidence from many independent investigators, however, it is not too much to believe that such a period may belong to the early future. To demonstrate the causal relationship of germs to disease, the micro-organism in question must be isolated, or separated from any other material which could be called in question, be it "liquid ambient matter," organic, or chemical poison having relationship to the disease. This organism thus separated must, upon inoculation into the tissues of a healthy, living animal of the same species, cause a reproduction of the disease under consideration, in other words, the micro-organism must "breed true."

The objection already referred to was that, to carry out the requirements here given, "the germ must be isolated, well washed, and then introduced into a sterilized, culture fluid."

To accomplish a purpose, believed to be equally satisfactory, the process of so-called pure culture has been devised. This is to infect a sterilized bulb or solid culture with a minute quantity of the original virus, and upon development to inoculate from this a second, and so on to the end of a given series. Pasteur was among the first to devise this method, and show the extreme subdivision of the original material thus obtained. I quote an illustration of this from the experiments of Dr. Sternberg: "My culture-tubes contain about a fluidrachm of sterilized bouillon. The amount of infective material introduced into culture No. 1, as seed, was considerably less than a minim; but for convenience I will suppose that one minim is used each time to start a new culture; that is, the original material is diluted 60 times in the first culture, 3,600 times in the second, 216,000 times in the third, and in the eighth culture it will be present in the proportion of 1 part in 1,679,611,600,000,000. Yet a few minims of this eighth culture possesses all the virulence of the first."

Let us grant that a certain quantity of the so-called sepsin, a chemical poison of any conceivable virulence, accompanied the primary infection, and that it was possible for it to be produced by chemical changes set up in the nutrient fluid *pari passu* with the growth of the organism; then we would find that upon subcutaneous injection into an animal it would act promptly and bear an effect in direct relation to the quantity thus used, either killing the animal, or being eliminated and recovery ensue. Contrast the effect of a septic inoculation. Hours after the injection the animal appears in its usual health, and slowly sickens. If death ensues, it is never until sufficient time has elapsed to allow the reproduction and growth of the micro-organisms; and, upon examina-

tion, the tissues and fluids are found to contain, in active development, immense numbers of organisms, in morphological characteristics identical with those of the original infection. These experiments may and have been repeated in long series with unvarying result. In still further evidence that the morbid poison is particulate and dependent upon the micro-organisms present, the experiment of filtration has been repeatedly made where the most virulent of septic, poisonous material was thus treated, and the filtrate injected into a healthy animal with negative results. Klebs first showed that filtration caused anthrax blood to lose its infectious properties, although the filtrate acted as a local poison. Toussaint repeated these experiments with similar results, and Eberth's experience with the filtrate of diphtheritic poison gave at the points of injection only local inflammations, without any marked general symptoms.

In anthrax, where the rôle of the bacilli has been very carefully demonstrated, seemingly beyond the denial of the most captious critic, only recently did I hear it publicly and seriously urged that death was not caused by the bacilli of anthrax, but was mechanical, and, as it were, accidental, since the extraordinary size of the bacilli caused a plugging of the capillary circulation in the lung, and death ensued as by strangulation.

How such puerile objections could for a moment be seriously advocated, or accepted, acknowledging but ignoring the *causa causans* of disease, is beyond comprehension. However, by such queries, we are led to consider, if disease and death are the result of the growth and development of such organisms in the living body, in what way is such result brought about? Is it by occluding the blood-vessels, causing stasis, arrest of circulation, and, as a result, local death of tissue; *i. e.*, mechanical? Does it devitalize the tissues by abstraction of nutriment for its own uses, deoxygenizing the blood? Does it also generate in its growing a morbid virus which is inimical to life; or does it, by its abstraction of certain constituents necessary to its development, cause chemical changes in the construction of highly organized, vital elements, as the yeast plant in its growth in saccharine solutions produces alcohol?

There can be little doubt but that in each of these several ways, sometimes separately, more often combined, does injury result by the development of these minute organisms. Did it not carry us beyond our present limits we should discuss the individualistic resistance to the invasion and growth of micro-organisms within the body of the living animal. This must, at least in a large share, be ascribed to a property in the living organism, a vitality which renders the development of the bacterial growths abortive, or imperfect. Reduce this standard, lower it to a hypothetical given point, and the complex organism becomes an easy prey to the omnipresent, unseen, yet potential forces which are ever in waiting to take it to pieces and refit it for new and perhaps higher uses.

The vital equations in the life processes are among the most complex and difficult of all in the study of the animal economy. They meet us at every turn

when we investigate any of the pathological changes. The reason why, in some animals, micro-organisms cannot be made to grow at all, while in others, seemingly equally healthy, they fructify and speedily cause death, must be sought in the peculiar vital or resisting power of the individual or the species. This has evidently been overlooked or underestimated by many in their deductions upon this subject. The cell changes which follow localized irritation furnish an excellent illustration. Lymphoid, epithelioid cells, or granulation tissue, is proliferated in protection and, in the development series, connective tissue ensues and repair is completed. Arrest the process at its earlier stages and degenerative changes take place, and it is in this way that conditions are produced favorable to germ development. Thus, simple depreciation of vital force may be the first term of a series ending in death, to which, as it were, are added only accidental factors.

There are many questions relating to the subject upon which we are at present and perhaps must ever remain ignorant. How do certain forms of infectious disease grant immunity from subsequent attack? Answers only of a purely speculative character have as yet been suggested. In what way, upon recovery from attack, do the morbid, germinal materials disappear? Here again all positive demonstration is wanting. Sternberg suggests that the disappearance of the bacteria from the circulation may be effected by the superior vitality of the white corpuscles which in their amœboid motions may surround and assimilate the captured bacteria.

What are harmless and what are pathogenic bacteria? May the one develop from the other; are they modified by the media in which they grow, may a micrococcus develop into a bacillus, a bacillus into a spirillum? Do each of the infectious diseases have its *sui generis* germ? These again are questions of intense interest engaging the attention of many scientists at the present, but upon which little can be declared as settled. Reviewing these phases of the subject, beset with so many difficulties, it is encouraging to be able to differentiate somewhat clearly, however, the known from the unknown, and to be certain of the establishment of facts of fundamental value and importance.

In this review of the more recent demonstrations of the germ-theory, we must limit ourselves to a small number of diseases. The study of anthrax is the most instructive because the most complete and demonstrative. Pasteur followed a series of one hundred cultures to find the last as virulent as the first. Koch continued the experiments in septicæmia with mice to over fifty repetitions, not only to demonstrate the breeding true, but also that as a rule one-tenth of a drop was an ample quantity to induce a fatal result. Contrary to that found in anthrax, the bacilli here are extremely small.

The rôle of the bacillus tuberculosis has been so satisfactorily established by Koch that a large number of our best observers accept the conclusion of cause and effect as demonstrated. No one subdivision of the question probably holds an interest and importance equal to this at present. Dr. Ferguson publishes in the *Medical Record*, July, 1883, a compila-

tion, as a statistical table, in which he states that in 2,509 cases reported, 2,417 cases contained bacilli. The most noteworthy fact in reference to the cultivation experiments of the bacillus tuberculosis is their slow growth. Koch cultivated them at a temperature of one hundred and four. It was not until the tenth day that active development supervened. Five successive cultures occupied fifty-four days. With this culture four guinea-pigs were inoculated, and upon the thirty-fifth day all were found undergoing extensive tuberculosis. A series of injections into the eye gave somewhat similar results. One inoculated with pure serum, "liquid ambient matter," remained healthy. Three inoculated from a series of cultures which had been carried on for one hundred and thirty-two days gave reproduction of typical tuberculosis. Similar experiments with greater or less care have been repeated in various countries giving in large share confirmatory evidence. In the discussion of the subject, unfortunately the partisans of their various views have often lost a wise judicial discrimination, and at such hands the advancement of science suffers.

Dr. Formad, of Philadelphia, has imparted much knowledge in his publications upon the subject, but he has failed in his attempts to reproduce from his so-called tubercle of irritation true tuberculosis.

Evidently the first point to define is, what is tubercle? If only consisting of lymphoid, embryonal, or epithelial cell-growth, more commonly known to us as a low order in vitality of granulation tissue, then we must admit with him that any irritant may produce tubercle, and the more finely divided and widely disseminated the irritant, the more finely miliary and widely diffused the resultant tubercle.

If it can be shown that such tuberculous material, devoid of germ infection, will reproduce upon inoculation into healthy animals, resulting in disseminated tuberculosis, and so on in a given series, then the objections and negative evidence will stand upon the same basis as the positive, and we will be ready to admit the exclusive production of tubercle as not due to bacillary infection. This we had expected would be shown by Dr. Formad, since in his second report which he has published upon the subject he states: "In my own experiments, I found that tubercle produced by inoculation with innocuous material under antiseptic precautions was likewise capable of producing tubercle when inoculated into other animals, having thus the same action as the innocuous material primarily used." Dr. Formad believes the rôle of the bacillus in tuberculosis is simply that of an irritant.

Malassez and Vignal have recently published a most interesting series of studies, experiments, and observations upon tuberculosis produced by micrococci in zoöglea masses in which no bacilli were found. The following are in brief their conclusions:

1. There exist tuberculous lesions presenting no bacilli, and which inoculated give place to tuberculosis equally without bacilli, and yet similar in appearance to bacillary tuberculosis. Similar results were obtained with their culture products. If the presence of the bacillus suffices, according to Koch, to characterize the tuberculous nature of a lesion, the

reciprocal is not true, namely: their absence does not suffice to deny the tuberculous nature of a lesion.

2. In tuberculosis from inoculation without bacilli there are tubercles which are characterized by the presence of zoöglea masses of micrococci which play, in the tissues which they infect, the rôle of foreign irritating bodies and determine in them thus the so-called tuberculous lesions.

3. There are also other tubercles of inoculation, not bacillary, in which we distinguish no well-defined zoöglea masses. They seem due to the presence of micrococci of the same kind as those of the zoöglea masses, but which, instead of being grouped in masses, are strewn through the tissue of granulation and it may be just this dissemination, which, in absence of the special coloring reagent, prevents distinguishing them sufficiently. That which proves this is, that they may, by inoculation, produce anew zoöglei tubercles. It may be possible that these are some in which that form of parasite may have indeed disappeared.

4. These same tubercles, not bacillary, with or without distinct zoöglea, may produce after a greater or less number of generations of inoculations, bacillary tubercles, as if the zoöglea, the diffused micrococci, and the bacilli were simply different forms, or different stages of development of one and the same micro-organism. Yet this transformation from micrococci into bacilli, not having yet been directly established, we have no right to affirm that bacillary tubercle and zoöglea tubercle are of the same nature, although it may be perhaps the most probable hypothesis.

5. Although our zoöglea masses and our micrococci do not closely resemble the described parasites previously mentioned by Klebs, Aufrecht and Toussaint, they may, however, be in some way related to them; but the facts observed do not permit us to determine the question.

There is much difference of opinion upon the communicability of tuberculosis.

Dr. Formad denies that any proof has been produced showing communicability.

Dr. Dreshfield gives the following instance: "In a small town in Germany where in the period of nine years only five children had died of tubercular meningitis, there happened in the course of nine months eleven deaths from that disease in infants under six months, all these children had been assisted into the world by a midwife who was known to be phthisical and who died of phthisis and who was in the habit when attending a confinement to blow into the mouth of the child with the view of expanding the lungs. No mention is made of the number of confinements attended by this woman."

Dr. MacKenzie in the February number, 1884, of the Edinburgh *Medical Journal* details the result of examinations made in seventy cases of pulmonary and laryngeal disease. A little over one-half were well-marked cases of tuberculous disease and in all these the bacilli were found in the sputum and most abundant in the acute cases. The muco-pus taken from the larynx in laryngeal phthisis contained bacilli in abundance. In thirty-three cases bacilli were

absent, of which twenty-two were undoubtedly non-tuberculous, and the remainder, although of doubtful character at the time of examination, were proven by their subsequent examination not to be of tuberculous origin.

Bacilli have been found in glanders, intermittent fever, leprosy, malignant œdema, syphilis, and cholera with more or less evidence that they are the producing cause. Dr. Salisbury in our own country was probably the first to declare that the cause of intermittent fever was a minute vegetable growth. His experiments were numerous and made with a care worthy of commendation, when we consider that he was a pioneer in the field. That they were inferential instead of demonstrative is true, but he collated a series of facts and array of evidence which renders his observations valuable and well worthy of honorable mention.

Klebs and Tommosi-Crudeli announced the discovery of the bacillus malaria in 1879. Their experiments were made in the vicinity of Rome and have been repeated with confirmatory results by a number of Italian and German observers.

Dr. Sternberg¹ in New Orleans, in 1880, instituted a series of experimental studies with only negative results. He gives a critical review of the subject at some length and arrives at the conclusion that demonstrative evidence of the *sui generis* micro-organism is yet wanting. He found in the swamp mud near New Orleans and in the gutters of that city bacilli which closely resembled the described organisms. While the proof is wanting that these actually cause intermittent fever, he closes the discussion as follows: "On the other hand there are many circumstances in favor of the hypothesis that the etiology of these fevers is connected, directly or indirectly, with the presence of these organisms or these germs in the air and water of malarial localities."

There can be no doubt of the importance of a better knowledge of soil pollution and in this connection I would call attention to the admirable original work done by Profs. Pumpelly and Smythe, incorporated in their report to the National Board of Health. I am informed that a large amount of original, experimental research by the same authors still awaits publication, because the appropriation therefor was withdrawn.

Last autumn, during the construction of a large sewer in Brookline, to convey the waters of Muddy Brook, used for a long time as an open sewer, the bottom of the excavation was eighteen feet below the crossing roadway. The cut was through a stiff clay marl. In a specimen of this material taken from the very bottom, were found bacilli perhaps a trifle longer, but otherwise not unlike in their morphological characteristics to the bacillus tuberculosis. They were easily reproduced in sterilized bulbs, but no inoculation experiments were attempted. Last winter I examined a specimen of the clay taken from the bottom of a sewer excavation in Beacon St., Boston, in which I found abundance of active micrococci. The cut had extended through the filling into the

¹Bacteria. Page 317.

solid clay substrata and was probably more than twenty feet below the surface.

Dr. Andrew Smart, of Edinburgh, published a description of micro-organisms, with drawings, found in the disease called Rinderpest, in 1865. This is claimed to be the first demonstration of bacteria in living tissues.

In glanders several independent observers (Struck, Löffler, Israel, and Bouchardt) have found a bacillus and cultivated it. When inoculated into the nasal cavity of animals (horse and rabbit), it has produced typical glanders. Hansen, of Norway, has made a most interesting series of studies upon leprosy. In the tubercles or nodules he finds a bacillus which he describes and figures. It is in appearance not unlike the bacillus tuberculosis, and Neisser has confirmed Hansen's demonstrations. The bacilli were successfully cultivated, but the inoculation experiments have given only negative results.

A simple review of the work done in the study of the relation of micro-organisms to typhoid fever would in itself make an interesting paper. When we remember the intestinal canal in health is the home of an infinite number of actively growing bacilli, we can at once appreciate one of the difficulties which meets the observer at the very outset. These, undoubtedly, infect the ulcers and necrosed tissues; but by a number of observers, notably Eberth,¹ bacilli have been found in the mucous membrane, lymphatic glands, and spleen. Koch is of the opinion that the bacillus of Eberth is the only one which holds to the disease a specific relation. It is a short, thick rod, and stains less deeply than the bacilli of putrefaction. The member of the bacillary family which seems to play a specialistic part in the causation of disease, latest discovered, has been reported by Dr. De Lacerda, of South America, as the bacillus of beri-beri. His studies were carried on after the method of Pasteur, in the physiological laboratory of the National Museum at Rio Janeiro. Beri-beri is an obscure disease, introduced many years ago into Brazil from India, and in certain provinces is very fatal. Bacilli were found in the blood, but especially in the muscles and spinal medulla. These were isolated by cultures and inoculation experiments produced a reproduction of the disease in animals. From these again cultures were made and the series reproduced. It is believed the origin of the disease is found in certain conditions incident at times to the rice, and in the districts most subject to the disease rice is the principal article of food. Micro-organisms not unlike those of beri-beri were found on the rice, were cultivated, and injections of the culture were made, using guinea-pigs; death occurred from thirteen to twenty days with paralysis, and bacilli were found in the spinal cord and muscles. The demonstration seems complete, but farther investigations are promised.

Dr. Sternberg's admirable report of the Havana Yellow Fever Commission must be briefly referred to. His studies of the blood were certainly made with the utmost care, and his photo-micrographs are

of the greatest perfection and beauty. From the present better knowledge of the rôle of micro-organisms in disease, it is questionable if more satisfactory results might not have been obtained, if the lymphatic and glandular systems had been equally carefully studied. Although he demonstrated no micro-organism which could be considered as causal, there are a number of observers who claim to have found it. Dr. Freise, of Brazil, describes an organism which he thinks may remain indefinitely in the soil, and which he finds rapidly reproduced with fatal results in rabbits and guinea-pigs. His observations would, however, seem to require confirmation. The whole subject demands a most complete and painstaking examination.

Cholera holds the first place in popular interest at the present time, owing to its ravages in Europe, and the widespread fears that it may yet become far more general, and extend to America.

The medical profession have followed with an intense interest the investigations of the cholera commissioners in Egypt and India during the last year. Their reports must be considered by all as of great importance, and are contributions of especial scientific value. Few questions can be more complex, or investigated amid such an array of difficulties. The micro-organisms which in health infest the digestive tract are various, and in numbers utterly incomprehensible. Their histories and the modifications which they undergo, subject to a great variety of diseases, are but little known. Much work by reliable observers is requisite as a preliminary to the satisfactory study of an epidemic of cholera. I would urge that the attention of all practitioners possessing the requisite knowledge, should be given to a careful study of such conditions, and thereby contribute to the solution of many questions yet unsolved.

Another difficulty, which does not pertain to the study of many pathogenic germs, is the well-established fact that cholera does not infect the lower animals. Hence the very important evidence deduced from inoculation experiments with the organisms or their cultivations is here wanting. In the sixth cholera report written by Dr. Koch, it is stated that the bacilli which, in their earlier reports, the Commission were unable to determine as strictly limited to cholera, were now accepted by them as holding a specific relationship. The distinguishing characteristics given to the organisms are, briefly: "They are not quite straight, as are the other forms of bacilli, but are slightly curved, comma-like; this bending may be even so marked as to be almost semicircular. From these curved stems, S-shaped figures, more or less elongated, slightly undulating, linear forms may be developed in pure cultivations, of which the first two segments and the last correspond to the form of the bacilli as found in cholera, and which, continually increasing in number, remain attached to one another." Thus they closely resemble a spirillum, and may ultimately be classed with it. The voluntary movements were very active. These bacilli were found in all the intestinal discharges, and in the contents of the intestinal canal at post-mortem examinations, but not in any other

¹ "Der Typhus-Bacillus und die intestinale Infection."

disease, and only in one instance in the various specimens of dirty water examined.

Dr. Koch, in discussing the relationship of these growths, states that the development of the supposed specific bacteria can only be favored by the cholera process, or that the bacillus is the cause of the disease, and that the disease is only induced when it has found its way into the intestine of man. If the first supposition is allowed, these bacilli are always present in health, which is stated as not the fact. Therefore he concludes that the growth of the bacteria cannot be due to the cholera process, and there is nothing left but the inference that it is itself the cause of the disease. Many other circumstances are emphasized as pointing to the same conclusion. They are limited to the organ which is the seat of the disease. They invade its tissues, which become markedly metamorphosed. In the earlier dejections of a cholera patient, so long as they are still feculent, the bacilli are few, but the subsequent watery, nearly odorless, characteristic dejections contain the bacilli in immense numbers, and coincidentally all other bacteria disappear almost completely, so that in this stage of the disease an almost pure cultivation of the bacilli is obtained; conversely, the comma-like bacilli decrease and disappear completely during convalescence. This general relationship holds good, also, as observed from post-mortem examinations. There can be no doubt but the study of the present epidemic will contribute much to our knowledge.

The great majority of observers in India and elsewhere give it as their unqualified opinion that cholera is infectious, and may be transmitted not only from individual to individual, but in a variety of ways to great distances.

From this belief has arisen the very generally adopted system of quarantine. It is greatly to be deprecated that the English government, under advisement of Drs. Hunter, Foyer and Cunningham, themselves not only very distinguished men, but especial observers in Egypt and India, has given official expression to its disbelief of the value of quarantine regulations.

"Her Majesty's government offers a serious and well-founded objection to the theory generally admitted and the custom of quarantine. Sanitary measures have proved to be the only efficacious means of impeding the march of an epidemic."

I am free to confess, this was my own opinion formerly, and I held quarantine regulations to be respected simply because they had been formulated as laws. I must now think otherwise, since the weight of evidence would render it hard for the unprejudiced, judicial student to disbelieve in the communicability of cholera. A large volume itself would not contain the facts already collated. Dr. C. Macnamara, in a lecture published in the *British Medical Journal*, March 15, 1884, upon Asiatic cholera, states that for a long time he could not himself subscribe to the communicability of cholera, but a careful historical research convinces him of the fact, and he gives this illustration of his own personal experience: "A small quantity of a fresh rice-water stool, passed by a patient suffering from cholera, was accidentally mixed

with four gallons of dirty water, and the mixture exposed to the rays of the tropical sun for twelve hours. Early the following morning nineteen people each swallowed about an ounce of the contaminated water; they only partook of it once, but within thirty-six hours five of these nineteen persons were seized with cholera. In this case the cholera evacuation did not touch the soil; as it was passed, so it was swallowed, but (and this is the most important part to remember) it had been largely diluted with impure water, and the mixture had been exposed to the light and heat of a tropical sun for twelve hours. In the year 1872 I was engaged in making some experiments on monkeys. For this purpose I exposed to the sun some fresh cholera dejecta in a pail full of dirty water. The following morning, at about 6:30 A. M., I and my assistant were shut up in a close room with these monkeys, experimenting upon them with this diluted cholera stuff. By 2 o'clock the same day I was suffering from a severe attack of cholera, and the same evening my assistant was seized with the disease. We were both of us very dangerously ill, passing into a state of collapse in a few hours after the commencement of the symptoms. The monkeys escaped without the slightest ill effects from our endeavor to give them cholera."

In the same journal for October, 13, 1883, (page 727) Surgeon General James Irving of the Bengal Army adduces certain facts showing the conveyance of cholera in India and they seem so conclusive that I briefly reproduce a portion of them here: Surgeon-Major H. B. Purves was stationed at Darjeeling in 1876. This is in the Himalayas, forty miles above the plains, 7,000 feet above the level of the sea and approached by a single road. The population was scanty, the climate healthy, and numerous tea gardens were scattered about the adjacent country. "Early in June, there was a regular cholera wave over the whole district, lessening in the plains, but rapidly increasing among the hills. Large gangs of coolies who had bolted from the lower ranges, had entered the hills, and were roaming about the forests, in some instances carrying their sick with them." In July a great and general improvement took place, and by August the disease had disappeared. The mortality reported by the police (who are the collectors of medical statistics in India), was 1,729 out of a population of 94,712, though Mr. Purves considers that there were at least twice as many deaths. Mr. Purves instances "special cases where human intercourse seemed undoubtedly to be the immediate cause of the appearance of cholera." He does not name the gardens referred to, but alludes to them by numbers.

"Garden No. 1.—The disease had been prevalent for some time at an adjoining estate. No case occurred until a man happened to go to the infected garden to bury his sister, who had died of cholera. Shortly after his return, he was attacked and died; and the result was a severe and fatal outbreak, causing a mortality of 150 among a population of 1,500.

"Garden No. 2.—The manager states that the infection was distinctly traced to communication with a bazaar close by. Seven hundred deaths.

"Garden No. 3.—It was discovered that new coolies from an infected garden had lately settled in the lines when the first case occurred. Eighty-five deaths among 650.

"Garden No. 4.—The outbreak was traced beyond doubt to the advent of new coolies from infected parts of the terai. Two hundred and eight deaths in 1,700.

"Garden No. 5.—Eight new coolies offered themselves for employment at a garden near Darjeeling and were entertained. Shortly afterwards, cholera broke out among them, and every one of the eight died. It was ultimately discovered that they had fled from an infected garden in the terai. The other coolies, who had hitherto been healthy, were also infected by the new-comers.

"Garden No. 6.—Seven new coolies from an infected part of the Kursang neighborhood arrived at a hill garden on which there had been no signs of cholera. Shortly afterwards the disease broke out; and, in twenty days of June, 72 died from the disease out of a total population of 100. It is worthy of note that a few villagers living in scattered huts in the same garden, but not working as coolies, escaped entirely."

Certain enthusiastic sanitarians, especially English, encouraged by the semi-official statements of governmental character, have lately broadly asserted that cholera cannot be communicated or transmitted, but is a local disease dependent upon pollution of the atmosphere, water, or soil. Sir W. G. Hunter, in his observations in Egypt, emphasized as cause the filthy conditions found there. Miss Florence Nightingale, in a letter recently published, repeats these views, and enforces sanitary measures as our only safe-guard, stating that quarantine, isolation, and the like, by distracting the attention from such measures, may tend fatally to aggravate the disease, and she quotes Dr. Cunningham as authority.

All this must not be underestimated. The truth lies very probably in the particular cause of infection, but this seed must find a soil favorable for its growth and dissemination, and here we find abundant cause to enforce all sanitary measures, just as in the entire class of zymotic diseases.

As in consumption, we must have not only the bacillus tuberculosis, but must find conditions favorable for its development; an unhealthy mucous membrane lining the respiratory tract, its ciliated epithelium impaired, or destroyed, furnishing a soil fitted for its growth.

In the present lax condition of English surveillance of her commerce, it becomes our Government to exercise a doubly careful enforcement of our wisely framed quarantine laws, while it behooves every citizen to look especially after his own sanitary surroundings. In something of the same spirit which actuates the English government, a leading editorial in the *Boston Medical and Surgical Journal* of Oct. 9, upon "Cholera and Rags," deprecates the action of our Government, and finds fault with the order issued by our indefatigable Surgeon-General Hamilton, forbidding the importation of rags for three months.

The wisdom of such an order could only be called in question by the superficial or prejudiced critic.¹

Having given so much space to the diseases in which bacilli are believed to play an important part, we must pass over more rapidly the group of diseases in which the round cell or micrococcal growths predominate. In this group have been classed, with greater or less evidences of a causative character, cholera of fowls, pyæmia and septicæmia in rabbits, swine-plague, pleuro-pneumonia of cattle, hydrophobia, small-pox, vaccine, gonorrhœa, whooping-cough, measles, scarlet fever, diphtheria and erysipelas.

The presence of micro-organisms is easily proven in the products of diphtheria. Ten years ago I demonstrated them in diphtheritic membrane. Recklinhausen, Klebs, Eberth, and many others have discovered them in many organs and tissues. Oertel and Eberth are very sure of the causal relations of the micrococcus diphtheria. Klebs produced diphtheria in animals by the inoculation of pure cultures. None are of greater value and interest than the studies of Drs. Wood and Formad. They inoculated pure cultures in a number of instances, resulting in the death of the animal. Micrococci were abundant in all cases. Last autumn I instituted a series of cultures from a portion of tracheal membrane removed after tracheotomy. Careful microscopic examination was made at each inoculation, and the developing and the massing of the micrococci were carefully noted. Zoöglea masses were abundant in each instance. The tenth in the series covering a period of about 40 days was selected for inoculative experiments. From this six guinea-pigs were inoculated in the cornea of the eye. One died upon the second day, and three were killed on subsequent days. A membrane developed in the eye infected in all, and micrococci were numerous in each. The other two recovered with loss of the eye inoculated. During the inoculating experiments my assistant, Dr. Nelson, was infected and suffered a severe attack of diphtheria, from which he slowly recovered. Micrococci presenting the same appearance and characteristic massing were abundant in the proliferation about his tonsils. From this I reproduced in culture micrococci with the same characteristic appearance.

Fehleisen detected in several cases of erysipelas micrococci, especially in the parts and the periphery of the erysipelatous patch, at the very commencement of the process. He found them in the interstitial tissue, and also in the lymphatics, and in their neighborhood he found accumulation of leucocytes. He was able also to cultivate the organisms in a solid gelatine soil, and went on cultivating them to the twelfth and thirteenth generation. He noticed a different naked-eye appearance of the cultivated masses from that of cultivating masses of other septic micrococci. The cultivated organisms, when injected into a rabbit's ear produced, after an inocula-

¹Space forbids any farther discussion of the cholera bacillus, but we would urge a careful study of Dr. Koch's address upon the cholera and its bacillus, delivered before the Imperial German Board of Health in Berlin, and translated and published in the *British Medical Journal*, August and September, 1884, at the close of which Prof. Virchow, after thanking Dr. Koch for giving this long and detailed account of his view, said: "I say decidedly for myself that, from the beginning, I thought it very probable that the bacillus was, indeed, the *ens morbi*; but from what I have heard to-day, my conceptions on the subject have arrived at a much greater degree of certainty."

tion period of twelve to eighteen hours, typical erysipelas, spreading to the head and the neck. In the affected parts, the micrococci were again seen. Removing the rabbit's ears twelve hours after inoculation stopped the process. Bearing in mind some well-known observations by Nélaton, Thiersch, and Volkmann, that patients suffering from malignant tumors improved, when contracting erysipelas, Fehleisen inoculated patients, some suffering from cancer of the breast, others from sarcomatous tumors, others from lupus, with the cultivated micrococci and produced, in seven out of nine inoculations, typical and in one case most severe erysipelas."

From the fluid in blisters of erysipelas patients I have cultivated and studied the micrococci very carefully. They were easily reproduced in a given series, but two or three injections and inoculative experiments failed of a development of the disease in the guinea-pig.

The relation of erysipelas to puerperal fever has long been suspected. An unfortunate series of cases occurring in the practice of a brother physician recently is worthy of notice. Three of the fatal cases I saw in consultation. Following a case of erysipelas early in January there supervened in his practice five fatal cases of puerperal fever, the last developed at about the tenth day, erysipelas following what seemed a slight abrasion in the middle line over the coccyx, up the back, and then diffusing laterally until it became general and before death had extended over quite the larger portion of the body. In bulbs infected at the bedside with secretion taken directly with much care from within the cervix uteri, micrococci were reproduced in rapid growth, and, in appearance, the micro-organisms could not be differentiated from the cultures from the blisters of erysipelas.

In the pus from gonorrhœa Neisser detected a micro-organism, a micrococcus; this he was able to cultivate and found its naked-eye appearances, as cultivated on gelatine, different from the septic micro-organism. Inoculations performed by him were not successful. Bockhardt has, however, recently repeated the experiment, cultivated the micrococci and obtained positive results or inoculations.

Dr. Queist, of Russia, reports that he has successfully cultivated vaccine virus, and that with this he has vaccinated with typical pustules and thereafter granting immunity against a second vaccination. No test has been offered as to the prevention of small-pox. He states that the micrococci developed into bacilli and these again into micrococci.

By the politeness of Dr. H. A. Martin, of Boston, we were enabled to inoculate bulbs directly from the animal serum. In these developed an abundance of micrococci single and in chains; they are very minute and active, combined in twos they resemble short bacilli and require high powers to differentiate. Our vaccine experiments, however, failed.

I would enter an earnest plea that every medical school should train a corps of competent observers, that each hospital set apart the needful appliances for the proper study of diseased tissues and secretions, and that the profession generally be requested to col-

lect material which, in capillary tubes, enclosed in melted paraffine, and other ways, may safely be transmitted by mail. By such means our present knowledge would be materially enhanced.

Although I have omitted much of real value, I believe we may conclude from this review that the time has passed when the critic of the germ-theory of disease can content himself with captious remarks "upon fashions in medicine, deluded followers of speculative theories, etc." As well might the geographer deny the existence of Africa because a topographical survey had not been made of its interior. All along the border lines of the unknown are enthusiastic explorers engaged in the difficult and dangerous work of investigation with a heroism and determined fortitude of a Livingstone or a Stanley. In these directions science is not without its martyrs. The investigations of a cholera commission in Egypt and India or yellow fever in Havana are not less dangerous than an expedition to discover the sources of the Nile or a ship's company in quest of the northwestern passage.

Let us, in common with grateful republican France, hold in loving remembrance her peasant-boy Pasteur and his school of followers; with the great and learned empire of Germany recognize in Koch and his distinguished collaborators the important discoveries already made; with England vie in doing honor to a Lister and his students who have revolutionized surgery; and shall we forget in our own country a Sternberg, a Belfield, a Formad, and many others whose work has added to our national fame? We are glad to pay tribute of loving remembrance to Johns Hopkins, the founder of a University in whose halls we are now assembled, which ennobles science; to a Senney who reaches a climax of national benevolence in founding a hospital; and last, not least, to the railroad prince of America who enlarges the boundaries of science by his magnificent gift to one of New York's most famous schools of medicine. We emphasize the ingratitude of kings and emperors as we hold up to our sons the glowing picture of a republic. As scientists, however, we must remember that we lack political potency. For us, no "Harbor and River Bill," under the flattering representation of national commercial development, carries the open sesame of patronage and votes. A National Board of Health is shorn of its usefulness and unmeasured good through ostensible motives of economy, while our millions are expended with a lavish hand to aid "the power behind the throne." Just now, the personal aggrandizement of some possible President is, in political estimation, of far greater consequence and importance than the prevention of contagious and zymotic diseases which annually carry to untimely graves their hecatombs of victims.

Let the medical profession arise to its just prerogative and power as conservator of the public health. Memorialize Congress to aid in the better solution of the important questions of preventive medicine, and the great wealthy government of the New, rival the Old World in a generous emulation in the settlement of questions fundamental to the health, happiness, and long life of her citizens.

HYDROCHLORATE OF COCAINE IN THE NOSE AND THROAT.

BY E. FLETCHER INGALS, M.D.,

PROFESSOR OF LARYNGOLOGY, RUSH MEDICAL COLLEGE.

After having noticed the statement by M. Du Cazal, that tincture of coca would relieve painful affections of the throat, I made several trials of the remedy, but failed to get satisfactory results; and since the publication of Dr. Agnew's report on the hydrochlorate of cocaine, being unable to obtain any of the latter, I have made trials of a strong solution of the extract of coca, and also of citrate of caffeine, which, from its close resemblance to cocaine, I hoped might produce similar local effects; but in both I was completely disappointed.

I was unable to obtain any of the hydrochlorate of cocaine until the 13th of this month, when I received a 2 per cent. solution from New York. My first trial was in a healthy subject, who, however, had a very sensitive Schneiderian mucous membrane. I ascertained by experiment that, with the moderate pressure applied, only about 10 per cent. of a spray applied to the nostrils would be lost. I then applied the solution in the left nasal cavity, first by a spray, and afterward by a hypodermic syringe fitted with a long probe-like nozzle. I applied in this case 26 minims of the solution during the space of forty-five minutes, from two to four minims being applied at intervals of three to six minutes, with the following result: Fourteen minutes after the first application there was a decided loss of sensibility, though pressure caused pain. In thirty minutes anæsthesia was nearly perfect, 18 minims having been used, and in forty minutes sensitiveness was returning. In forty-five minutes the membrane was quite sensitive, and in fifty minutes sensibility was almost normal, notwithstanding the continuous use of the cocaine. The soreness caused by the probing caused considerable pain, which radiated to the eyes and side of the head, and lasted for three or four hours.

CASE II. Male, aged 19. Naso-pharyngeal fibroma. In this case a portion of the fibrous growth, which was attached to the side of the posterior border of the septum, had to be cauterized.

Two previous cauterizations had given the patient very severe pain, which "shot through his whole head." The nasal cavity was first washed out with Dobell's solution, and afterward with a weak solution of hydrochloric acid. It was then dried by absorbent cotton, and the two per cent. solution was applied with the syringe to the part to be cauterized.

I used 30 minims during thirty-six minutes, in quantities of four to five minims every five minutes, with the following results: In seven minutes sensitiveness was considerably diminished. In fourteen minutes sensitiveness greater than before. Thirty-six minutes after the first application, half a drachm of the two per cent. solution having been applied, he could feel the probe, but it caused no pain excepting in one spot. I then applied the cautery thoroughly about three times as long as on previous sittings, causing very

little pain—he thought about one-tenth as much as formerly.

CASE III. Male, aged 62. At two previous sittings I had removed from this gentleman's nares large mucous polypi, but to-day I found the base of one springing from the middle meatus of the right side. I dried the parts with cotton, and during ten minutes applied ten minims of a two per cent. solution as thoroughly as possible immediately about the polypus. Nineteen minutes after the first application, I removed the polypus with snare and forceps, and then cauterized its base with the galvano-cautery. He said the pain was very slight, not more than one-tenth what he had experienced from previous operations of the same character. He was exceedingly pleased at the result.

CASE IV. Male, aged 34. Nasal polypi, with exceedingly sensitive Schneiderian mucous membrane. Applied first five minims of a two per cent. solution, five minutes later four minims more. Six minutes later parts not sensitive to probe. Cauterized base of polypus in middle meatus with galvano-cautery, with about one-fifteenth the pain he had experienced from a similar operation a week previously.

CASE V. Male, aged 29. Hypertrophic catarrh. This patient came from Iowa, and as he wished to return the same evening, I desired to relieve him as completely as possible at one sitting. To the left naris, which was very sensitive when touched with the probe, the two per cent. solution was applied as in the preceding experiments in quantities of one to four minims at intervals of one to four minutes, with the following results: There was some numbness at the end of seven minutes, and very little sensitive at the end of eleven minutes, but eight minutes later, notwithstanding the continual use of the drug, the sensitiveness was about the same. I then transfixed the lower turbinated body and applied the snare without pain, though he felt it; but when the snare was tightened considerable pain was experienced. Three minutes later the sensitiveness of the part was about one-third that of the side not treated.

While doing this operation I received word that the cocaine ordered from Germany had arrived. I immediately sent for it and had a four per cent. solution made.

Second trial in Case V.—An hour and a half later I applied the four per cent. solution to the right naris. The cavity was first dried with cotton and twelve minims applied in quantities of one to two minims at intervals of two or three minutes during twenty-three minutes, at the end of which time he said the sensitiveness was more than at first, though it had been much obtunded ten minutes earlier. I then swabbed out the naris carefully and applied four minims more of the solution. Five minutes later I cauterized the inferior turbinated body thoroughly, causing about one-fourth the amount of pain ordinarily experienced from similar though much shorter operations.

CASE VI. Female, aged 33. Anosmia dependent partially on submucous thickening of the upper part of the septum which was swollen so as to protrude three-

sixteenths of an inch. I first dried the mucous membrane with a jet of compressed air and then applied the four per cent. solution by means of the syringe, dropping upon the surface half a minim every half minute for three minutes, and afterward every three minutes until ten minutes had elapsed, when I found anæsthesia of the part complete. I then cauterized the swollen tissue thoroughly, passing the hot wire twice through its base without causing the slightest pain. A similar operation in the opposite naris had previously given this patient severe pain.

CASE VII. Male, aged 21. Deflection of the septum with exostosis forming a spur $1\frac{3}{4}$ inches long, projecting a fourth of an inch from the normal plane of the septum and decreasing the normal calibre of the air passage 80 per cent. The nasal mucous membrane was unusually sensitive. I applied a loose pledget of absorbent cotton below the spur, and having dried the membrane with the jet of air, repeatedly dropped upon the upper surface of the spur, from one end to the other, a four per cent. solution; averaging half a minim every half minute for the first six minutes. Some of this ran down into the cotton below the spur, but at the end of several minutes from the first application when the upper surface was completely benumbed I found the lower still acutely sensitive. I then removed the cotton and dried the passage with the air jet and applied more of the solution in the same manner as before, both above and below the spur. Twelve minutes after the first application, having used eight minims of the solution, I found the parts to be operated upon completely anæsthetized, I then sawed off the spur (this part of the operation requiring about four minutes), without causing the slightest pain. In removing the detached bone some pain was caused by touching the outer wall of the naris which I had not attempted to anæsthetize. Twenty minutes after the first application, sensibility was rapidly returning, and five minutes later the parts were again sensitive to the probe.

CASE VIII. Mrs. W. Small cystic tumor at the lower part of the left side of the base of the tongue about half an inch below the tonsil, with several diseased follicles in the tonsil filled with their desiccated secretions. I wished to destroy part of these with the galvano-cautery. But the patient so feared pain that I attempted to numb the parts by injecting on the upper part of the tonsil the four per cent. solution, which trickled down so that I supposed the membrane over the cyst would be reached. Five minims were used in the course of five minutes, the mouth being kept open. Three minutes later the patient complained of something being lodged in her throat which made her retch and nearly caused vomiting, this sensation which was due to the numbing effects of the cocaine, lasted about five minutes; as soon as the tendency to retch ceased I destroyed the cyst with the galvano-cautery, but the anæsthetic effect of the cocaine seemed to have entirely disappeared.

CASE IX. Male, aged 31. Hypertrophic catarrh. Dried the parts with the blast of air and then applied the four per cent. solution of hydrochlorate of cocaine to the inferior turbinated body of the right

side, eleven minims in thirteen minutes, from one-half to one minim every minute.

In this case, as in others of hypertrophic catarrh, the solution caused the swelling to almost completely disappear by the time anæsthesia was complete.

The turbinated body was cauterized thoroughly without pain. The patient complained of a sense of dizziness and slight dyspnoea for ten minutes, but had no unpleasant sensations afterward.

CASE X. A little girl, aged 6. Adhesion of turbinated body to septum, causing stenosis of right naris.

Applied the solution as in the last case, excepting that half of it was used with the atomizer and only eight minims were employed.

In fourteen minutes anæsthesia was complete and the adhesions were broken down without pain.

Second application in case II. On the patient's next visit to my office I applied the four per cent. solution to the naso-pharynx, which still contained quite a large mass of the fibrous growth. He has always complained bitterly on any manipulation of the part, but after having used ten minims by the atomizer, a minim every minute, the surface was anæsthetized, however, by the probe I found that deeper parts were still sensitive.

I then introduced, by means of the probe-pointed syringe nozzle, six minims more in various places where the contact of the probe caused pain. In twenty-five minutes the parts were so thoroughly anæsthetized that I commenced the operation of removing the mass with cutting forceps. The operation lasted about ten minutes and gave no pain, excepting in one small spot, though he said he felt the instrument whenever introduced or moved.

From my experience with cases, one to five inclusive, I concluded that when the solution is applied in the naris, every four or five minutes a partial anæsthesia occurs in ten or fifteen minutes after the first application, and that it is followed, like the first effects of ether when given slowly, by a period of two or three minutes of exalted sensibility, and that if its use be continued (possibly without further use) the maximum effects of the anæsthetic are quickly reached. The anæsthesia disappears in about five or ten minutes. These cases also suggest the query, whether, after a short time (thirty to forty-five minutes) it might not be very difficult to maintain anæsthesia even by repeated applications? These same cases also convinced me that a two per cent. solution is not ordinarily strong enough for use in the nose. From all the experiments, I conclude also that the drug does not act satisfactorily unless the mucous membrane is free from secretions, and wiping out the nasal cavity with cotton, though it dries it for a few seconds, excites excessive secretion directly afterward, therefore drying may be much better accomplished by the jet of air.

These cases, as far as they go, also suggest the advisability of overcoming the sensitiveness as quickly as possible by frequent applications, which keep the surface constantly bathed in the solution. When used in the fauces, it was entirely unsatisfactory in one case, but I attribute this partly to the

particular patient and partly to the imperfect application of the solution. Dr. Solis Cohen's experiments with it in the larynx have not been satisfactory, but we will doubtless soon learn how to obtain better results from its use in the fauces and larynx.

One of the remarkable properties of this drug, which I observed when I first applied it to the swollen mucous membrane of the turbinated bodies, is that of causing prompt and rigid contraction of these tissues. This action has proven to be uniform, and I have learned by experiment that the contraction may continue several hours. This property will render the cocaine almost a specific for the relief of the "stuffing up" of the nose which occurs in acute colds, hypertrophic catarrh and hay asthma, as well as for the throat deafness, which results from swelling of the mucous membrane lining the Eustachian tubes.

64 State St., Chicago, Nov. 18, 1884.

MURIATE OF COCAINE IN OPHTHALMIC PRACTICE.

BY CHAS. J. LUNDY, A.M., M.D.,

PROFESSOR OF DISEASES OF THE EYE, EAR AND THROAT IN THE MICHIGAN COLLEGE OF MEDICINE, DETROIT.¹

MR. PRESIDENT AND GENTLEMEN:

I take the liberty of calling your attention to the new local anæsthetic, muriate of cocaine, a solution of which I here show you. The opportunity of making some remarks upon this important drug affords me much pleasure, because my former preceptor, Professor H. D. Noyes, of New York, was the first to bring it to the notice of the profession in this country. While attending the Ophthalmological Congress, in Heidelberg, in September, Professor Noyes witnessed the experiments of Dr. Koller before the meeting, and in the *Medical Record* of October 11 he relates what he observed. The news that a valuable local anæsthetic had been discovered—one which would, in many instances, obviate the necessity of administering general anæsthetics, such as chloroform, ether, etc.—naturally excited great interest, especially among ophthalmic surgeons. Indeed, medical men all over the country are using it in operations on the eye, the nose, the uterus, etc., and already many successful cases have been reported.

I have made several experiments with it, and have employed it before operating in a large number of cases.

Applied to the conjunctiva it produces anæsthesia of that tissue which is nearly, if not quite, absolute. Applied to the mucous membrane of the lip or cheek it produces a feeling of numbness which finally becomes tolerably complete anæsthesia. Employed in the nose it produces such complete anæsthesia that the actual cautery has been employed without pain. It is evident, therefore, that muriate of cocaine is capable of producing paralysis of sensation in any part

of the trigeminus, the great sensory nerve of the head and face. It has been used successfully in operations on the uterus, and it is but fair to presume that it will temporarily paralyze sensation in any part of the human economy. This, however, has been denied, and some experimenters claim that it does not affect the iris. In this latter view I do not concur. It paralyzes the ophthalmic division of the fifth very generally, and it is not at all probable that it would exert a paralyzing influence over one part of a nerve and not over all of it. The ciliary nerves supplying the iris with motion and sensation contain branches derived from the ophthalmic division of the fifth, with branches from the third and from the sympathetic. Now that muriate of cocaine does affect the iris we have positive proof, for it produces partial paralysis (as we shall see) of the sphincter of the pupil. If it paralyzes sensation in other parts of the ciliary nerves, and produces motor paralysis of the iris, it seems impossible that the iris should escape its anæsthetic influence. Indeed my observations and experiments lead me to believe that if a sufficiently strong solution of the muriate of cocaine be employed, the iris also loses its sensibility for a time. I can readily understand that it will be much more difficult to produce paralysis of sensation in the iris than elsewhere, for the aqueous humor which bathes the iris dilutes the medicine which passes into the anterior chamber by endosmosis. Could the anæsthetic come directly in contact with the iris there can be no doubt that tolerably complete anæsthesia would follow.

In eye operations I now employ a four per cent. solution of the muriate. Of this I instil into the eye two drops every three or four minutes, until eight drops are used. From its use in this manner I have observed the following effects: The cornea begins to lose its sensibility in three or four minutes, and in many cases the corneal anæsthesia is complete in five minutes, while in other cases it requires eight or ten minutes to produce this result. In one patient, who had an irritable, painful ulcer of the cornea, all pain was relieved in less than five minutes, and a few minutes later the ulcer was touched with a sharp instrument without producing the slightest sensation. The conjunctiva loses its sensibility in six to ten minutes, and can be firmly grasped by a fixation forceps without the knowledge of the patient. The anæsthesia of the cornea and conjunctiva lasts from twenty to thirty minutes, after which normal sensation is soon restored.

Its action on the pupil and on the muscle of accommodation (ciliary muscle) was observed as follows: In five or six minutes the pupil began to dilate. The dilatation increased slowly for fifteen or twenty minutes, at which time the pupil was twice the normal size. In no case did I observe that the pupil was dilated *ad maximum*. The dilatation of the pupil lasts from twelve to twenty hours, according to the quantity and strength of the solution employed. At no time was the pupil wholly irresponsive to light. In twelve to fifteen minutes I observed the first signs of failure in the power of accommodation. In twenty minutes the effect on the ciliary muscle was tolerably

¹ A paper read before the Wayne County (Mich.) Medical Society.

well marked, and print which, before the use of the medicine, could be seen at five or six inches, could not now be seen nearer than twelve to fourteen inches. Repeated attempts to fully dilate the pupil, and render it wholly irresponsive to light, were not successful in my hands. Neither did I succeed in producing anything like complete paralysis of accommodation.

From these experiments it will be seen that muriate of cocaine not only produces tolerably complete paralysis of sensation, but that it is also capable of producing partial paralysis of motion. However, the drug seems to exert slight influence over motion as compared with its influence over sensation.

It was observed that slight hyperæmia of the parts followed its use in all cases. It was also observed that the parts bled more freely than is usual when incisions were made. This would indicate that it exerts at least some paralyzing influence over the vaso-motor nerves. However, the bleeding in such cases was by no means so free as to indicate anything like complete vaso-motor paralysis. I should be inclined to believe that its influence over the vaso-motor nerves was, like that over motion, rather slight.

In operations I have employed it in extraction of cataract, in enucleation, in strabotomy, in paracentesis of the cornea, in the removal of tarsal tumors, in canthoplasty, in lachrymal operations, etc. In one extremely nervous, timid boy a little chloroform was administered, but not on account of pain.

In one case of enucleation the operation was almost complete before the patient gave any evidence of feeling pain. Then a little chloroform was given and the operation completed. This was in a bad subject for an anæsthetic, and the risk of complete anæsthesia from chloroform was avoided. I am confident that a less nervous patient would have gone entirely through the operation without requiring any general anæsthetic like chloroform. In an operation for cataract the patient said he felt no pain whatever, and was cognizant of any operation only by feeling a pressure upon the ball—possibly the pressure of the shell scoop in stroking the cornea in delivering the lens. In operations on the lachrymal apparatus, Bowman's operation was done with very slight pain. In one case the slitting of the nasal duct produced as much suffering as usual. Where I succeeded in getting any of the medicine through the duct into the nose, the passage of the knife produced but little discomfort. In one very nervous subject who fainted away during a previous operation for tarsal tumor, no pain was felt in a similar operation after the cocaine had been used. Patients upon whom I operated for strabismus say they experience a sensation of drawing or pulling when the muscle is raised upon the strabismus hook.

In my experiments upon the skin the results were not entirely satisfactory. In some cases the sensibility of the skin was perceptibly diminished, while in other cases it seemed to produce little or no effect. It is probable that to produce anæsthesia for general operations in surgery, it will be necessary to inject the cocaine hypodermically.

Just what will be the range of usefulness of muriate of cocaine, we cannot now say positively, but

from present indications it seems that it is destined to fill an important place in our armamentarium. Should there be no dark side to the picture which now seems so bright, great things may be expected from this new drug, which is now attracting such universal attention. Many exaggerated statements will undoubtedly be made regarding it, and it will be some time ere we will be able to correctly estimate its real value.

MEDICAL PROGRESS.

SURGERY.

GASTROSTOMY FOR STRICTURE OF THE ŒSOPHAGUS.—Mr. John Fagan (*British Medical Journal*) narrated before the British Medical Association the leading features in the histories of two cases of stricture of the œsophagus; the first was in a man 46 years of age, on whom the catheter was passed until it would no longer penetrate the stricture. An opening into the stomach was made, after which the patient lived for three weeks, with very little improvement, dying suddenly from collapse. The union between the stomach and abdominal walls was complete, except at one point at the upper angle, where the attachment gave way. As the patient died suddenly after being fed, it is more than likely that some fluid passed into his peritoneal cavity. In the second case the patient died thirty-six hours after the operation. Mr. Fagan suggests the following rules regarding the performance of the operation of gastrostomy:

1. In cases where the obstruction is partial, it should not be entertained in non-malignant cases so long as a bougie can be passed, or a tube worn to enable the patient to take sufficient nutriment. But should the passing or wearing of an instrument cause great irritation, while the difficulty in overcoming the obstruction is increasing, the operation may with justice be undertaken. For by it the affected parts are placed in a state of physiological rest, which tends not alone to the improvement of the part, but renders it more amenable to other forms of treatment.

2. In cases due to malignant obstruction, where the dysphagia is becoming both painful and more marked if the permanent wearing of a tube cannot be tolerated, there should be no time lost in performing a gastrostomy.

3. In cases where complete obstruction has existed for a short time, the patient's strength being fairly sustained by enemata, and there is no malignancy, the operation may be undertaken with hopes of improvement; in malignant cases, at this stage, it should not be urged.

4. In the advanced stage of complete obstruction, no matter what the cause be, the operation should not be undertaken, for the patient, if he survive the immediate shock from it, cannot live more than a few days, that are passed in increased discomfort.

Regarding the mode of performing the operation,

Mr. Fagan does not think it makes much difference how the incision is made, provided it is just large enough, and so placed as to allow of the stomach being seized and easily drawn through the wound.

Theoretically, an improvised sphincter to guard the fistulous opening is a very desirable thing; but if the vertical incision renders the operation more tedious or difficult, it is questionable if the practical advantages supposed to be gained by it will make up for that. The usual incision is the oblique, commencing a little below, and to the left side of, the tip of the ensiform cartilage. By this the stomach is best exposed and most easily secured. Here the mistake is generally made of placing the line of incision too near the border of the costal cartilages. The finger's breadth that is usually recommended looks, before operation, just sufficient for the purpose; but after the incision is made the upper flap is retracted and gets tucked up close to the ribs, rendering it impossible to pass the outer ring of sutures. The incision should be begun about an inch below the tip of the ensiform cartilage, a little to the left of the median line, and extended obliquely downwards and outwards, keeping at least fully two inches from the border of the costal cartilages.

The ordinary method of attaching the stomach to the abdominal wall by a single ring of sutures, although simple and expeditious, is not a secure one. Professor Ditch, of Vienna, after incising the abdominal wall, attaches the parietal peritonæum to the skin by numerous points of fine suture. By means of a stout curved needle in a needle-holder, he passes a circle of sutures, forming broad loops, through the outer circle of the stomach, and then through the whole thickness of the abdominal wall, about half an inch from the edge of the incision. By this means he brings a broad band of visceral and parietal peritonæum in contact. Between the large sutures he passes a number of fine ones, and in this way secures a close attachment of the stomach to the abdominal wall; this completely occludes the peritoneal cavity, and removes any risk of the passage of fluid into it.

To establish immediately a fistulous opening in the stomach, a suture armed at one end with a curved needle, at the other with a straight one, should be used, the curved one should be passed by means of a needle-holder through the outer coats of the stomach, and then through the abdominal wall, about an inch from the edge of the wound; the straight through the wall nearer the incision; and the suture then tied in the usual manner over some suitable resisting medium. In forming the fistulous opening Mr. Fagan, after his incision, introduces two ordinary silver probes bent at right angles about an inch from the point, and pulls with them at right angles to the muscular fibres of the stomach, until a No. 9 catheter passes in readily. After the catheter is withdrawn the opening is closed, and no regurgitation occurs.

In malignant cases he would complete the operation at once, in non-malignant, and in the very early stages of malignant obstruction, Howse's method of dividing the operation into two stages is the more preferable, as by it a more permanent and accurate attachment is more likely to be secured all round the

fistula; besides the patient is in a better condition to be subjected to such treatment.

Mr. Macnamara also reported a case of a woman, 57 years of age, where, after the usual incision of the abdomen, a fold of the stomach was drawn out through the wound, transfixed by a needle and thick silver wire, and so secured to the skin as to remain outside of the wound. On the seventh day after the operation, an opening was made through this fold of the stomach, sufficiently large to admit of the passage of a No. 7 catheter. At the end of a month she was able to get up and move about the ward, a small fistulous opening remaining, through which she was able to inject her food by means of a properly fitted tube. She passed natural motions and her health had much improved.

In the discussion which ensued Dr. Edwyn Andrew said that as the colon had been opened by good operators, instead of the stomach, he would mention a very ready test; that was that the external coats were much thicker over the stomach, and might be readily pinched up by the finger and thumb; so that, if they were once felt in the dead body, this mistake could not occur.

TREPHINING IN MASTOID AND TYMPANIC DISEASE.

—Dr. W. S. Wheeler, in the *Dublin Journal of Medical Science*, records the particulars of three cases of this treatment with successful results. He gives seven different ways in which suppurative inflammation of the dura mater follows carious disease of the osseous structures, petrous portion of the tympanum, cavity of the labyrinth (carious disease of), and the wall of the external auditory meatus, etc.

1. Through the internal auditory meatus, in which are prolongations of the membranes.

2. Through the hiatus fallopii.

3. Through the aqueduct of the vestibule.

4. Through the tegmen tympani, always thin in the normal state and sometimes deficient over a limited area, so as to place the lining membrane of the tympanum in direct contact with the dura mater.

5. Through the fissura petro-squamosa the dura mater sometimes sending in a vascular process its entire length into the tympanum and mastoid apophysis, and by means of which the central envelope is placed, with regard to its nutrition, in more intimate relation with the middle ear.

6. Occasionally by means of a slit for the dura mater, situated between the epiotic and opisthotic elements, near the aqueduct of the vestibule.

7. Through the canals of Verga and vascular canals of Maas; the latter are behind the superior semicircular canals, and connect the middle ear with the middle cranial fossa.

The record of the results of this operation show that it is a fairly successful one; and, on the other hand, that, from the expectant treatment in suppurative inflammation, there is little to look forward to but a fatal result. Ninety-eight cases of perforation of the mastoid process have been collected by Poincot (*Dict. Méd. et Chirurg.*), in 35 of which the trephine or trepan was used; in the remainder other instruments—gouge, drill, trocar, etc., were employed.

Of the total number of cases, 15 terminated fatally; in 2 the result is not stated; in 5 there was no recorded result; 5 others were under treatment at the time at which their cases were reported; the rest were successful. Of the 35 cases in which the trephine or trepan was used, 4 terminated fatally; in the total number of cases, the results of which are differently specified, 17 per cent. were fatal, and 21 per cent. successful. Buck (of New York) has collected 37 cases of suppurative inflammation in which the cases were left to nature (expectant treatment); 34 were fatal.

That the operation should be practised early is a self-evident fact; it is useless when pyæmia, meningitis, or phlebitis of the sinuses have appeared, although the first cerebral manifestations should not intimidate the surgeon from operating. Setons and issues are of little use. A well-accomplished operation will always give free vent to pus when existing, and prevent its passing to the brain through some of the numerous channels as recorded, and will thus save the patient. Dr. Wheeler deprecates the use of the gouge and galvano-cautery over the mastoid process, such a process being likely to set up irritation and inflammation. Unless the suppuration is comparatively superficial, he would not operate over the mastoid process, where one cannot remove the entire portion of the bone, on account of the proximity of the lateral sinus, and so cannot expose the dura mater, which is very essential. The site selected for operation should be such as to place the lower border of the trephine on a level with the external auditory meatus, and anterior to a line dividing vertically the mastoid process. By adopting this course, there will be no danger of wounding the lateral sinus, the tympanum and mastoid cells will be opened, giving full exit for discharge, the dura mater will be exposed, and should pus exist between it and the cranium, there will be ample freedom for its escape.

OPENING OF GALL BLADDER AND EXTRACTION OF BILIARY CALCULI.—Dr. Langenbusch, of Berlin (*Independence Belge, Midland Med. Miscellany*), has recently performed this operation upon M. Eugene Anspach, the Deputy-Governor of the National Bank of Belgium, who has been for many years suffering from a collection of gall stones, which have kept him in a state of aggravated suffering, and have latterly defied all measures of relief. M. Langenbusch, summoned specially from Berlin, proposed to lay open the gall bladder, with antiseptic precautions, admitting, however, that he had only performed this operation four times, and that but one of these cases recovered. M. Anspach's family and friends were much dismayed at this announcement, and begged that the operation should not be performed. M. Anspach was firm, and reflecting that without it he would not live long, and that in the mean time his life would be worse than death, decided on the operation. Even at this supreme moment the banking mind asserted itself, and M. Anspach remarked: "After all, one in four is 25 per cent., and that is a fine dividend." "You have had one recovery already, doctor," he remarked, "and I will be the second," an element of

confidence which no doubt had something to do with the result. The operation was performed on the 9th of September, and 125 calculi were extracted from the gall bladder. M. Anspach suffered a good deal, but is now out of danger and in complete comfort.

MEDICINE.

INTESTINAL INTUSSUSCEPTION.—Mr. A. K. Young, (*British Medical Journal*), reported a case of intestinal intussusception to the British Medical Association, in which there had been no evacuation from the bowel for two weeks, large enemata of soap and water, castor oil, and opium failing to produce any effect. Mr. Young connected the long enema tube to a strong elastic one coming from the waste cock of the water tank on the roof of the house about 30 feet above the patient. The tank-water was agreeably tepid from the rays of the very hot sun to which it lay exposed. The enema tube was passed into the rectum as high as it could be without violence, and this very enormous and steady pressure was sustained for five minutes without the slightest effect. This was repeated on the following day and accompanied with kneading, and was repeated a third time without effect. The belly was swollen but no especial discomfort was felt.

Mr. Young next proceeded to introduce mercury into the stomach, through a tube by means of a glass funnel, first using two pounds of the quicksilver and four hours later, one pound and two drachms—making in all three pounds and two drachms of the metal. From the record, although aided by succeeding enemata of oleaginous substances, this remained in him, producing pain and vomiting, until the third day thereafter, when the man left the hospital to die at home, and drove six or seven miles in a cart over a rough mountain road. On the fifth day he had two evacuations containing quicksilver, which from that time on gradually forced its way out, *i. e.*, during the succeeding nine days. Neither during the time the mercury was blocked up in the abdomen, nor at any time after its discharge, were there any symptoms, constitutional or local, to indicate its presence.

Mr. Young justifies his treatment by stating that he desired to give a sufficiency of quicksilver to liberate by its weight the strangulated part. In general terms, we may look upon the containing and contained portions as forming a bag, the floor of which is formed by the narrowed descending bowel, and the sides of the bag by that portion of intestine immediately above and continuous with it. The exterior descending portion is reflected from the lowest part of the strangulated gut, and upwards external to it as far as the upper part of the strangulation, then turns downwards on itself externally, and is continuous with that which is below the strictured part. In all these reflections, the serous membranes are opposed to and in contact with each other. When the upper portion descends and is strangulated, at that point of strangulation the bottom of the bag is formed with the aid of the up-

per portion which descends to the stricture, and is capable of containing more or less of whatever falls into it. If we could take this part of the bag immediately above the strictured point, and pull it upwards, or distend it laterally, the strictured part would be pulled upwards or outwards by the distension, the lymph attachments of the opposing serous surfaces would yield, and ultimately the strictured portion would be raised out of its narrowed bed, and the bowel set free. By introducing into this bag a considerable weight of mercury the sides of the bag would be distended by the heavy and movable medium, every movement of the body would keep this in continual motion, and as this pouch was thus increased, and the weighty mercury constantly exerting pressure and a dragging, now on this side, now on that, and more and more still as it became more and more distended, and the tendency of all this to pull at the upper descending part of the intestine, and drag it over the reflected brim of the detained gut, the end in view might ultimately be attained.

That there was a true invagination there can be no doubt; the different discharges at uncertain times, with varying quantities of the metal, until the channel of the intestine became sufficiently open, and then followed by the enormous discharges, from the doughy beds of retained feces, the perfect health the man enjoyed for weeks, the recurrence of his symptoms excited by violent exertion, and the perfect occlusion of the bowel until he died, all prove this to be intussusception.

CASE OF LIPOMA OF THE ARACHNOID—Dr. Braubach (*Arch. für Psych. und Nervenkrankheiten*) records a case of lipoma of the arachnoid of the cervical cord, and extending to the point of exit of the fourth and fifth dorsal nerves. The cord was completely compressed and displaced to the left side. Below the region of compression there was descending degeneration of the pyramidal columns.

The nature of the tumor is very rare in this situation. Very few such cases have been recorded: one by Abré, one by Athol Johnson, one by Virchow, and a case of myo-lipoma by Gowers. The paraplegia of the lower limbs, their extreme anæsthesia, the bladder weakness, the extreme contraction of both lower extremities, the increase of their tendon reflexes, need no comment. They depend partly on the compression of the cervico-dorsal cord, partly on the descending secondary degeneration of the lateral pyramidal tracts.

Of greater interest is—

1. The fact that, in spite of the extreme compression and degeneration of the affected part of the cervico-dorsal cord, the conduction through it, at any rate of intense impressions of pain, was still retained.
2. The fact that, in spite of the great degeneration of the compressed parts, the roots on the right side that came off from these affected regions showed only very slight degeneration, the roots on the left side none.
3. The fact that the left upper extremity could be moved as in health, without any paralysis or contrac-

tion; whilst the right arm was paralyzed and extremely contracted. The latter symptom was, doubtless, due to the great amount of stretching of the right spinal roots, in consequence of the displacement of the cord to the left; and a permanent state of irritation was present throughout, which gave occasion to tonic contraction of the right upper extremity.—*Bristol M. C. Jour.*

MATERIA MEDICA AND THERAPEUTICS.

ON THE USE OF CHLORATE OF POTASH IN BURNS AND SCALDS.—Dr. J. Walton Browne (*British Medical Journal*) recommends the use of a solution of chlorate of potash in burns and scalds as of the first importance. In the treatment of burns and scalds of the second and third degree the lotion is especially useful; in many of these cases perfect healing has taken place in four to five days. In severe burns of the fourth or fifth degree it is also useful, seeming to favor the formation of granulations after the separation of the sloughs, and certainly no other remedy so thoroughly keeps the wounds clean and sweet. In superficial forms, after a few applications, a zone of new skin appears at the margins of the broken surface, and proceeds towards the centre until healing is perfect. It is quite common to see a border of newly-formed cuticle in the short space of twenty-four hours. The method he adopts is as follows:

In superficial burns he directs the blisters to be punctured, and a bread-and-water poultice to be applied over all the injured surface every fourth hour, until the cuticle has been detached; this is generally accomplished upon the removal of the second poultice. Then pieces of lint of the required size, saturated with the solution of chlorate of potash, five grains to the ounce, are applied four times a day. The lint is covered over with gutta-percha tissue or oiled silk; all dressings being retained *in situ* by a bandage. The lotion must not be of greater strength than five grains to the ounce; of this strength it acts as a sedative, although at the same time stimulating the capillaries to the formation of new skin. If applied much stronger it causes pain—in fact, it acts as a caustic. In some cases, where the lint occasionally adheres to the wound, and is difficult of removal without injuring the capillaries and causing bleeding, Dr. Browne adds to the chlorate of potash solution some glycerine, in the proportion of two ounces to the pint.

In the treatment of very deep burns he advises the application of poultices until all sloughs are separated. Granulations then spring up, and nothing seems to increase their activity and vitality equal to the potash solution, of the strength of five grains to the ounce. Should the granulations become weak, flabby, or too exuberant, we then use a potash lotion of the strength of ten grains to the ounce, and at the same time prescribe a mixture of chlorate of potash and tincture of perchloride of iron to be taken three times a day. At any time, should there be offensive discharges, one can combine the potash solution with some permanganate of potash.

SATURDAY, NOVEMBER 22, 1884.

DIAGNOSIS OF DILATATION OF THE STOMACH.—In Vol. 3, No. 9, of this JOURNAL we called attention to M. Bouchard's paper upon this disease, as presenting some novel points of interest. He, it will be remembered, diagnosticates ectasis of the stomach by the presence of the succussion sound below an imaginary line, connecting the umbilicus with the last rib of the left side. Du Jardin-Beaumetz objected to this as unreliable.

It is interesting and instructive to see what other French and German authors regard as the chief diagnostic feature of this disease. Dr. Enrique de Argæz, in a recent monograph on "Adynamic Dilatation of the Stomach," (The *Medical Record*, Oct. 18, 1884) states that in typical cases he has observed a prominence of the epigastrium, and, more rarely, seen the peristaltic movements of the stomach through the abdominal parietes. Palpation generally yields the splashing sound, characteristic of the presence of gas and liquid in the organ; but the actual dimensions of the dilated stomach can only be determined by percussion. M. Germain Sée who was on service in the Hôtel-Dieu where de Argæz observed his cases, considers the existence of ectasis of the stomach proved, if gastric resonance extends more than twelve or fifteen centimetres beyond the line of the left nipple, or, if a succussion sound can be obtained six hours after eating.

Doubtless the most accurate method of determining the size of the stomach is by percussion, the low-pitched tympanitic resonance, elicited over the organ, being readily recognized when heard alone and unmixed. If the stomach contains liquid, or if the

intestines be strongly distended with flatus, or if there exists enlargement of the liver or spleen, the characteristic gastric resonance is masked, and it becomes impossible to outline the organ. Moreover, the position of the patient's body is of influence, and hence a diagnosis should only be attempted in the dorsal *decubitus*. Even under the most favorable conditions, it may be doubted if a diagnosis by this means is possible, unless the degree of ectasis be considerable. Roughly speaking, the normal situation of the stomach is between the median line and left hypochondrium, and the area of gastric tympany extends but a hand's breadth to the left,—to the lower curving border of the ribs downward and outward, while according to Lichtenstern its upper boundary is on the sixth rib, just below the cardiac impulse, at the apex of the angle formed by the liver and lung. This point is where the stomach most nearly approaches the anterior wall of the trunk and corresponds to its uppermost limit.

Lichtenstern was in the habit of percussing the abdomen by means of a pleximeter, and was thereby able to bring out a note of metallic quality, known in German as "*Metallklang*." He even went so far as to state that in several instances, in consequence of rapid peristaltic contractions of the stomach, he has recognized a scale of metallic notes of different pitch. This, however, is a refinement of diagnostic skill beyond the attainment of most practitioners. As a rule the general practitioner of medicine will have to content himself with his ability to detect the extreme degrees of gastric dilatation. W. P. H. Wagner, who has investigated the boundaries of the organ in question by Frerich's method of distending it with carbonic acid, states that during such temporary dilatation the left border of the great curvature reaches close to the left anterior axillary line, while a portion (one-seventh) of the lesser curvature passes beyond the median line to the right, thus leaving six-sevenths lying toward the left hypochondrium. Gerhardt ("Auscultation and Percussion," Tübingen, 1876) considers the diagnosis of this condition in most cases a difficult task, but rendered quite certain if gastric resonance can be elicited below the umbilicus, and to the right of the median line. Valuable aids to diagnosis are epigastric bulging, visible peristalsis of the organ, succussion sound, dyspeptic symptoms, etc. Gerhardt also says the pressure of adjacent organs does not displace, but only alters the shape of the stomach. Hence, percussion, by detecting the characteristic note of the stomach at some point outside of its normal limits, ought to afford the surest means now at command of an accurate diag-

nosis. According to Dr. de Argaez the diseases from which this condition of adynamic dilatation is to be differentiated, are gastalgia, gastric ulcer, chronic gastritis of alcoholism, fibrous stenosis of the pylorus, and carcinoma. In many respects the symptoms are similar, but in all cases the distinction turns on the discovery of ectasis in the way already detailed.

STATE BOARDS OF MEDICAL EXAMINERS.—A few weeks since we received from a member of the Ohio State Medical Society a copy of a proposed law for establishing a State Board of Medical Examiners in that State, accompanied by the request that we would publish the same and commend or criticise its provisions, as we might deem proper.

Accordingly we published the proposed law in full, under the head of State Medicine, in the number of the JOURNAL for November 1, 1884, and accompanied it by a short editorial in the same number, not criticising in detail the provisions of the act, but simply alluding to the difficulty of framing such laws in a way to accomplish practically the objects for which they are designed, and stating in general terms the principles on which they should be based and the essential provisions they should contain, leaving it for each reader to see wherein the provisions of the proposed Ohio law differed from what we deemed the proper ideal. For this we speedily received a sharply deprecatory letter from the learned Secretary of the State Board of Health of West Virginia, which we give our readers in full under the head of State Medicine, in this number of the JOURNAL. It will be seen that our correspondent has based his whole letter on the assumption that in our editorial we had opposed the establishment of State Boards of Medical Examiners altogether, and has therefore been deprecating the work of an enemy existing only in his own imagination. We commenced advocating the entire separation of the business of teaching medicine from the authority to grant licenses to practice and the establishment of State Boards of Medical Examiners, together with the adoption of a fair standard of general education before permitting the student to enter upon the study of medicine, before our correspondent was old enough to know the members of one profession from another. And we have continued to advocate the same on all suitable occasions from that time to the present. And in the editorial which our correspondent so much deprecates, we stated clearly the grounds on which the enactment of such laws could be justified, and the essential provisions they should contain. And if our correspond-

ent or the readers of the JOURNAL desire to examine our views on the whole subject of medical legislation, it is only necessary for them to turn to the address we delivered before the Association of American Medical Editors, at the meeting in Cleveland, June, 1883, which was published in full in Vol. 1, No. 2, of this journal. The proposed law for Ohio is in many of its features a good law. It is better in some respects than the law regulating the practice of medicine in Illinois, to the practical operation of which great benefits have been ascribed. Consequently, if the friends of medical legislation for securing a higher standard of education and usefulness for the profession in Ohio cannot agree upon certain alterations and additions, we would strongly urge its adoption by the Legislature as it is, trusting to the wisdom of future Legislatures for the removal of its defects. But we would much prefer that the first section of the proposed law should be amended by striking out the proviso, constituting the last three lines of the section. And from the second section we would strike out all after the word Governor. We can see no possible good to result from incorporating into legislative acts a recognition of any so-called "systems of medical practice."

The only legitimate object of such a law is to secure to the people the services of medical men or doctors, of thorough education and fair practical skill. Consequently neither in the selection of members of Examining Boards, nor in the methods of examination, should the law recognize, or attempt to make, any distinction regarding systems, sects, pathies, or isms in medicine. The appointing power should only be restricted in the selection of members of the Examining Boards to such members of the medical profession, as had themselves, received a thorough general and professional education, had been actually engaged in practice in the State not less than ten years, and had acquired a good moral and professional reputation. There should be no such distinction in the examination of candidates by the Board, as is made in Section six of the proposed law. The sole object of the examination is to determine the extent of the candidate's knowledge of the various branches of medical science and art, and of all the branches included in the list, none are of so much direct importance to the sick as those called, Principles and Practice of Medicine and Therapeutics. Consequently, instead of inquiring as to what theory or pretended system of practice, the candidate intended to adopt and shaping his examination accordingly, the Board should preserve the same uniformity and impartiality in the examination on these

as on all other branches. Indeed, the examination on these important branches should be so broad and thorough in all their ramifications, as to show the candidate to be possessed of sufficient knowledge of diseases and medicines to make him a reasonably safe practitioner under any supposed system of practice; then simply license him to practice medicine, in its broad and unqualified sense.

Section 8, of the proposed law, should be amended by striking out all after the words "of good moral character," and inserting in its place the following: "and has devoted three years to the study of medicine, including human anatomy, histology, physiology, chemistry, general and medical, materia medica, therapeutics, general pathology and pathological anatomy, hygiene and sanitation, medical jurisprudence, practice of medicine, surgery, obstetrics and diseases of women (the three latter including all the specialties carved from them), with clinical medicine and surgery in hospitals containing not less than fifty beds and an average attendance of not less than thirty patients; at least six months of each year having been spent in direct attendance on some legally established medical college having the necessary facilities for instruction in all the departments named, including laboratories for practical anatomy, chemistry, and microscopy."

Such a provision in the law, at once, defines what constitutes the necessary field of medical study for the guidance alike of the student, the college, and the Examining Board, and places the main condition for admission to an examination, not on the possession of a diploma from some supposed reputable medical college, but on proofs of having actually devoted at least three years to the study of medicine, in institutions having the necessary facilities for imparting instruction, both theoretical and practical.

This relieves the Examining Board from the delicate and doubtful work of legislating or making rules as to what shall constitute a reputable medical college, and strengthens its appropriate executive function in exacting the positive requirements of the law. It would relieve the student from the pernicious question as to where he could get a college diploma the easiest and cheapest that would admit him to an examination or a license by the State Board, and confront him with the positive necessity of studying medicine at least the minimum of time necessary, and in the institutions capable of giving him the necessary facilities for prosecuting his important work.

It would also strongly discourage the multiplication of medical colleges in every town where six or seven ambitious members of the profession might de-

sire to form a joint stock company, incorporate themselves under some general incorporation law, and thereby establish a so-called "legal medical college," whether they had at command any facilities for either clinical or laboratory work, or not.

If our much aggrieved correspondent in West Virginia will stop long enough to examine the bearing of the suggestions we have made, we think he will be constrained to admit, that the adoption of the amendments we have proposed would add very much to the practical value and efficiency of the law proposed for the great State of Ohio.

We do not think the condition of the profession in that State is so desperately bad that it is necessary to enact at once a very imperfect law, when further temperate, candid discussion might result in framing a much better one. It must be remembered, however, that our suggestions are not made for the purpose of opposing the enactment of any particular law in Ohio or elsewhere, but rather to direct attention to the correct principles on which all such legislation should be founded.

NO CURE NO PAY—A JUST DECISION.—The *Evening Star*, of Washington, D. C., dated Oct. 24, 1884, gives the result of a case in the Circuit Court of that district, which had been brought there on appeal from a Justice's Court, against a medical pretender of that city by the name of W. H. Hale, who publishes a paper or circular called "Health and Home." The doctor had received from a colored man named Meredith \$100, on a written agreement to cure the son of the latter, sick with consumption, or refund the money. In due time the son died, and Mr. Meredith brought suit in a Justice's Court to recover the money. The suit was twice tried before the Justice, and both times judgment was rendered against the Doctor for the sum which he had received. An appeal was taken to the Circuit Court, Judge Hagner presiding. After hearing the evidence on both sides, and examining the written agreement, the Judge promptly affirmed the judgment obtained against the Doctor in the court below.

CHOLERA.—During the past week the cholera epidemic has continued in Paris, but with some diminution in the number and severity of the attacks. Dispatches from Paris of the 17th and 18th of November, indicate an average of about forty deaths per day.

DR. DONALD McLEAN's case of nephrectomy and double ovariectomy, to which we alluded last week, has continued to progress favorably and is now considered convalescent. A full history of the case is promised for the JOURNAL in due time.

SOCIETY PROCEEDINGS.

CHICAGO MEDICAL SOCIETY.

Regular semi-monthly meeting of November 10, 1884.

A large attendance of members and visitors were present.

The following recent cases in the surgical practice of Dr. Edmund Andrews are of interest, because of the numerous unsettled questions which cluster around the operations referred to:

The first two cases instanced, viz: gastrostomy, which by way of preface was stated by the author to be a barbarous word—an etymological blunder so far as literary usages are concerned, composed partly of Greek and partly of Latin. The “philological monstrosity” being apparently an attempt by its author to enlarge the word gastrotomy, which literally signifies stomach-cutting, and by the addition of a syllable to signify a mouth, so as to make the compound mean a cutting of the stomach to make a mouth—literally a stomach-mouth-cutting. The writer dilated further upon the word relative to its derivation, meaning, etc., and closed by saying that the word should be gastrostomy, and even then there would be nothing left in the compound to signify the cutting; therefore to express the full meaning of stomach-mouth-cutting would require the form gastro-stomatomy, a term whose length and harshness of sound is sufficient for its condemnation. Suffice it to say, euphony in sound and scholarly composition, are two important requisites which are often ignored by skilled surgical authors as well as by those of pedantic pretensions. The following is a brief synopsis of the balance of the paper:

CASE I. was a little girl, aged six years, who swallowed some concentrated lye several months previously, cauterizing the lower part of the œsophagus and gradually inducing a stricture. Dr. E. P. Cook, of Mendota, Ill., dilated the stricture, after which the child was sent home greatly improved. After leaving his care she relapsed. She was then placed in care of the writer. Upon her arrival it was ascertained that she had been unable to swallow anything for a number of days. Dilatation was essayed, and the patient improved for a time, regaining a partial power of swallowing liquid food. However, it was soon perceived that the advantage thus gained could not be maintained, and after faithful trial it became evident that the little one was gradually starving. So-called gastrostomy was then performed [The surgeon insisted, however, in his remarks that gastrotomy is the more scholarly term.—Ed.] in a room which had been sprayed for an hour with carbolic acid, but the spray was not permitted to touch the peritonæum. The usual incision was made in the hypochondrium from the xiphoid cartilage downward and to the patient's left. The colon was found partly in the way, but it was easily pushed downward. The stomach was then drawn out with long-toothed forceps, the viscus was identified by the relations of the gastro-epiploica vein, and secured to the abdominal wall by a long suture

on each side. As starvation was feared, the stomach was opened at once, and its edges sewed closely to the skin all around the incision. There was a good deal of shock, but reaction occurred and union by first intention followed without difficulty and with no peritonitis. Peptonized food was regularly inserted, and on inspection was found perfectly digested, except when meat was used. This, whether raw or cooked, would be ejected from the wound unchanged even when retained 24 hours. For some days the patient improved, but it soon became evident that most of the food though digested did not pass through the pylorus. It seemed that this orifice of the stomach required a little pressure to unfold it, and that whenever the stomach contracted for the purpose, the chyme escaped by the fistula into the dressings, and did not pass on into the intestines. A rubber pad tight enough to stop the outflow could not be tolerated. A soft rubber tube with a flange and valve was substituted, in which the inner disc could be adjusted to the inner wall of the stomach. Then by clamping the tube outside of the outer disc to the wall of the abdomen a perfect valve was obtained, which prevented leakage. The effect of the inner disc on the walls of the stomach was feared at first, but it produced no perceptible irritation. The opening in the stomach was purposely made pretty large, the surgeon hoping at a future time to introduce a finger upward into the lower end of the œsophagus, and then by pushing down upon it, would succeed in restoring the natural passage. As above stated, the valve retained the food perfectly, and the patient took an abundance, and even learned to know when she was hungry and to call for her meals. The improvement was but temporary, however, and she began slowly to fail without obvious cause. The power of assimilation seemed to exhaust itself, and she constantly grew weaker. At the 35th day after the operation, it became evident that she was at about the end of her life. The last 24 hours were accompanied by an obscure fever.

CASE II.—An adult male patient. Six months ago he swallowed some caustic ammonia, producing a contracting ulcer of the lower part of the œsophagus. In September last he placed himself in the care of the writer, having been unable to swallow anything for some days. By a persistent use of bougies the stricture was dilated and the power to swallow liquid food restored. He then returned home, having learned to introduce the bougie himself. In time, however, he lost the art of passing the instrument, and in October returned, in the same condition as before. Diligent trials to dilate the stricture a second time gained only a slight temporary power of passing small quantities of liquids a day or two at a time, and within a week or so it was perceived that his progress was downward and that he was slowly starving; moreover the points of the bougie seemed to be creating a local inflammation in the right lung, as if they were making a false passage in that direction; to continue their use, therefore, was not deemed judicious and they were accordingly discontinued, and an operation was decided upon at once and not allow the patient to become weaker. The operation

was the same as in the former case except that the opening was smaller. The same difficulty of regurgitation of the food occurred and was controlled by a similar valve. The patient is now doing well and bids fair to recover, and at time of reading the paper, thirty-two days since the operation, is improving nicely. The plan pursued by Mr. Howse, of London, and those of other surgeons was dwelt on to some extent, with their advantages, disadvantages, etc., etc. The operation should be done with extreme caution. Regarding the statistics of this operation, this is not very cheerful. Of 207 recorded cases, forty were for cicatricial stricture of the œsophagus like those just recited. Of these forty, twenty-one died. Yet, when no other hope of life or relief is offered, an operation which gives them one chance in two is a great benefit.

Excision of the rectum, of which the author cited two cases that he at present has under treatment, as follows:

Case I. was epithelioma, not reaching down to the verge of the anus. In operating, the entire external sphincter was saved, the incision was carried from an inch in front of the anus back to the coccyx, opening the anus anteroposteriorly and cutting off the gut just above the verge. After dissecting it upward a little and tying numerous vessels, the rectum was separated from the pelvic chamber mainly with the finger and the *tube* divided about three inches upward, just above the top of the cancer. There was no shock and not much subsequent pain or inflammation.

The second case was almost exactly a repetition of the first, except that the verge of the anus was involved in the disease, and consequently was dissected out with the rest. Both patients are doing well and are exceedingly comfortable, but it is too early to state whether there will be any return of the disease.

Statistics: The statistics are much like those of epithelioma elsewhere. Billroth, of Vienna, thinks he permanently saves about one-third of the cases. Other authors were cited, and lastly, of 608 cases collected, 140 died of the operation, and of one hundred of those who survived the operation whose accounts were traced up, thirty-one were doing well at the end of the year, and seventeen were alive and well with no return at the end of three years.

LITHOLOPAXY.

Dr. Andrews has operated twenty-three times, with one death. He is confident that the plan he pursues, of keeping the nerves of the bladder benumbed during the operation by filling it with carbolic water, tends powerfully to prevent both shock and inflammation. It is worthy of inquiry, said he, whether the remarkable local anæsthetic properties of the new agent, cocaine, would not enable us to operate without ether and without producing shock. * *

A new instrument for operating on varicocele was the next topic discussed by the writer. Operations for destroying the veins in varicocele have produced occasionally death, and in other cases resulted in neuralgic scrotum with or without atrophy of the testicle. Many surgeons have followed the lead of Prof.

Frank Hamilton in preferring Sir Astley Cooper's plan of shortening the scrotum sufficiently to make it its own suspensory bag. This operation is vexatious, because the imperfect character of the old-fashioned adhesive plasters rendered it difficult to support the sutures sufficiently to secure union by first intention. Now that we have the rubber plaster, which never lets go its grip, we can cut the scrotum very short, and still hold the wound firmly together and secure a triumphant success. Sundry clamps have been invented to hold the skin of the scrotum firmly while the surgeon cut it off and sewed it up. The evil of the clamp is that it compresses the arteries, so that after cutting away the pouch, the surgeon is unable to find and ligate the vessels. If he sews up the wound without attending to this point, experience shows that after the clamp is removed hæmorrhage often takes place inside the scrotum, distending it with clot and forcing open the wound, thus delaying the cure. To meet this difficulty the author has devised a kind of varicocele bow, which he exhibited and described as follows: It consists of two curved parallel bows connected at the ends and enclosing a slot three-eighths of an inch wide between them. Twelve holes are drilled through the bars of a size to admit ordinary pins. The surgeon draws the scrotum through the slot (having the concave border toward the base of the scrotum) to such a distance as he deems sufficient, secures it there by inserting one by one as many pins as he finds necessary to hold the pouch securely. He then cuts off the scrotum outside the convex border of the bars. As the scrotum is not pinched by the instrument, the blood spouts freely, especially from the artery at the raphe. The operator can carefully and deliberately secure every bleeding point. This being accomplished, he sews the cut edges together, and then drawing out the pins removes the bow and applies his plasters. The neatness and despatch of the operation are thus greatly enhanced.

An interesting and appropriate paper, "The Fourth Annual Report of the Shan-Tung Dispensary and Hospital at P'ang-Chia-Chuang," prepared by Dr. Henry D. Porter, who was for a number of years a resident missionary in China, was read by Dr. John H. Chew.

The report was an able one, and contained the essayist's views and experiences in Oriental diseases. The address also of the gentleman delivering it was keenly appreciated, by the expression from the Society in the form of a vote of thanks. But for want of space we are obliged to forego its publication at this time.

In behalf of the Committee on *National Sanitation*, Dr. John Bartlett presented the following report:

Mr. President: The committee appointed at the meeting of this Society, Sept. 15, 1884, to consider and report upon a series of resolutions presented by Dr. Liston H. Montgomery, having reference to *National sanitary* matters, respectfully report the following preamble and resolutions as suitable to be adopted.

WHEREAS, Experience has firmly established the fact that the ravages of certain infectious and conta-

gious diseases may be in good measure prevented, controlled or arrested by the enforcement of suitable sanitary regulations, and

WHEREAS, The United States is constantly exposed to the importation of disease from foreign countries, and, because of the facility and rapidity of inter-state transit to the rapid spread of infection once finding lodgment on our borders; and

WHEREAS, This exposure, because of the prevalence of cholera in Europe just now, is unusually great, and

WHEREAS, The facts are that matters of sanitation are in some of the States of this Union entirely neglected, while in others they are simply taken cognizance of by the appointments of Boards of Health, in their functions, advisory only, and not vested with powers of authoritative action; and

WHEREAS, Either of these State Boards of Health as now constituted may prove derelict or inefficient in its duties, or act without concert with, or even in antagonism to the Boards of other States, and

WHEREAS, The exigencies occasioned by the appearance of violent epidemics, demand organized means for the prompt recognition of the outbreak of disease, and vested authority, limited in its area, by the boundaries of country only, to take such immediate steps in matters of protection, as vaccination, isolation, quarantine, etc., as experience has taught to be useful; and

WHEREAS, No National authority in sanitary matters now exists, therefore

Resolved, That it is the judgment of the Chicago Medical Society that the sanitary interests of the United States demand the establishment of a National Health authority, which shall have for its main functions, the detection of pestilential and epidemic diseases, and the enforcement, where necessary, of sanitary regulations tending to prevent, to abate, or to suppress them.

Resolved, That as a step toward the consummation of the idea suggested in the foregoing resolution, a committee of three be appointed by this society to collate facts, tending to show the usefulness, and necessity of a National sanitary organization, and to compile the same in such form as may be available for disseminating information upon, and creating an interest in National sanitary legislation.

Resolved, That the said committee be empowered and instructed to urge the importance of national sanitary legislation upon the attention of the congressional delegation from Illinois, and fittingly to present the subject to the Representatives of the People in both Houses of Congress.

All of which is respectfully submitted,

O. C. DE WOLF, <i>Chairman</i> .	} Committee.
R. E. STARKWEATHER,	
L. H. MONTGOMERY,	
JOHN BARTLETT,	
J. H. ETHERIDGE,	
A. R. JACKSON,	
J. H. HOLLISTER,	

Upon motion duly seconded, the resolutions were voted for "seriatim," and were unanimously carried.

Then another motion that the suggestions embodied therein be adopted, also unanimously prevailed, and Drs. John Bartlett, Ralph E. Starkweather and John H. Hollister were appointed members of the committee.

The following interesting papers were then read by Drs. Boerne Bettman, and Jefferson Bettman.¹ And at a late hour, a motion prevailed that the society do now adjourn.

"MURIATE OF COCAINE AS A LOCAL ANÆSTHETIC," BY
DR. BÖERNE BETTMAN, M.D., CHICAGO.

Hardly two months have passed since the introduction of this valuable adjunct to medical science. Already many clinical and physiological observations have been made and noted down in our medical archives. Glowing indeed are the descriptions sent to us from the East of the wonderful effects of this drug. To Dr. Noyes must be assigned the honor of having first called the attention of American physicians to this new anæsthetic. In his letter from Kruznach, dated September 19, he briefly reviews the work performed by the Ophthalmological Congress in Heidelberg, and devotes particular attention to the interesting experiments performed by Prof. Becker in the presence of the assembly with the muriate of cocaine. These remarks relating to the new discovery were the first intimation of the existence of so powerful an anæsthetic and of so great a boon to suffering humanity.

The next number of the *New York Medical Record*² contains short articles by Drs. C. R. Agnew, W. Oliver Moore, and James L. Minor, relating to the matter in question.

These gentlemen report eight cases treated and operated on under the effects of this drug. The results elicited appear magical, and have called forth unbounded enthusiasm. The publications of Drs. Gruening³ and Claiborne demonstrated the wide range of utility of the article. Tenotomies, iridectomies and cataract operations have been made after instilling a few drops of a 2 per cent. solution of cocaine into the eye, without the slightest discomfort to the patient. A case of hypertrophic catarrh is also mentioned, where the galvano-cautery was applied to the inner part of the anæsthetized nose without pain. Dr. Knapp's experiments relating to the physiological action of the drug, demonstrate its numbing effects on the eye, rectum, urethra, and other mucous membranes of the body. My friend, Dr. A. W. Harlan, has in several instances filled teeth, which were rendered insensible to touch by a drop of the cocaine. Dr. Polk has used it successfully in two operations upon the cervix uteri.⁴ It appears that Dr. Koller, the student of Vienna who discovered the application of muriate of cocaine to the eye, became aware of its anæsthetic qualities from

³ *New York Medical Journal*, Nov. 7, 1884.

⁴ *Medical Record*, Nov. 1, 84.

seeing it applied to the larynx by German specialists to deaden the sensibility of the vocal cords.

The remedy is the alkaloid, the active principle of the leaves of erythroxylon coca, a shrub growing extensively in South America. I succeeded in obtaining a few grains of the highly prized drug, which I used with excellent results in the following cases. In order to acquaint myself with the action of the remedy, I first tried it on the left eye of my brother; also on my right eye. A short account of my observations may serve as an introduction to the clinical data:

I instilled two drops of a 4 per cent. solution of muriate of cocaine into the left eye of my brother, Dr. Jefferson Bettman. After a few moments he remarked that the eyelids felt stiff. In two minutes complete anæsthesia had set in. I now was able to touch the inner surface of the lids, the cornea, and other parts of the globe, with a probe, brush and finger, without giving him the slightest pain; in fact the only intimation of these manipulations was revealed to him by the sense of sight.

His myopia in this eye is equal to 2.5 dioptrus, with a glass of this strength $V=\frac{6}{6}$. Sensibility began to return at the end of ten minutes, application of a probe, brush or finger to the eye, now caused him to wink; though producing but slight discomfort. Complete sensibility returned only after 15 minutes. The pupil began to dilate at the expiration of 16 minutes, the mydriatic effects of two drops of cocaine was moderate.

Dilatation gradually increased, at 12 o'clock, two hours after the application, the mydriasis was middling. These experiments were repeated the next day, the effects were more pronounced and lasting on repeated application of the remedy. Four drops produced complete, ad maximum dilatation in 25 minutes, still the iris responded promptly to light. The pupil did not regain its normal size until the next day, 24 hours later. The range of accommodation was not perceptibly influenced.

At five minutes past two in the afternoon two drops of cocaine were put into my right eye. Three minutes later sensibility was decidedly diminished, two drops more were instilled at ten minutes past two, and at 2:14 two more drops. A quarter of an hour after the first instillation, the eye was in a complete anæsthetic condition; pressure of a probe against the cornea was not felt, neither did the application of a brush, pin or forceps cause the slightest annoyance. Dilatation of the pupil became perceptible after a quarter of an hour. My eye is emmetropic, the weakest convex glass + 72, produces a cloudiness of vision. After the eye had been rendered insensible to touch, my distant range of vision remained the same, + 72, producing slight obscuration of sight. My near point had receded from 4 inches to 12. It required a convex glass of 14 to enable me to read Snellen 0.5, at 4 inches from the right eye. This I could do with the left eye unaided. At the expiration of half an hour my pupil was dilated almost ad maximum, sensibility now began to decrease, the benumbing effect of the remedy had entirely passed away in three-quarters of an hour.

The Mydriasis lasted eight hours.

The outer surface of the right lower lid was also rendered insensible to touch, the pricking of a pin not being noticeable on this lid, while it was painfully evident when applied to the left lower lid.

CASE I.—Oloff D., æt 33, on examination was found to be hypermetropic 2.d. in the right eye, 1.5.d. left eye; there was also a chronic dacryocystitis and stricture low down in the nasal duct. Before attempting the passage of a Bowman's Probe I instilled several drops of 4 per cent. sol. of the muriate of cocaine. In not quite two minutes a probe was pressed against the cornea and not felt by the patient. The pupil dilated ad maximum in ten minutes. Weber's knife was introduced into the canaliculus, shoved forward into the sac and the duct slit open. The last act of the operation caused some pain, while the first steps passed unnoticed. I now injected by means of an Anel's syringe, several drops of muriate of cocaine through the sac into the nose. At the end of about five minutes I passed the probe and forced the stricture which was very firm. The pain was but trifling, 75 per cent. less than that experienced five years ago, when he had been subjected to a similar operation. A stronger glass was rejected. The anæsthesia began to decrease in twelve minutes, when he left my office a few minutes later, the parts had returned almost to their normal state. The accommodation was decidedly affected in the near point having receded several inches.

CASE II.—A policeman came to me with a foreign body embedded in the cornea. The eye was very sensitive, the piece of steel having been in situ three days. Two drops of cocaine produced complete insensibility of the eye in two minutes. The digging out of the mote with a spud was entirely painless. The drops of cocaine mixed with tears ran down over the cheek into his mouth and produced a numbness of that side of the tongue bathed by the fluid.

The application of this remedy in other parts of the body is equally beneficial.

CASE III.—Mr. M. consulted me for a terrible ear ache, due to an Otitis Media Purulenta Acuta. He was suffering great pain and would barely permit the introduction of a cotton holder into the outer meatus. The introduction of two drops of cocaine was followed by almost immediate cessation of pain. I syringed the ear, cleansed it thoroughly, several times I purposely touched the M. T. with the probe and he felt absolutely nothing.

CASE V.—The most striking results I have thus far obtained were in the case of Mrs. T., on whom I operated for cataract November 2d. The instillation of several drops of cocaine, repeated every few moments, produced in ten minutes complete anæsthesia. The patient was placed in bed, a speculum introduced between the lids. This the patient felt slightly.

The eye was now grasped with a fixation forceps, which I afterward found was entirely unnecessary, since she held admirably well. The corneal section was made without the patient being aware of the fact. She at least did not make it known either by motion of the eye or a cry of pain. The only step in the operation which caused the slightest pain was excision

of the iris. At this stage of the operation when questioned as to the sensation, she remarked it felt as if a pin was pricking her. The cataract was hypermature. The lens was expelled with some difficulty. She expressed herself highly pleased with the action of the drug, assuring me again and again that with the exception of the pricking pain just mentioned she felt absolutely nothing. She had been advised years ago to have the eye operated on, but owing to the dread of any surgical interference and the pain, she had delayed it so long.

In reviewing the above we may tabulate the physiological action and therapeutical effects as follows:

1. It is a powerful local anæsthetic not penetrating in nature, rapid in its effects, which, however, are only temporary.

2. It is a mydriatic, the effect of which is regulated by the strength of the solution.

3. It produces paralysis of the ciliary muscle, the near point receding from the eye. Distant vision is not influenced.

4. By virtue of its benumbing powers it may be classified as an anodyne.

LISTON H. MONTGOMERY,
Secretary.

STATE MEDICINE.

STATE BOARDS OF EXAMINERS.

WHEELING, W. VA., November 5, 1884.

N. S. DAVIS, M.D., EDITOR OF THE JOURNAL OF THE
AMERICAN MEDICAL ASSOCIATION.

My Dear Doctor:—I have read your editorial on "State Boards of Medical Examiners" in last Saturday's JOURNAL with inexpressible sorrow, for the reason that your words and opinion on the subject, however untempered and erroneous in argument, will be instantly caught up—because of your high professional position and great influence—and effectively used by cunning quacks to antagonize and defeat the passage of the proposed law in Ohio to protect the people of that State against ignorance and villainy in medical practice.

Within the past three years Ohio has become a sort of *penal colony* for medical quacks who have been driven from Illinois and West Virginia by the operation of wise laws in these two States for the protection and safety of the people against ignorant, incompetent, and unprincipled persons calling themselves physicians. Indeed, to such an extent has Ohio been invaded by pretenders in medicine and surgery, that at present the State is almost overrun by that class of doctors, and the medical profession proper is thereby accordingly disgraced. Yet this large army of quacks are trembling in their boots from fear that the next Legislature will deprive them of their present liberty to trifle with human life and the public health.

How they will thank you for coming so unexpectedly and influentially to their aid in opposing the deliberate judgment and earnest, heartfelt wish of the Fellows of the State Medical Society! They will

carry in their hearts and on their lips your comforting opinion that "to establish State Boards of Examiners, and confer on such Boards unlimited power to determine what shall constitute a proper medical education, * * * is not only contrary to the genius of our governments, State and National, but is putting into the hands of a few men a power which they may wisely and honestly exercise in such a way as to elevate the standard of medical education, * * * or they can just as readily wield it in such a way as to lower that standard, and foster both ignorance and oppression."

But admitting the possibility of the appointment of unworthy and bad men, is that a sufficient argument to discourage the establishment of such Boards? May not the highest office in the national government, as well as within the gift of the State, be abused and disgraced by an unfaithful and incompetent officer? Are not such examples found both in Church and State? And should organized government, therefore, be opposed because of the possibility that bad rulers may endanger the liberties of the people? Should holy religion be decried because of the unfaithfulness sometimes of priests and bishops?

Your argument, to have point, should have given an example of the abuse of power by an Examining Board, and the community in which such "ignorance and oppression" have lowered the standard of the medical profession.

Can you for a moment doubt the good effect of the law regulating the practice of medicine in your own State—Illinois, its success as a means of restraining quackery and encouraging higher medical education? Can you question the wisdom of the Legislature in passing the law? Also the learning and justice of the decision of the Supreme Court in maintaining the constitutionality and validity of the Medical Practice Act? Can you doubt the higher standing of the medical colleges in the State of Illinois since the establishment of the State Board of Health? And can you deny that the *esprit de corps* of the medical profession in Illinois has been greatly improved by the labors of the State Board of Medical Examiners?

If you answer "Yes" to these questions, then let me beg you to turn your attention to West Virginia and compare the present rapidly rising standard of medical education under the influence of the statute regulating the Practice of Medicine and Surgery, with the situation four years ago, when any ignoramus could don the name Doctor and prey without hindrance upon the lives and property of the people; when the *passport* of such disgraceful diploma mills as the *Physio-Eclectic Medical College of Ohio*, run by Nicely, Van Sickel & Co., at Cincinnati (now, the *American Eclectic Medical College of Cincinnati, Ohio*), could not be questioned; and when traveling medical-showmen were permitted to beguile the people and carry off their substance,—I say compare the days of such unlicensed medical practice with the present orderly registration of those legally qualified to practice, and you will find many complete and convincing answers to your surprising and, I think, pernicious criticism on "State Boards of Medical Examiners," as well as to your vigorous protest against

the passage of laws that hinder the liberties of impositors in medicine.

In neither of the States having Boards charged with the duty and power to regulate medical practice has there been shown the slightest excuse for your seeming *dread* of official discrimination against "any sect" or so-called school in medicine. Like the sciences of mathematics and philosophy, anatomy, physiology, chemistry and pathology are precisely the same in all languages and in all colleges or schools of medicine; and it is the *quantity* of correct knowledge of these and other elementary branches that fits a man or woman for the office of physician and surgeon, and entitles him or her to legal protection—not that he is "regular" "homœopathic," or "eclectic" in his practice or treatment of diseases.

But you may challenge my presumption in demurring to your utterances disfavoring the passage of the proposed Medical Bill in Ohio. If so, let me assure you of West Virginia's hearty sympathy with Ohio in this matter. We are gathering every day good and substantial fruits from the operation of the law regulating medical practice, and earnestly desire that our professional neighbors "o' the border" shall be saved from the continued shame and mortification of witnessing the coming to their midst of quacks who have been denied a resting-place in West Virginia.

Last week the Supreme Court of Appeals of West Virginia placed the State Board of Health on high legal ground; and thus our labors in medical registration have not been in vain. In a case brought up from an inferior court by a man who had been refused registration on the basis of a diploma from *The American Eclectic Medical College of Cincinnati, Ohio*, the Court unanimously decided: 1st, that the law regulating the Practice of Medicine and Surgery is constitutional and valid; and, 2d, that the question of the reputability of a medical college is to be decided by the State Board of Health—not by the courts.

And now, if I have shown much earnestness in my effort to parry your hard blow at State Boards of Medical Examiners, you must charge it to my fear that your opinion may do great harm in Ohio, and indeed wheresoever an effort shall be made to secure similar legislation. But I beg you to believe me none the less

Your sincere friend,

JAMES E. REEVES.

BOOK REVIEWS.

DISEASES OF THE NOSE. By CLINTON WAGNER, M.D. New York: Bermingham & Company. Cloth. 247 pages. Price, \$2.50.

After introductory chapters on the anatomy and physiology of the olfactory apparatus, the author fully discusses the diagnosis and treatment of the various diseases affecting its several parts. Respecting nasopharyngeal polypi of a malignant nature he quite properly recommends radical treatment. This requires a formidable operation in order to sufficiently expose the growth for complete removal. It is im-

peratively demanded at an early day as the natural termination of the disease is death, and delay simply increases the difficulty of the operation. The book contains some very good illustrations and the report of numerous interesting cases.

C. E. W.

VISCERAL NEUROSES. By T. CLIFFORD ALLBUTT, M.A., M.D. P. Blakiston, Son & Co. Philadelphia: 1884. Cloth, 103 pages. Price, \$1.50.

This brilliant little book contains three lectures delivered at the Royal College of Physicians in March, 1883.

The author in his preface calls attention to the humbuggery of modern specialists, and in his introductory lecture makes a most telling attack upon the bad practice of gynæcologists.

The second and third lectures consider respectively gastralgia and enteralgia, differentiating these affections from hysteria, a distinction often lost sight of.

His plan of treatment is based upon the general principle that neuralgia is the result of an exhaustion of the general vitality of the patient.

The work is written in charming style, illustrated by many cases from the author's practice, and published in a good type; thus it is easily read, entertaining and instructive.

ORIGINAL ARTICLES.

REPORT OF A CASE OF CONGENITAL EN- CEPHALOCELE.

BY JOHN H. DUNCAN, M.D., KANSAS CITY, MO.

Read in Section of Diseases of Children of the American Medical Association, May, 1884.

The comparative infrequency of encephalocele as a congenital malformation, the caution advised by authors as regards operative procedures for it, and the gratifying results which I have recently had in the management of a case, lead me to make this report. It was to me a very interesting case and one which I followed closely, though I regret, that owing to the bad hygienic surroundings, I did not watch it as assiduously as I should. Before presenting the case, I ask your indulgence for a few moments, that I may review cursorily the history of encephalocele, for it may be of interest to you as it certainly has been instructive to me.

The writers of the latter part of the eighteenth and beginning of the nineteenth centuries spoke of it only as "Hernia Cerebri" and "Fungus Cerebri." It is a protrusion of the brain tissue from the cranial cavity, generally in the course of a suture or fontanelle, when congenital, and in other situations when traumatic. Its size varies and it increases gradually, becoming sometimes very large. Gross reports a case in which the tumor was as large as the child's head. There are then two varieties of encephalocele; the one a congenital malformation, the other, traumatic. In this paper, we only consider the former. Being situated in the course of the sutures and fontanelles, it was supposed by the older writers to be due to deficient ossification, which is partially correct, though the real cause certainly is within the cranial cavity and associated oftentimes with ulceration of the dura mater at the point of the tumor as well as sometimes with cerebritis. In by far the great majority of cases reported the integument was perfect but in a few even that was wanting. Dr. Burrows, in 1810, describes a case of this kind as follows: "The whole of the forehead, summit, and greater part of the occiput were deficient, and in lieu of them a substance projected of a light mulberry color and of the mushroom form, except that it was proportionately broader. From the deficiency of bone the

eyes appeared to project much more than usual. The child lived six days without even taking sustenance or having an evacuation." Bryant, in his work, refers to a case, by Lichtenberg, in which the tumor was hanging from the child's mouth, through an opening in front of the "Sella Turcica." Cooper reports a case which lived 33 years without any marked change in the intellect. Prescott Hewett, in "Holme's System of Surgery," reports two cases in which the cerebral structure protruded from the anterior nares and external auditory meatus, both of which proved fatal. The same writer also presents two other cases, one occurring at St. Bartholomew's Hospital, the other taken from the *American Journal of Medical Science* for 1859, wherein the brain tissue appeared at the above mentioned situations, and which ended in recovery. Spring, in 1853, mentions a case in which the encephalocele involved the entire left hemisphere: patient recovered and lived eleven years. Laurence has recorded seventy-nine cases, only six of which reached adult life. The cases to which I have just referred are certainly remarkable ones and not by any means typical cases of congenital encephalocele. Ordinarily the tumor is either in the occipital region or at the anterior fontanelle. It pulsates, bleeds freely if irritated, grows gradually if it is progressive, creates primarily very little if any general disturbance, but secondarily stupor, vomiting, etc.; especially does pressure upon it produce momentary coma and cerebral disturbance. Patients may die from asthenia or cerebral hemorrhage. Bryant says it may be mistaken for a simple cyst, and unless positive as to its character we had better leave the case to nature.

Various methods of treatment have been recommended from time to time, among which are: (1) compression, (2) ligation, (3) complete and immediate excision.

In comparing the treatment of the surgeon of to-day with that of those of 75 or 100 years ago, I find that we are more prone to trust to nature for the excision of the tumor by ossification, than we are to operative means. I suppose this is correct as a rule, but I am satisfied that it will not suffice in all cases. On the other hand, the earlier surgeons favored more the knife, but I was surprised to learn that among them only one, Van Swieten, recommended and practiced with success in several cases *ligation*. As to compression by zinc plates, caps, etc., which has been recommended, they have been found to be only of slight value, and of course utterly valueless and harmful after the tumor has become larger than the

opening through which it came. From my investigations of the subject and my experience in this one case, I would advise trusting to nature to check the growth of the tumor or to remove it by closing the fontanelle or sutures, and when she fails the removal of it by ligations. This simple operation is safer than, and certainly just as effective as the knife. While, however, the removal of an encephalocele by excision is generally accompanied by copious and maybe fatal hæmorrhage, yet Quesnoy reports a case in which the patient tore off the protruded mass himself, and the parts healed without any bad results.

I will now report the case I have recently seen.

Willis M., colored, born August 28, 1882. When about seven (7) weeks old he was brought to me by his mother. I found a tumor about $\frac{3}{4}$ of an inch in diameter, situated immediately over the anterior fontanelle. This mass was covered by integument, was not smooth but regularly grooved, moved with each cardiac pulsation and even at this time had the characteristics of brain tissue. The following was obtained from the mother: She is a short, muscular, healthy woman, 40 years old and weighs about 200 pounds. She is the mother of 12 children, all of them with the exception of this one, without any deformity. She says that the week just previous to her last labor she was daily engaged in carrying coal up several flights of stairs; also that her labor lasted, to use her expression, "longer than with any three of her other children and the suffering much greater." I questioned her closely on this point, and from her repeated statements on various occasions, I believe labor lasted from twenty-four to thirty hours. She says that as soon as she looked at the child, she saw a small lump about the size of a bean on the fore part of the head, bluish in color and smooth. However, this lump grew, and as it grew it lost its smoothness and blueness, until when I saw it seven (7) weeks after birth it was as I have described above. I presented the case to my class and it was also examined by various members of the medical society of the county. Before interfering with it and as the child was not suffering in any way perceptible from it, I decided to follow the advice of surgeons and wait and see what nature would do in the case. I, however, gave the mother a simple ointment to allay any irritation and ordered that the child be returned to me every two weeks and oftener if necessary.

This course was followed until about the middle of December following, during which time the tumor was gradually but very slowly increasing in size. Now there was slight nausea at times, some emaciation and some stupor. Two days after the last regular visit which was December 11, the mother, very much excited, returned with the child. And I must say, when she uncovered its head and I saw the condition of affairs, I was, until she gave a history of the last two (2) days, surprised at its size and appearances. The tumor now was as large as an ordinary orange and in short it was 5 or 6 times larger than when I saw it only two days before. Brain tissue was now distinctly marked, no indications of hydrancephalocele; pedicle filling up the opening in the skull and the mass moving with each pulsation of the heart. The

child now was extremely nauseated, even throwing up its milk. I think I can give a rational explanation of this sudden enlargement:

During the two days that the tumor enlarged so rapidly, the mother was compelled to be absent from the child the greater part of both days. The grandmother was left in charge, and she informed me that during that time the child cried a great deal and very violently, and that during the fits of crying she could plainly see the tumor getting larger, or, to use her expression, "see the lump filling out."

I concluded I had given nature a fair trial, and decided to remove the mass. It was now bleeding freely when touched, and fearing hæmorrhage, I ligated it. From the moment I ligated it, all nausea and vomiting ceased. I re-applied the ligature about Jan. 1st and 15th, and had the satisfaction of learning from the mother, in the latter part of January, that the tumor had dropped off. I visited the child and found the proximal end completely healed, thus cutting off all communication with the cranial cavity through the anterior fontanelle. I saw the child last February, or one year after the removal of the tumor; there were no indications of its reappearance, and physically and mentally it was as well developed as children generally are at its age.

REPORT ON THE DISEASES OF THE EAR

IN LOCOMOTIVE AND OTHER ENGINEERS, FIREMEN AND CONDUCTORS, WHICH MAY ENDANGER THE LIVES OF THE TRAVELING PUBLIC.

BY LAURENCE TURNBULL, M. D., PHILADELPHIA,

Aural Surgeon to Jefferson Medical College Hospital, and Instructor in
Otology Post-Graduate Course, Jefferson Medical College, Philadelphia.

Read in Section of Ophthalmology, Otology and Laryngology of the
American Medical Association, May, 1884.

In 1875¹ we made a series of experiments on the perception of "Musical Tones by the Human Ear."

Before giving the writer's experiments, in detail it will be proper to state the results obtained by other observers. The discrepancy, in our opinion, can only be accounted for in three ways. First, variations in the sound conducting portion of the auditory apparatus; second, defect, original or acquired, in the perceptive portion, and third, want of cultivation.

"Savart" fixed the lowest limit of the human ear for musical sounds at eight complete vibrations a second, by means of a toothed wheel and an associated counter, and the highest limit at twenty-four thousand vibrations. "Helmholtz" has fixed the lowest limit at sixteen vibrations and the highest at thirty-eight thousand. "Vierordt" gives the highest tone as forty-eight thousand, and "Desprets" as seventy-five thousand. The following table contains a series of

¹Proceedings Am. Ass. Adv. Sci., 1875.

experiments which were found to vary with the age and condition of the hearing apparatus of the individual.

FIRST SERIES OF EXPERIMENTS.

Age.	Distance.	No. of Vibrations.
15.....	35 feet.....	40,000
18.....	" ".....	40,000
21.....	" ".....	35,000
25.....	" ".....	30,000
30.....	" ".....	25,000
50.....	" ".....	25,000
60.....	" ".....	20,000

In only one instance in a trained musical ear were sixty thousand vibrations in a second heard.

In May, 1879, I called the attention of the medical profession to the fact that I had found a number of persons who were naturally insensible to sounds above a certain pitch, just as it has been ascertained that there are individuals who cannot distinguish between different colors or certain rays of light of high refractive power.

Accidents have occurred to the public from such causes when persons so defective have had charge of the signals or sounding apparatus, such as are usually employed in case of danger to life.

In the following is a second series of experiments made in May, 1879. The subjects were all scientific men, either physicians, medical students or lawyers. The rods were of steel held within two inches of the ear; their temperature was about 70° F. The observations were conducted in a room remote from noise; weather cloudy and drizzling.

Years.	Initial.	Vibrations.
From 20 to 30	22 G. H. R.	50,000
	23 A. De W.	50,000
	24 D. J.	55,000
	24 J. M.	40,000

	48 R. M. S.	40,000
	52 E. R.	45,000
	57 L. T.	30,000

It will be seen by these and numerous other experiments which have been made by us, that the highest musical tone obtained in a normal healthy ear, not specially trained, did not exceed in any instance a fraction over forty thousand vibrations in a second. Education of the ear, to the recognition of musical tones, is as necessary as the training of the athlete to walk, run, box, row, bat or lift weights.

It was discovered that many individuals, even

professional men who considered their hearing perfect, were found to be defective in one ear, either from cold or hereditation, or from sea or fresh water bathing, or from inflammation passing along the nostrils, pharynx and Eustachian tubes, to the middle ear, from what is termed an influenza, a coryza, or simple cold in the head.

Cases have been found by us where one or even both these defects have existed from birth in the same individual, that is, a person who was color-blind, also, had "no ear for music." Defective hearing was also discovered in engineers who have charge of stationary or marine engines, and also in conductors on steam trains, also on ordinary passenger cars of our city railroads. By this defective hearing the signal call with the voice or bell is not heard, and collisions have taken place, individuals been injured, and valuable lives have been lost.

The following are a few of the causes which I have noticed produce such attacks of deafness. Intense cold and exposure to cutting winds, snow and rain. The intensely shrill whistle of the locomotive near the ear, especially when in deep cuts or tunnels, or while running at high speed. The influence of long journeys, as from Edinburgh to London, causing in one case, which came under my personal observation, also inflammation of the brain. In two instances deafness was produced by a railroad trip from Philadelphia to California, producing vertigo, with roaring in the ear by the noxious influences of the dust and gases with the dry heated atmosphere during the summer months. The ears when examined were found to be filled with hard matters, particles of carbon, silica united with the epithelium and cerumen, causing irritation and inflammation by pressure, etc., on the membrane of the drum. In firemen it is noticed that the sudden change of temperature exerts a powerful influence upon the skin, in "firing up," causing excessive perspiration, and again passing into cold winds or deep depressions or tunnels, which in turn chill the body, causing disease of the nasal and respiratory organs, and extending into the Eustachian tubes causes deafness, which, if not promptly treated, becomes permanent. This disease of the ear or ears may have been originally acquired from the ordinary diseases of childhood, as scarlet fever, measles, whooping-cough or cold in the head, affecting, perhaps, only one ear. It is remarkable how long persons can get along with one deaf ear until some impairment takes place in the other, utterly unfitting them for important duties. When the deafness is caused by such employment on the railroads, where no organic change had taken place in the individual before entering upon his duties, and when the best years of a man's life have been spent in the service of the company, we would not advocate that such an individual should be thrown helpless upon the world; we would have his place changed to one of less importance, and where there would be no risk from his defective hearing. In the numerous positions on or about railroads there is found even employment for deaf men; and a discharge from active duty on part or full pension should be awarded, and would be but a small outlay in comparison with the risk of life or damages which the

company would have to pay. Another form of deafness I have noticed was in a conductor, namely, when his car was in motion he was able to hear well, but the moment it stopped his hearing became imperfect.

Owing to the profound deafness of a driver of a street railway car, a fire engine with a bell being constantly rung was not heard, and collision took place, and so great was the shock that the fore feet of the horses went through the windows of the car, and the only passenger in the car, a lady, was badly injured on the side and limbs, and her nervous system was completely shattered.

A mechanical engineer who had charge of a locomotive and subsequently a marine engine on board of a steamship, was so injured during a storm, that when he applied to be treated he could with one ear only hear the watch one-eighth of the normal distance, and with the other on close contact.

A case is also reported of a locomotive engineer who had his hearing so decreased during two years, from traveling through tunnels, that he had, while making up his own, caused a collision with another train, thus doing considerable damage.

Another case was of an engineer who had suffered from deafness of several years' standing; when his train was composed of more than twelve cars he could not hear the signal; he could only hear it four car-lengths.

On September 2d of 1880, Professor S. Moos, Heidelberg, read a paper before the second otological congress at Milan, on the diseases of locomotive engineers, firemen, etc., and stated that during the last few years he had been consulted for diseases of the ear by four locomotive engineers who had already resigned their post for other reasons, these cases had this in common that all four dated the origin of their deafness to the time when they still pursued their calling, that both ears were affected and the hearing was greatly diminished. Two of them suffered from constant subjective noises in both ears, one in one ear only, while the fourth heard no subjective noises at all. All four cases could be classified under the heading of sclerosed form of catarrh of middle ear. This fact led him to turn particular attention to the subject in question, especially of similar observations which he has since made of locomotive engineers and firemen—these being still in active duty had brought so vividly before him the danger which these affections might cause to the traveling public.

Entertaining similar views with those of "Moos" and knowing the large number of lives lost upon our railroads, I presented the subject to the careful consideration of the members of the Medical Society of the State of Pennsylvania, in May, 1881, and a committee was appointed to draft a resolution as follows:

Be it Resolved, therefore, that the Legislature of the State of Pennsylvania be petitioned at its next annual session to pass a law requiring all railroad employes to be examined for their acuteness of hearing, by means of the voice, watch, clock, bells, whistles, etc., before taking charge of any fast train on any railroad in the State of Pennsylvania.

After the reading of said resolution, which was approved by this Society, and on motion of Dr. John

L. Atlee, of Lancaster, the author of the paper was appointed chairman of a committee of his own selection, to bring this important matter to the attention of the various railroad authorities, and obtain their aid and coöperation to carry into effect the following suggestions—

To the Presidents, Directors, and Superintendents of the various Railroads in the State of Pennsylvania.

GENTLEMEN: At a meeting of the Medical Society of the State of Pennsylvania held at the city of Lancaster, May, 1881, composed of representative medical men, from nearly every county of the State, who are convened yearly to discuss and devise measures for the conservation and improvement of the health of the community, and with special reference to the prevention and cure of diseases, accidents, and injuries to human life, a paper was read in which proof was given that, owing to deafness the result of disease or injury of the ears, railroad accidents have occurred, causing loss of valuable lives and property, for which enormous sums are paid for damages recovered from your companies in cases of such accidents.

(1) Locomotive engineers, firemen, and conductors are liable to affections of the ear with decrease of hearing, usually on one side, which may have been originally acquired from disease in their childhood or youth, or which is to be attributed to their employment.

(2) This deafness appears to be more dangerous than color-blindness, because the latter is usually a congenital defect which can be defined precisely before the individuals are placed on active duty, while the deafness is an acquired disease but slow in its approach, and sometimes unknown to the person affected until an accident, *e. g.*, a cold or an injury, diminishes the hearing more and more on one or both sides, or destroys it completely, if it is not properly and promptly treated.

In May, 1882, this committee reported that copies of the resolutions of 1881 of this Society¹ had been sent to all the presidents and superintendents of the railroads of Pennsylvania, and the subject of the defective hearing of locomotive and other engineers has elicited much interest, and we are also happy to state that the Pennsylvania Railroad has adopted the following rules in regard to the hearing of those in their employ:

This is to be carried out by the superintendent. A competent person is to note the number of feet or inches distant from each ear at which a watch having a loud tick is heard distinctly, using a stop watch, to detect any supposed deception; and the number of feet at which ordinary conversation is heard.

In testing as to hearing, if a person who has good ears hears the watch at five feet distant, and the person examined hears it only at one foot, his hearing would be one-fifth, and may be recorded in fractions. Conversation in any ordinary tone should be heard at 10 feet.

It should be understood that all employes examined, failing to come up to the requirements of the above standard, shall be accorded the benefit of a professional examination.

¹ Transactions Med. Soc. State of Pennsylvania, May, 1881.

The above method has been submitted to a practical experimental test extending over nearly 2,000 men, employed as conductors, engineers, firemen, and brakemen.

As an evidence of this Dr. Thomson cites¹ two complete detailed reports including 1,383 men in all, who were in the service of the Pennsylvania Railroad, and, of this number, 21 were found defective in hearing. It will be well to compare the results of this examination with another branch of service, namely, the military, who are not so much exposed, except in time of war, and show how important it is for the United States Government to excite a livelier interest in otology among its surgeons, since there are many in its army whose health and usefulness suffer from ear affections, and indeed many who lose their lives simply from a want of knowledge on the part of their physician and surgeon.

The reports of the health bureau of the Prussian and Wurtemberg armies for 1874-78, show that during those four years there were removed on account of ear disease :

Died.....	23
Rendered unable to perform duty...	1,701
Partial invalids.....	33
Complete invalids.....	126

Total.....²1,883

We have also found that both military and naval surgeons, owing to the want of final examination in practical details in treating the diseases of the ear, are so much at a loss that they allow obscure cases of disease of this organ to continue for months without efficient treatment. The objections to the use of the watch alone as a test of the defective hearing of locomotive engineers, conductors, etc., is that it has but two tones or sounds, or two notes of the musical scale, and certain individuals will hear conversation with ease, and yet be unable to distinguish the ticking of a watch except when pressed against the ear. The perception of these tones does not furnish us any knowledge as to the condition of the ear in general, and especially as to its capacity of hearing the human voice.

We would advise that several other tests should be employed, as speaking tubes and bells, whispering, and certain agreed sentences of uniform value. During the year 1883-84 I have examined numbers of engineers and firemen, and many of them are noble fellows, and like the oldest railroad locomotive engineer of the Philadelphia and Reading Railroad, "Squire" Lufkins, who has for nearly 40 years devoted his whole thought and energy to his plain duty, to the carrying of his passengers in safety to their destination, and on time; when he began he was just 20 years old, but was a well-trained machinist, and a locomotive was his delight, and when he got one to run, his ambition was realized. He loved his work and never let his mind run off the track, as he well observed, "When an engineer's mind goes off on side trips, his train is apt to make a violent attempt to

follow." "Didn't you feel the effects of the work and responsibility on your nerves?"

"I can't say I did. I've read of doctors saying that no man can stand the physical and mental strain of running an engine more than twenty-five years. I don't believe this is so. If it is, I am a great exception. I am just as capable to-day as I ever was in my life, and I think I could go on and complete my second twenty-five years. Of course the engine shook me up, and there was noise and exposure all the time, but I got used to these things. They got to be as matter of fact as eating. As to the sense of responsibility, I felt it, of course, but it sustained me instead of breaking me down. Why, it is the soul of engineering—this thought that one is taking care of the lives of others. If I didn't have it I wouldn't run an engine. It would be like running a church without any God. And I would not work on any railroad if the safety of the passengers was not the very first thought in every department, from president down."

"Did your train ever meet with an accident?"

"Nothing bad. I've had little mishaps, but I never received a censure from my superiors or my own self. One time a man was hurt on my train, and I heard he afterward died. He was on a platform, where he had no right to be, when a cow ran into my engine. She got caught in the wheels, and two coaches were derailed. The passenger was thrown off and badly hurt. I think there was a suit against the company, and the company won it. That's the only accident I can remember. It was this freedom from trouble for so many years that led me to resign my position about two years ago. Thinks I, I am getting rather old in years. I'll have to quit anyhow before a great while. If I quit after some misfortune people will blame me, and the company, too, for keeping me at work. I am just as good an engineer as ever, and I'll end my service on my own motion. So I sent in my resignation, and the company gave me a satisfactory place as detective between Broad and Callowhill depot and Belmont."

"Have you kept any record of your mileage?"

"Yes, a sort of record, but it would take months to make up any figures from it. It was a sort of account book that I carried in my pocket. I would enter my boarding-house expenses, my mileage and other things all together. But I was an engineer thirty seven years, and ran all the time between Philadelphia and Pottsville. This is a distance of ninety-three miles, but the run actually made is 100 miles, for there is a lot of side running. For five years, at the start, I had a freight engine, and all the rest of the time a passenger engine. For the last fourteen years I doubled the run most of the time. Now, you can make a calculation from these figures and facts. You say 1,890,000 miles. That seems a great deal, but I suppose it will do. I think an average of 150 miles a day for 350 days in the year for thirty-six years, would be a moderate statement. That drops a whole year for safety's sake. But I do not take much pains to study out such sums in arithmetic. If I were a Frenchman I suppose I'd know how many times my travels would have carried me around the

¹Medical News, Jan. 14, 1882, p. 38.

²E. Weil, Archives of Otology, March, 1882, p. 54.

world, and all such things. I only know they carried me so often between Philadelphia and Pottsville, that I know every tie in the track and almost when placed there."

LOCOMOTIVES OF OLD.

"No doubt you witnessed many changes and improvements?" "Yes, but they came like a boy grows and it wouldn't be easy to tell when any one occurred. When I began there were no cabs on the engines and we had to dress warm for outdoor work. Sometimes it wasn't easy to hang on, but the time made in those days was nothing to that now made. At 60 miles an hour, which is an ordinary rate, it wouldn't do to be without a cab in cold weather. The wind would cut your eyes out. I remember when the cab engines were first introduced here. It was on the Pennsylvania road, which then belonged to the State. The engineers all raised a great row at the change and there came near being a strike. They said the houses were death-traps, and if an accident happened there would be no way to escape. They soon changed their minds, and if the houses were taken off now there would be a riot, sure enough. But I've heard that some of the English locomotives have no cabs¹."

This is one of the remarkable instances in which an engineer had the requisite knowledge, was young, robust, and of perfect health of body and mind and fully prepared for his life's work, and received his reward not in being turned off in his old age, but placing him as we have suggested in another situation. In the year 1883-84, I have been consulted by five locomotive engineers, men in middle life, on account of defective hearing, and four of the five have been so much improved by treatment as to be able to hear the ordinary voice and watch at five feet, and resume their care of their engines, one being still under treatment.

Two conductors were examined and found to have disease of the drum membrane with relaxation and progressive deafness. Neither of these could hear the ordinary voice well except when the train was in motion, and every one's voice when speaking had a higher pitch and the drum made tense. In nearly all of the engineers and firemen, deafness was the result of cold applied to the ear directly by looking out of the window in cold winter weather when in rapid motion.

Another cause was plunging the whole head into a bucket of cold water, to get rid of the dust, cinders, and other material which fill up the hair, nostrils and ears. We found that one of the conductors between Elkhart and Chicago, on the Lake Shore and Michigan Central railroad, was so deaf as not to be able to hear when a person spoke to him even in a loud tone. In another instance a driver on a street railroad could not hear a passenger call to him to stop, and in consequence he attempted to get off and fell and died from his injuries. As recently as April 12, 1884, an inquest was held in Philadelphia in the case of James Hastings, nine years old, who was struck and killed by a "dummy" engine of the Frankford and South-

wark railway. The conductor and engineer were called as witnesses, and the latter, who gave his name as Frank Golden, indicated the possession of this peculiar deafness. The deputy coroner asked him a number of questions to which he gave irrelevant responses. "Are you hard of hearing?" inquired Mr. Ashbridge. "I am now, but not when I am on duty," explained the witness. "Then you can hear when you are on an engine, and there is a great deal of noise?" "Yes, when there is a noise around me I hear first-rate, but when everything is quiet it affects the drum of my ear."

Since the investigations of Prof. Moos on this important deterioration of the hearing of engine-drivers in 1880-81, the results have been confirmed by Drs. Bürkner, of Gottingen, and Dr. Hartmann, of Berlin; Dr. Wm. Thompson, of Philadelphia, and the writer; while with Dr. L. D. Schwabock and Dr. H. Pollnow, of Berlin, results were as follows:

1. The torpedo-signal (or a similar sound, like the breaking of a tire), the steam-whistle signal, and the lesser noise of the dry buffer, were accurately perceived by two engineers whose hearing for slight noises was diminished to $\frac{1}{25}$ — $\frac{1}{50}$, respectively, and for whispered voice to about $\frac{3}{4}$ of the normal amount.

2. No one, even with perfect hearing, they state, can hear the conductor's whistle or any noise in the rear of the engine while the train is in motion. The experiment with the torpedo-signal was afterward tried in the case of others, whose hearing was greatly diminished for watch ($\frac{8}{125}$ cm.). But these employees heard the signal promptly. Finally another employe who heard $W\frac{1}{8}$, $W. V. \theta 0$, 5 m.—2, 5 m,¹ was tested with the mouth whistle. He could hear it very plainly at 60 m, and said that the distance could have been doubled without any danger of his not hearing it. After summing up the results of their observations they came to the following conclusions: *That no great claims need be made upon the hearing of locomotive engineers or firemen, since a considerable diminution of hearing in these employes does not endanger the security of railroads.*

Dr. Hartmann states that it is not alone necessary that ordinary signals should be distinguished, but that there are other circumstances under which an engine-driver is placed, which render hearing more difficult, such as running in storms over a frozen track and through tunnels, etc. According to his experience, there are again other conditions which cause an engine-driver, who already hears badly, to hear much worse after having made a long journey, but recovers his hearing after leaving his engine. Some hesitation may be reasonably expressed and felt in accepting the conclusions of "Pollnow," viz.: "That so long as a conversation in ordinary voice can be heard, their defect involves no danger to the public."

The following facts were testified to by experienced engineers of the United States, who must depend largely upon their organ of hearing in order to assure the safety of the many lives entrusted to their care

¹ Abbreviations. H. for hearing; W. for watch; T. F. tuning fork; B. C. for bone conduction; W. V. for whispered voice; cylinder watch, 1-25 m.

¹Phil. Times.

and skill: The sharp crack of a broken crank, the dull thud of a shattered connecting rod—in short, any of those obscure noises which signalize the approaching disability of a great machine, and any of those accidents which interfere with smooth running, may often, if readily discovered, save largely both of lives and property.

A veteran engineer says that two years ago a slight difference in the aggregate quality of the tones which came to his ear caused him to stop his train and look over the engine. "I found the trouble," said he, "to be due to the loosening nuts of two cylinder heads, which had been put in place without the usual precautions to prevent their working off. Had they done so, I would have carried in a crippled train, and changed the whole business of the road for some hours." "Then you consider quick and reliable hearing of importance to the locomotive engineer?" "No man," he replied, "has a right on an engine who has not all of his senses in perfect running order. The very feel of an engine when she is running is of the highest importance. A moment of rashness on the part of the engineer might in some instances lose him his engine."

The driver of a Hudson River Railroad locomotive said: "I was affected with deafness but once. There was some heavy artillery firing in Yonkers which lasted about ten minutes; my ears were very sensitive, made so, I think, through the habit of careful listening, and the moment I started up I felt there was something wrong about my hearing. At the end of ten days I put myself under the care of a physician. He found the trouble a considerable distance inside, and told me the concussion of the air had affected me. I was all right in ten days."

An instance in point is given in London *Lancet*, December 24, 1881, in which an accident occurred in Canonbury, England. Three trains collided in a tunnel, in which the signalman stated he gave a word of caution to the passing driver, which the latter asserts he did not hear. A similar accident happened in France, in October, 1880, fortunately without loss of life, but with a very great impediment to travel. It has been well expressed by Moos that, for the safety of the traveling public and for the prevention of accidents on railroads, not only a certain minimum of hearing is to be required, but both sight and hearing should be perfect, since sometimes reliance must be placed in one, sometimes in the other, and often in both combined. By such requirements only can danger and accident be reduced to a minimum.

CARBONATE OF TITANIUM.

BY A. B. LYONS, M.D., DETROIT.

Read before the Detroit Academy of Medicine, November 18, 1884.

GENTLEMEN OF THE ACADEMY:

The use of a class of remedies whose composition is either wholly the secret of the manufacturer, or else is deliberately misrepresented in the statements purporting to give an account of their composition,

seems to be gaining ground among reputable physicians. I cannot but regard this as a misfortune to the profession. A few years ago there were few educated physicians who would attempt to defend the use of nostrums and secret remedies. Now I meet often with men who hold a high position in the medical profession who openly maintain that the physician ought not to be restricted in any way in the choice of his remedies. They take apparently high philanthropic ground, and say that we have no right to deprive our patients of the benefit they might obtain from the use of a secret remedy, merely on account of our ignorance of its constituents. They argue, further, that our knowledge of therapeutics is all or nearly all empirical; when we prescribe opium or potassium bromide, or any other article of the recognized *materia medica*, we do so merely because clinical experience has shown that patients in conditions similar to those existing in the case on hand have been benefited—not because we know how the remedy acts. Why, then, should we refuse to prescribe St. Jacob's Oil or Swaim's Panacea, if we have evidence that these nostrums, better than anything described in the pharmacopœia, will ameliorate our patient's condition? The reply has always been this: Manufacturers of nostrums are not in possession of any remedies unknown to the profession; their claims are based on falsehood, and if we are unable to obtain from known remedies the results we see produced by the combinations offered by charlatans, it is simply from our own ignorance of the subjects to which we are supposed to have given the closest study. To prescribe a quack medicine is therefore practically to admit that our own pretensions have been hollow and false.

For the pride of our profession, therefore, we should hold strictly to the requirements of our ethical code. But it is not necessary to place it on the ground of pride simply.

Notoriously the statements of charlatans are, to express it mildly, untrustworthy. In studying the effect of a quack medicine, too, we have to bear in mind the fact that the exaggerated statements which generally accompany the remedy have a powerful moral influence. Influences of this kind ought to emanate from the physician himself, and they must of necessity complicate all studies of the action of remedies; in the case of patent medicines they are not only a disturbing element, but one which must antagonize the personal influence of the physician. It is moreover so easy in most cases to penetrate the disguise under which well-known remedies masquerade as patent medicines, that the physician is inexcusable who prescribes the nostrum in ignorance of its real composition—and, certainly, equally inexcusable if, with such knowledge, he continues to prescribe it.

So long as the question relates merely to patent medicines and quack nostrums, the profession is as yet pretty well united—if not in practice at least in theory.

But within the last few years a new class of secret remedies has made its appearance and the old battle has to be fought over again, but with the foe now conspicuously displaying a flag of truce.

Pharmacy, we are told, is making such rapid strides in our age that the pharmacopœia is quite unable to keep up with the march of progress. Hence enterprising manufacturers come to the rescue, seizing upon each valuable discovery in therapeutics and embodying it in the form of a proprietary preparation. Then, too, remedies must be offered in this civilized age in a palatable form, and a preparation of any well-known drug, if only it possesses this recommendation, is hailed with satisfaction by physicians of the old school of practice who observe that their patients are drifting over to their homœopathic rival—because they do not have to take such nasty medicines. The large body of professional pharmacists who have endeavored to serve our profession by devising palatable and elegant preparations which should not be the property of any individual, but freely given for the good of humanity, find themselves put one side by the “enterprising” egoist who advertises iodia, or viburnum compound, or celerina or caulocoria—and a thousand other proprietary articles of which the formula is withheld. The properties and uses of preparations of this class are generally stated in language intelligible enough to the laity, and often the certificates of a score of distinguished medical professors are appended. You see no real difference between them and ordinary patent medicines—even in the prices, and yet the manufacturers distinctly state “For physician’s prescriptions only”—it must be all right.

It is not surprising that physicians are perplexed, especially when all the medical journals, many of them conducted by men having an honored place in the profession, publish the advertisements of these secret remedies. To me it seems not difficult to decide where the discriminating line should be drawn. We cannot object to any preparation of acknowledged merit of which the formula is honestly published. When the formula is withheld we should refuse our sanction, especially when the preparation is offered under any fanciful name, such as papine, hydroleine, etc. By consistently adhering to such a course we should be very soon rid of the nuisance we all alike complain of, for manufacturers would find it suddenly to their interest to make common cause with scientific pharmacists, to the ultimate advantage of all parties. Any other course opens the way inevitably to frauds without number—and already we find instances not a few in which physicians have cut a sorry figure as dupes of the manufacturing charlatan. A short time since, a brazen attempt was made to impose upon the profession, as a great discovery, a medicinal preparation called “cohothedræ compound” (disregard of grammatical form is one distinguishing peculiarity of these innovators in pharmacy), a cure for typhoid fever, an *analysis* of the preparation by a distinguished chemist being offered in lieu of a formula. It makes little difference how often or how completely these frauds are exposed, the same medical journal which in its editorial columns may call attention, possibly once, to the exposure, continues week after week or month after month to publish advertisements of the preparation, often with a long list of references to eminent physicians. It seems to

me that the only way we can protect ourselves against imposition is to put quackery in pharmacy on the same level as quackery in medicine, judge it by the same laws, and guard ourselves against it by adhering to the same ethical regulations. If a practitioner of medicine claims to have some remedy or gift of healing peculiar to himself, we withdraw from him our fellowship—rather let me say he places himself of necessity outside the pale of professional fellowship. The same principle applies equally to the man who claims to have a pharmaceutical secret. We are sure that such a man has not the interests of pharmacy at heart; it is unreasonable to suppose that his claim has any better foundation in fact than that of the medical charlatan. As one reasonably familiar with pharmaceutical products, I may go further than this and say that as a matter of fact these much advertised proprietary medicines do not evince either inventive genius or any high order of pharmaceutical skill.

After all this preface I come to the immediate subject of this paper. The September number of the *Medical World* of Philadelphia, contains the following notice of a new emmenagogue, which we quote *verbatim et literatim*:

“The pill used by the French women to produce barrenness I have found a valuable emmenagogue. Each pill contains two grains each of aloes and carbonate of titanium. They have never failed to bring on the menstrual discharge at the next epoch. Stoppage produced by cold is restored by this preparation in forty-eight hours. It is a most powerful direct stimulant to the sexual organs. I have no doubt that it would produce barrenness if persevered in. A married woman using the pill does not become pregnant.

“My usual formula is as follows:

“*R* Pulv. aloes (soc.).....

Carb. titan.....āā 3i

Fiant pilulæ No. xxx. Sig. One pill
three times daily.

“No particular nicety need be paid in regard to dose; from one to three pills may be taken *ter die*. They should be commenced from one week to ten days before the expected menstrual period. I have employed them in many cases of amenorrhœa, both in retention and suppression, and almost invariably with the utmost gratifying results. So certain are they to restore the uterine secretion when suppression does not depend upon organic disease that I almost regard them as a specific. Their action is peculiar; they seem to possess the power of restoring the secretion when suppressed, and of promoting it when deficient. This pill is, in fact, a female regulator. When the obstruction is from cold, these pills, with warm pediluvia, are sufficient. They operate kindly and without excitement; the patient hardly knows she is restored.”

The communication is from Dr. M. M. Griffith, of Du Bois, Pa., who a few years ago brought to the notice of the medical profession crude petroleum mass as a therapeutic agent.

There is no intimation in the communication that the carbonate of titanium is not a perfectly well-

known compound, and possibly it may be that the name, at least, was not an unfamiliar one in Pennsylvania. Elsewhere in the United States, however, it had a strange sound. In the *Medical World* for October it was stated editorially that the carbonate of titanium was a rare drug, expensive and hard to obtain, and that it was not to be had in any of the large cities, but that a supply had been ordered from abroad, while a later notice stated that one firm in Philadelphia was prepared to furnish the article, at the moderate price of 50 cents per ounce.

I have left it to members of the Academy to form their own opinions in regard to the value of a drug which will inevitably produce barrenness in a married woman; but I cannot forbear quoting a few sentences from the editorial alluded to as indicating the drift of popular sentiment inside as well as outside of the profession.

"The article of Dr. Griffith in the September *World* has created a widespread interest in carbonate of titanium. We have received numerous inquiries concerning it. Telegraphic orders were received for it in New York from Boston, Louisville, and all parts of the country. * * We invite a report of further experience with this drug, *hoping that the gratifying results of Dr. Griffith will be verified.* Menstrual irregularities are becoming more and more prevalent, [among married women?], and any drug promising so much as carbonate of titanium should be fully tested."

Whether the six to eighteen grains a day of aloes prescribed would not of itself be sufficient to induce barrenness in a delicate female, I leave also to my hearers to judge.

My own attention was especially caught by the evident incongruity in the name itself. Carbonate of titanium to the ear of the chemist sounds about as plausible as pterygium of the iris to an oculist. I had a curiosity to see a chemical compound realizing such a singular freak of chemical affinity. Accordingly I awaited with some impatience the arrival of a supply of the drug. I have with me a sample of the article received with the written, not printed, label "carbonate of titanium." Any one familiar with drugs would guess at once that it was what formerly was known as iron sub-carbonate, but that compound, which is in reality ferric oxide, is tasteless, while this has a disagreeable ferruginous and bitter taste.

I found that a portion only of the substance dissolved in water, and this portion gave reactions for iron (ferrous) and for sulphuric acid. It consisted in fact, almost entirely of ferrous sulphate. After most of this salt was washed out, however, water continued to dissolve slowly something which had a bitter taste, and communicated to the water a strong orange tinge. The solution contained a vegetable alkaloid which proved to be sanguinarine, quantity too small to be easily estimated.

The residue insoluble in water was treated with hydrochloric acid, which dissolved it slowly, without effervescence, leaving only a few fragments of vegetable tissue, which were referred to the blood-root otherwise shown to be probably present, but were not positively identified. The solution consisted almost

wholly of ferric chloride, showing that the insoluble substance had been in fact sub-carbonate of iron. Besides these principal constituents, the powder contained traces of calcium, potassium, sodium, silica, and titanic acid.

Quantitative analysis showed the composition of the powder to be approximately as follows:

Ferrous sulphate (cryst.)	54.8
Ferric oxide	40.5
Lime salts	} 2.2
Soda "	
Potassa "	
Titanic acid and Silica	1.0
Organic matter (blood-root) and loss	1.5

100.0

Practically, therefore, it consists of a mixture of nearly equal parts of sub-carbonate of iron and sulphate of iron, partially exsiccated, with addition of an insignificant quantity of blood-root, and the "new" emmenagogue proves to be the old familiar combination of aloes and iron.

I am entirely ignorant of the source from which this powder was originally procured. It was sent to me by a leading wholesale drug house in New York, who undoubtedly were dealing in good faith. Possibly it has really come from France under the name it now bears, and that name may have been given it without any intent to deceive. But chemical names have a definite invariable significance, and when a substance is labelled titanium carbonate, you have a right to expect at least that it will prove to be a carbonate, and it is not unreasonable to feel some disappointment if titanium is so nearly absent that the blowpipe fails to show its presence. Yet it is to precisely such impositions as these that the medical profession lays itself liable when it pleads ignorance as an excuse for accepting the dicta of men who confessedly tell only a part of the truth. I do not know who is the responsible person in the present instance, but I resent, as a gross insult to the profession, the attempt, if such has been deliberately made, to pass off a mixture of well-known medicinal agents as a new remedy of extraordinary power, and that under a name so impudently false.

Since writing the above I have come across some additional items of information in regard to titanium carbonate. In the *Druggist's Circular* for October, 1884, we find S. W. D., of Mansfield, Pa., asking for a short account of the physiological action of carbonate of titanium. Observe that he does not inquire what it is or where it is to be procured, and note that he writes from a town or village not a hundred miles from Du Bois.

His query is promptly answered in the November number of the *Circular*—not by the editor, but by M. Milton, M.D., who writes from Du Bois, Pa., a townsman, therefore, it seems of Dr. M. Milton Griffith, and possibly, we may conjecture from similarity in name, a near relative.

From the reply we quote a few sentences, which leave no doubt about the character of the preparation, and settle conclusively the question what atti-

tude the profession must take toward the newly discovered "emmenagogue."

First, we are told that "titanium is found in several mineral species, in combination with magnetic iron ores. It is of a red color, and resembles copper. It is used to some extent in the arts." (Neither of the two latter statements, by the way, is true.) "Carbonate of titanium is made by double decomposition of sulphate of titanium and carbonate of sodium. It is a reddish-brown powder of a disagreeable, bitterish taste, partly soluble in water." This volunteered information is highly interesting, especially to one who has keenness enough to read between the lines. Its cunning blending of truth with fiction shows consummate genius in the perpetrator of this most daring fraud. Now listen. Properties: "It is tonic, alterative, and emmenagogue. It has produced abortion in many instances, and is commonly resorted to for that purpose by reckless women, and advised by still more reckless physicians. It seems to act without producing the very alarming symptoms usually attending such cases. It has the reputation of preventing married women from becoming pregnant, by its use in combination with aloes; it has surely done it in a number of cases that have come under my observation. It is generally used in domestic practice, in the form of a saturated tincture with whisky." How singular that a compound of the rare element, titanium, should first come into use as a domestic remedy, and that in the rural districts in Pennsylvania! "My attention was first called to it by its domestic use for purposes not altogether legitimate. It is a valuable remedy, and is worthy of further consideration."

Emmenagogue forsooth! Was there ever a more unblushing advertisement of a foeticide? It matters not that the drug is innocent of the active properties attributed to it; it will be bought for illegitimate purposes, and no other. In view of this fact, I am sure that no member of the Academy will regard the carbonate of titanium with any favor or indulgence, or will fail, indeed, on all fitting occasions to denounce it as an attempt to drag the profession into association with a class of criminals whose practices we utterly abhor and condemn.

A CASE ILLUSTRATING THE APPLICABILITY OF MURIATE OF COCAINE IN NASAL SURGERY.

BY JEFFERSON BETTMAN, M.D., CHICAGO.

(Read before the Chicago Medical Society, Nov. 11, 1884.)

The introduction of muriate of cocaine will no doubt create an era in ophthalmic surgery, the glowing tributes it has already received in Europe and in the East render irrefutable its qualities as a most efficient and innocuous local anæsthetic. Both Knapp and Gruening, of New York, have already tested its action on the nasal mucous membrane, and the re-

sults attained thereby fully equal those in anæsthetizing the eye. Due to the extreme scarcity of the drug in Chicago, it is only at a late hour that I have been able to obtain a small quantity and to apply it in practice. Although my actual experience, so far, has been limited to the case subjoined, the striking results attained are sufficient to fulfill my most sanguine expectations and to regard it as a most valuable adjunct in nasal surgery.

Dr. K., a physician of this city, has been under treatment for some time, suffering from asthma nervosum. Observations render it beyond doubt, that the asthma is purely reflex, induced by great hypertrophy of both inferior turbinated bones. Barring occasional obstructions to the free nasal respiration, but little discomfort is experienced during the day. A recumbent position, the warmth generated by the bedding are sufficient to produce reflexly a sudden turgescence of the turbinated bones, blocking up of the respiratory fissure, a serous discharge, and to finish the clinical picture, a culminating, violent attack of asthma. The hyperæsthesia of the nares is truly extraordinary, the simple introduction of the speculum is painful. The doctor has to exert all his self-control to permit the mere application of the probe to the parts. Endeavors had heretofore been directed to reducing the cavernous tissue by means of the galvano-cautery. The extreme sensibility would not permit of a thorough and prolonged application of the cautery, sufficient to act upon the deeper lying structures, so the results obtained were but partially successful. Last Saturday the doctor called at my office and we resolved to apply the muriate of cocaine prior to cauterization. Gruening,¹ according to his report, instilled the solution into the inferior meatus, the patient's head being placed accordingly.

The small quantity of the solution at hand, compelled me to adopt another method, which impressed me as being more expedient, and at the present not unworthy of consideration, as far more economical. A pledget of cotton, sufficient in bulk to occlude the inferior meatus, was soaked with 15 drops of a 4 per cent. solution of cocaine and placed in the left nostril, between the septum and enlarged turbinated bone. At intervals of five minutes, two or three drops were instilled upon the cotton *in situ*. At the lapse of ten minutes, the left narium was so anæsthetized as not to perceive the touch of the probe. However, as a precautionary measure, I only removed the cotton at the expiration of a quarter of an hour. The anæsthesia of the parts was now so profound, that the gentleman could hardly give credence to my assurances that I had thoroughly and vigorously probed the parts. In marked contrast was the undiminished sensibility of the right nostril; the introduction of the probe compelling him to cry out lustily. Previous cauterization had been made with the flat, surface electrodes, our aim, however, being to destroy the underlying cavernous tissue, we resolved to use a sharp, cutting point which had been made according to my design by Dr. McIntosh, of this city. The plates of the battery (a large Bruns battery

¹ Medical Record, November 1, 1884.

composed of two elements) were immersed sufficiently to produce a white heat when connections were made. The electrode was introduced and applied for fully three seconds ere calling forth any expression of pain on the part of the patient. As the doctor assured me, the discomfort was so minimum as hardly to be dignified with the title "pain." A striking proof of the almost total painlessness of the application, is the fact that our hitherto sensitive colleague permitted me to make another prolonged application at the same sitting. The action of the cautery was so thorough, that I am certain its ultimate results will far eclipse the benefit derived from the previous, more superficial applications. After a period of 25 minutes, the sensibility was fully restored. The doctor now began to experience the slight soreness that is always felt after cautery.

More extended observation, I trust, will tend to confirm the results already obtained and to strengthen faith in this remarkable anæsthetic. The range of its applicability is so wide, that it is nearly impossible to predestine its possibilities. It is certainly not irrelevant to state here, that its use in nasal surgery will probably enhance the popularity of galvanocautery, and increase the field of utility of this most serviceable and effective mode of treatment.

113 Adams St.

UNILOCULAR OVARIAN CYST, WEIGHING NINETY-FIVE POUNDS, SUCCESS- FULLY REMOVED.

BY GEO. E. RANNEY M.D., LANSING, MICH.

The following case is one of interest for a number of reasons, and especially so on account of the size of the tumor, which, as far as I know, is the largest of the kind ever removed, while few tumors of any variety have exceeded it in weight. A case (occurring in a negro woman) of fibro-cyst of the uterus, weighing 130 pounds, including seventy-one pounds of fluid drawn from the cyst, six days before the death of the patient, together with the solid portion of the tumor, and twenty-four pounds of fluid removed after death, is reported by Dr. C. C. Stockard, of Miss., in the *New York Med. Record*, Aug. 16, 1884, concerning which he says it is, as far as he can learn, the largest one on record. In this case the question may arise as to whether the most of the twenty-four pounds removed on post-mortem did not accumulate during the six days following the tapping.

Thomas, on the Diseases of Women, p. 543, second edition, says: "The unilocular tumor consists of simple dilatation of a Graafian follicle. This may go on until the size of the uterus in the eighth or ninth month of pregnancy is reached. Kiwisch has met with one whose contents weighed forty pounds, but such a development is exceedingly rare, as they seldom remain simple after passing the dimensions of an adult head." Further on he says of multilocular cysts: "The size to which these cysts will grow is truly wonderful. It has been already stated that uni-

locular or monocystic tumors rarely attain a great size as such; they become, as they increase, multilocular or polycystic, and then their growth may become excessive. Instances are on record of tumors containing over one hundred pounds of fluid."

Our distinguished countryman, Dr. Emmet, in his "Principles and Practice of Gynæcology," second edition, p. 826, reports the removal of a multilocular tumor weighing seventy-nine pounds, and adds: "This was the largest ovarian tumor I have ever removed."

The case in question was in the person of Mrs. T., of Grand Ledge, Mich.; a native of Michigan, æt. 55 years, married, and the mother of two sons, aged respectively 30 and 34 years. Her frame is below medium size, and up to 40 years of age she never weighed over 90 pounds. At about this age she became very fleshy, and weighed over 200 pounds. Her menopause occurred at the age of 45 years. At about the age of 49 years she discovered that the enlargement of her abdomen was more marked, and she experienced an uncomfortable fullness of it, and thought she felt through its thick walls an unnatural growth or accumulation, which led her to think she required medical assistance, and accordingly she selected her advisers from a "covey," or "brood," of ignorant homœopathic practitioners, such as afflict most of the towns of our beautiful State, where they are hatched out in as little time as it would take an egg to incubate, and where the law recognizes no difference between them and the most skillful physicians.

Her case was diagnosed by them as one of abdominal dropsy, and the patient labored under that delusion, and was treated for dropsy, up to within six weeks prior to my first visit, when Dr. Wright, of Grand Ledge, an intelligent practitioner, was called to see the case. He reports that he found her in a general anasarca condition, which anasarca, by appropriate treatment, became somewhat diminished. About one week before I saw her, and nearly two weeks before the operation, the doctor had attempted paracentesis with a medium-sized trocar, but only succeeded in drawing away a small quantity of straw-colored fluid and a thick gelatinous material of about the same color.

I was called to see her, with Dr. Wright, Oct. 2, 1884, and found her truly a sight to behold. Her abdomen was enormously distended, and its walls firmly stretched over what I diagnosed at the time, and what subsequently proved to be, a monocystic tumor of left ovary. The tumor had pressed the rectal muscles apart at the umbilicus, causing a hernial protrusion, which looked toward the floor as she stood up, so greatly was the abdomen above it distended. There had been a constant external dripping from the puncture made with the trocar—a circumstance disagreeable to the patient and attendants.

The tumor was so large and cumbersome that the patient had been, for a long time, unable to lie on her back, and for years past, in order to change from one side to the other in bed, she had to be raised, when she would stand upon the floor and approach her bed from the opposite side.

By digital examination per vagina, I found an œdematous condition about the womb, and by carrying my finger higher up, could recognize the harder, characteristic resistance of the tumor. Examination of uterus with finger and sound revealed nothing abnormal. The œdematous condition of pudenda and protrusion of abdomen rendered specular examination impracticable had it been desirable.

The walls of the abdomen would glide over the tumor, to a limited extent, and I was led to hope, notwithstanding its long existence and extraordinary size, that its adhesions were not extensive, as is generally the case in multilocular cysts. Desiring to ascertain of what the tumor was composed, and, if possible, to determine whether the tumor was monocystic or polycystic, I drew through an aspirating needle, at a site somewhat remote from the previous tapping, a substance small in amount, in color and consistence like that previously drawn by Dr. Wright, and proving, on examination, to be almost wholly albumen. The trouble was seriously telling upon the patient's health. The weight of the tumor was gravely telling upon her strength; impairing seriously her digestion and assimilation, and thereby lessening her flesh; its pressure upon the blood vessels, and consequent anasarca; its pressure against the ribs and diaphragm rendering respiration difficult and short, were conditions which rendered a practical illustration, in her case, of Dr. Holmes' remark, "That the latter stages of ovarian dropsy should be prolonged over months instead of weeks would be a matter of regret rather than congratulation." Indeed the patient expressed the belief that death would soon come to her relief, and she longed for that eventful time if she could not be relieved by an operation, which she not only expressed a willingness to submit to, but begged me to perform, regardless of its dangers, which had been greatly enhanced by rupture of the ovarian cyst, at the point of tapping, which permitted a discharge into the peritoneal cavity, which discharge enveloped the organs of the abdominal and pelvic viscera.

Accordingly, Wednesday, Oct. 8, 1884, was the time agreed upon for the operation. On the day previous the largest room in the house, which was carpeted and furnished, was tightly corked, and disinfected with sulphurous acid gas. The morning of the operation I thoroughly sprayed the room with a solution of carbolic acid. The family had recently moved into the house which is comparatively small, and unavoidable delay in making necessary repairs, rendered the house incommodious. I selected for the operating room an unfinished kitchen only covered by the roof, the walls being neither lathed or plastered. The day was a cloudy one, and though the room was poorly lighted it was well "ventilated." This room I also thoroughly sprayed. Every assistant was requested to bathe before coming to the house, and on their arrival they washed their hands in carbolized water and sprayed their clothes. Every instrument and thread was disinfected, as were all the dressings. The spray was continued during the operation, and the temperature of the room kept at 92° F., by means of the kitchen stove. I am under

great obligation for the efficient and able assistance in operating rendered me by Dr. Wright, who visited her daily before, and since the operation, also to Dr. Davis, of Grand Ledge, and especially to Dr. Jenks, of Detroit, and Dr. Post, of Lansing.

After etherizing the patient, who had to lie on her side, as previously stated, we made the abdominal incision in the usual place, finding the walls quite thick, owing to its fatty and œdematous condition. The incision was made through the site of the tapping, finding the sac at this point, which was friable, ruptured, permitting the escape of considerable of its contents into the peritoneal sac as previously mentioned.

By the ordinary means of exploration we found adhesions, though not extensive, which I readily broke up with my hand, and though causing at one time terrific bleeding, I was able to promptly control it by pressure and ligature. The pedicle was patulous and broad when compressed, though not large, as a whole, it was very vascular and supplied with three or four quite large arteries. The pedicle was held by hand and compressing forceps, while a double, stout, braided silk ligature was passed through it, carefully avoiding the large blood-vessels, looped on itself and firmly tied. The stump was then severed, fine silk ligatures applied to the ends of the arteries, and the end of the stump seared or cooked with a hot iron, the end of the stump cleanly wiped and dropped into the abdomen.

The remainder of the escaped material of the tumor was carefully removed by hand and sponge, from the abdominal and pelvic viscera.

The peritonæum was little if any inflamed. The long and persistent pressure of the tumor against the peritonæum, however, had caused a wonderful thickening of it, which was found studded with growths the size of a kidney-bean, which protruded, presenting a remarkable appearance, some of them looking like fatty material and others like pieces of raw beef, and were susceptible of being pinched off by the thumb and finger. The tolerance of rough usage which the peritonæum had acquired, accounts, I believe, in a large degree for the almost total absence of peritonitic symptoms, before and following the operation. The abdominal wound was closed with interrupted wire sutures, the disinfected gauze, mackintosh compress and flannel binder applied and the patient placed in bed in the room previously prepared for her. No drainage tube was used. The time consumed in the operation was three hours and twenty minutes. The tumor had the enormous weight of 95 lbs.

I remained with the patient twenty-four hours following the operation, during which time she thoroughly rallied and expressed surprise that she was alive and that she was able to lie on her back, which for years previously she had been unable to do. No nausea or vomiting has followed the operation. At 4:30 o'clock P.M., about three hours after the operation, her temperature was 99° F.; pulse good. At ten the same night the temperature had come up to 101½°, pulse full and strong. The bladder by

that time had become full and I drew from it a pint or more of amber-colored urine.

Oct. 9, at 6:30 A.M. the day following, temperature was $99\frac{1}{2}^{\circ}$, pulse 116 and quite good; slept well during the night; looked not bad, felt cheerful and asked if she could have something to eat; says she feels a little "wind pressure" in lower part of bowels. At 10 A.M. passed a pint of urine without the use of catheter; temperature $100\frac{1}{2}^{\circ}$; at 8 P.M., temp. 100° , pulse 120.

Oct. 10.—9 A.M. Temp. $98\frac{1}{4}^{\circ}$, pulse 100; at 12 M. passed gas from bowels; temp. $99\frac{1}{4}^{\circ}$.

Oct. 11.—9 A.M. Temp. $99\frac{1}{4}^{\circ}$, pulse 100; continues to pass gas from bowels; at 9 P.M., temperature $99\frac{3}{4}^{\circ}$.

Oct. 13.—12 M. Temp. 100° , pulse 100, after dressing wound for the first time since the operation. The peritoneal wound healed by first intention throughout its full extent, a fortunate circumstance, as it prevented the fluids entering the peritoneal cavity from the non-union of the anasarous tissues external to it.

Oct. 14.—Dr. Post visited the patient in my stead, finding her about as she was the day before, the wound suppurating, but healthy.

Oct. 15.—About the same; gas continues to pass freely from the bowels. At 11 A.M., temp. 98° , pulse 96, full and softer than previous. The tongue, which has worn a white fur and been somewhat dry, with red edges, is now more moist, and its coating diminished. She says she would like to sit up. I removed all the stitches except one, and strapped the wound with adhesive plaster. Up to this time the dressings were made under the carbolized spray. Thus far she has taken nothing on her stomach excepting water. She has thus far been nourished and stimulated by enemata, composed of beef tea, milk, brandy and sulphate of cinchonidia.

Oct. 16.—Temp. $98\frac{1}{2}^{\circ}$, pulse 108. She took a little milk on her stomach, which disturbed her somewhat, so it was discontinued.

Oct. 17.—Bowels moved naturally. Temp. and pulse same as yesterday. Gave her some peptonized milk, which she enjoyed.

Oct. 18.—Temp. 98° , pulse 100, and a little "jerky," and not quite satisfactory. Continued the milk whey and enemata.

Oct. 19.—Temp. 99° , pulse 108 at 12 M.

Oct. 20.—Temp. 99° , pulse 108 at 12 M.

Oct. 21.—Temp. 98° , pulse 102. Ate two crackers contrary to orders. No perceptible result followed.

Oct. 22.—About the same. From the last date to the present, appetite and digestion increased; strength improved. She has been cheerful all the time, and slept about twelve hours per day. No tympanitis existed since the first two or three days, though she has continued to pass gas freely from the bowels. Up to the time she commenced to take food on her stomach, she had two or three transient spells of vertigo. As she became better nourished, no further symptoms of the kind manifested themselves, and her strength gradually improved, when, on October 24 and 25 she sat upon the commode to defecate. Sitting up had not been permitted by me, and I interdicted

it as soon as I learned the fact. Her appetite has been, and is, voracious with slight interruption. Besides the food previously mentioned, she has been allowed eggs, also beef peptonoids, prepared by Reed & Carnick, of New York, and she has at times broken over my strict injunctions by eating more or less starchy food, when, finally, on October 30, she ate "sour krout" and drank sweet cider! These latter articles forcibly reminded her that she "had a stomach," and her bowels were rendered uncomfortable and moved slightly a number of times. Ten drops of laudanum injected into the bowels relieved the distress she experienced, and though her pulse seemed a little excited and flatulence increased, she declared that she felt firstrate.

The external wound has nearly healed, her temperature and pulse nearly normal; her tongue almost natural; strength good; countenance bright, and at the present writing it rests her to sit up a little while at a time, and it seems as though all danger had passed. It is worthy of remark that immediately following and since the operation, her kidneys have been quite active and that the dropsical condition of her limbs, which had rendered them two or three times their natural size, rapidly disappeared. No severe shock followed the operation; no hæmorrhage, peritonitis, septicæmia, phlebitis or abscess occurred. In short, with the exception of one or two days, which dates I omitted to note, she has had no untoward symptoms, and these exceptions were the result of disturbed digestion and assimilation from indiscretion in eating.

Since writing the above the patient has substantially recovered, she being able to walk, to ride out with comfort, and to do light work.

Lansing, Nov. 22, 1884.

SOME OBSERVATIONS ON THE TOXIC EFFECTS OF CHROME ON THE NOSE, THROAT AND EAR.

BY JOHN N. MACKENZIE, M.D., BALTIMORE, MD.,

Surgeon to the Baltimore Eye, Ear and Throat Charity Hospital.

Read in the Section of Ophthalmology, Otology and Laryngology of American Medical Association, May, 1884.

Among the many inconveniences from which those directly engaged in the manufacture of chrome suffer, the most prominent, perhaps, consist of a group of symptoms referable to the respiratory tract, and especially the nasal cavities and their dividing septum. In the chrome factory of this city, the workmen employed in the chambers where the bichromate is made, almost invariably acquire perforation of the cartilaginous portion of the latter from the irritating and corrosive action of the fumes and floating dust evolved during the chemistry of its manufacture. This destruction of the cartilaginous septum appears to be the most prominent anatomical lesion, and occurs with such striking frequency, that it may be looked upon as a characteristic and constant sign of this particular form of chrome poisoning. Perforation occurs, as a rule, with great rapidity; generally in a

few days after exposure to its exciting cause. I am told, by one of the workmen who has been engaged in the factory for over fifteen years, that extensive destruction of the cartilage sometimes takes place within 24 to 48 hours. It is commonly preceded by general congestion of the mucous membrane with more or less epistaxis, or by the symptoms of a well-defined coryza, such as obstruction of the nares, heaviness of the head, discharge of limpid fluid, sensation of foreign body in the nasal passages, reflex acts, etc. The mucous covering of the septum is quickly destroyed and the cartilage laid bare. Necrosis of the latter soon follows, and a communication between the nostrils is established by a gradual corrosion and breaking down of the septum, which produces finally a round or oval perforation. Or, the same result may be accomplished by the exfoliation of necrotic plates or layers of the cartilage, presenting the appearance as if they had been punched out by instrumental aid.

When the mucous membrane is destroyed, a crust forms which becomes closely adherent, and beneath which the corrosion of the septum proper goes on. After perforation takes place, there is also a tendency to crust-formation about the edges of the artificial opening. It is possible that the crusts may act to a certain extent as protective agents, thereby preserving the edges of the cartilage against the invasion of the floating particles and hence limiting the further progress of the corrosive action. The latter process seems, in the vast majority of cases, to be confined to the cartilage, and very extensive destruction of the latter may occur without change in the external appearance of the nose. The most frequent seat of perforation is the antero-inferior portion of the cartilage; or, in other words, that portion which is most directly exposed to the action of the irritant particles. The perforation itself varies greatly in size. I have seen almost complete destruction of the cartilaginous septum, nothing remaining but the merest rim of tissue to support the fleshy structures of the external nose.

Although this is its most frequent seat, the ulcerative process is not confined to the septum, but is occasionally met with in other portions of the nose, as the turbinated bodies and nasal pharynx. It is more likely to occur in the latter situation, as the voluntary removal of foreign substances from this cavity is more difficult than their expulsion from the nasal chambers. Ulceration, moreover, is also more likely to persist in the former than in the latter situation. The lower pharynx is also sometimes the seat of more or less clearly defined ulceration, and the same is probably true of the larynx, although I am unaware of its occurrence in the latter. The condition of the lower respiratory tract generally found is that of inflammation, characterized by intense redness, moderate swelling, with tendency to inspissation of secretion. These appearances are found as far down the trachea as the laryngoscopic view extends. In fact, the mucous membrane of the entire naso-bronchial tract is intensely hyperæmic, more or less swollen, and presents at various points evidences of capillary hæmorrhages and small ex-

travasations of blood. These appearances are more pronounced in the respiratory region of the nose. Ulceration also attacks the hair follicles in the nasal vestibule, causing a dryness and itching, with falling out of the vibrissæ.

As the ulcerative process in the nose and retro-nasal space advances, the secretion becomes mucopurulent, and portions of the necrotic tissues are expelled either in shreds or as a fine detritus mingled with the greenish-yellow discharge. In some the nasal flux is inconsiderable, and perforation of the cartilage may occur without the knowledge of the individual. There is often a great tendency to the formation of hard, laminated, or tough, leathery crusts, which adhere to the structures with great tenacity, and whose expulsion is attended with considerable difficulty. They may be expelled through the anterior nares, or may fall into the lower pharynx, and be expectorated. Occasionally detachment occurs during sleep, the crust entering the laryngeal vestibule and giving rise to suffocative paroxysms.

Accompanying the catarrhal symptoms, there is a sensation of heat or burning in the nose and throat, and sometimes intense headache which is referred to various portions of the cranium. The sensation experienced is sometimes described as that of a bubbling or boiling as of water in a cauldron, in the vertex, and constitutes one of the most annoying features of the case.

Attention has already been called to the inspissation of the secretion and its tendency to crust formation. Notwithstanding such disposition, however, and the profuse and purulent character of the discharge, there is little, if any tendency to the development of a condition of *ozæna*. Fœtor is, so far as my experience goes, always absent, or at least, is never a prominent symptom. This I consider a point of especial interest. The absence of odor here is certainly in a measure due to the fact that the agent which excites the discharge, at the same time destroys the forms of life, upon the presence of which the factor of such conditions is supposed to depend.

The corrosive action is not always limited to the mucous membrane of the nose and throat. Purulent inflammation of the drum cavities also occurs, with perforation of the tympanic membrane and the consequent development of *otorrhœa*. This is in part doubtless due to extension through the Eustachian tubes; but it is conceivable that the membrane may become corroded by direct contact of the bichromate dust.

There appears to be a decided limit, however, to the destructive action of the corrosive agent on the cartilage and mucous membranes, a certain self-limitation of its corrosive power, which agrees with the known comportment of the poison in the presence of organic matter. For, as is well known, every molecule of matter with which each molecule of chromic acid comes in contact, is not only immediately destroyed, but the acid, in accomplishing such destruction, is itself rendered further innocuous by its conversion into an insoluble oxide of chromium.

Experimental chemistry has chiefly concerned it-

self with the investigation of the toxic effects of chromic acid and its salts upon the nervous system, upon the stomach, intestines and kidneys, and its corrosive action upon the external surfaces, and little attention has been bestowed upon its action on the respiratory tract. Gmelin, of Tübingen, who was the first to study, experimentally, their poisonous properties, found that the bichromate of potassium, when introduced under the skin of a dog, produced on the fourth day difficulty of breathing and deglutition, and the post-mortem revealed general inflammation of the respiratory tract, with bloody and fibrinous effusion.¹ Some years later Berndt, in the course of a series of experiments with the same salt, found redness of the windpipe in a guinea pig and pigeon poisoned by its introduction into the stomach.²

The only observations in regard to perforation of the septum that I can find are contained in an article by Bécourt and Chevallier in the *Annales d'Hygiène*,³ and in the brochure of Delpech and Hillairet.⁴ The latter observers report cases where extensive destruction of the cartilaginous septum existed. Both unite in the observation that the sense of smell remains intact, and that those who take snuff are exempt from nasal trouble, an immunity which they explain by the frequent cleansing of the nostrils which the use of that article necessitates, and the protective layer which it forms in the nasal passages.

My own observations in regard to the perforation agree in the main with those of the above writers, of whose investigations I was ignorant two years ago, when the subject was first brought to my notice. The persistence of the sense of smell is doubtless due to the fact pointed out above, that the olfactory region is very rarely involved.

The only instance of ulceration of the throat that I have found is that reported by Heathcote and referred to by H. Rousseau in his Paris thesis on chromic acid⁵, whilst so far as I am aware, the perforation of the tympanic membrane and other phenomena referable to the ear have never been heretofore observed.

The injurious effects upon the mucous surfaces is most probably due to the corrosive action of minute particles of bichromate of potash which fill the atmosphere during the conversion of the neutral salt into the bichromate by means of boiling sulphuric acid.

It would appear, then, from the above, that the toxic action of the salt on the mucous membrane of the respiratory tract may be produced by direct inhalation, by the introduction of the drug through wounds of the skin, or its absorption through the mucous membrane of the digestive tract.

The extensive use of the salts of chromium in dyeing and painting confers upon their toxicological

relations a manifest interest and importance. For not only do those engaged in their manufacture come within the range of their injurious influence, but the host of articles for the coloration of which they are employed may become agents of possible harm wherever they are circulated and in the many forms in which they are applied. An additional importance, too, in this regard, attaches to the introduction into the system of the poison through abrasions on the cutaneous surface and its toxic effects, when thus introduced, upon the mucous surfaces of the respiratory tract. It is accordingly well to bear in mind the possibility of such an occurrence in estimating the etiological factors in obscure and intractable inflammatory conditions of the respiratory apparatus. In this connection I recall a case of virulent nasal discharge, whose causation was vainly sought for among the ordinary diseases of the nose, and whose management was a failure, until the accidental discovery that the patient dyed her hair with a preparation containing a salt of lead, and a timely conversation in her hearing concerning the injurious effects of such preparations in general upon the system.

The medico-legal question may, furthermore, arise, as to whether a given ulceration of the nasal cavities with perforation of the septum be due to poisoning by chrome (or an allied substance), or whether it be an accident of constitutional syphilis. In coming to a conclusion upon this point, the absence of ozæna, or fœtor, the effect of simple medication, the self-limitation of the process, and, when the ulceration is no longer active, the absence of deformity of the external nose so characteristic of syphilis, may be looked upon as important data in establishing a differential diagnosis.

The marked and rapid corrosive effect upon the cartilaginous septum, suggests, moreover, a certain caution in its use as a therapeutic agent in affections of the overlying mucous membrane, and the careful protection of that structure when the caustic is employed in other affections of the nasal passages.

MEDICAL PROGRESS.

MATERIA MEDICA AND THERAPEUTICS.

ANTIPYRIN.—Dr. Max Jahn, of Grevesmühlen, in the *Deutsche medical zeitung (Med. Press)*, reports a case of puerperal fever treated by antipyrin "with surprisingly good results." The preparation was given in 2 grm. and 1 grm., hourly doses, and then a pause. The patient belonged to the better classes, and was a chlorotic 2 para. The first dose relieved the tormenting pain of the peritonitis, not to return for five or six hours. This effect was spontaneously remarked by the patient as occurring on every occasion. The same relief was not obtained by a subcutaneous injection of 0.015 grm. of morphia. After the first series the temperature fell, two and a half hours after the first dose, from 107.2° to

¹ Vide Christison, Treatise on Poisons; Bell's Med. Lib., Phila., 1845, p. 385; and Ducatel, Balto. *Med. and Surg. Journal and Review*, 1833, vol. 1, p. 44.

101.3° F., without any perspiration, and from this to 100.1° F., not to rise again for twenty-one hours. The second series was given when the temperature had again risen to 104.8° F., after which it fell to 100.7° F. Other treatment—calomel, ergot, injections, etc.—was not suspended during the antipyrin treatment. The drug had a decidedly favorable action on the sensorium, ramblings ceased, the fixed stare, and all those appearances that give form to the facies puerperalis vanished, and repeatedly for longer or shorter periods a calm sleep came on. The pulse rate kept up to from 112 to 140, until the pelvic peritonitic symptoms abated, when it fell to 80 or 100. Collapse was never observed. No effect was observed on the meteorismus.

To this case by Jahn, the annotator of the *Press*, adds his experience in two cases: One a case of exomphalus with adherent omentum, on the second day after operation the temperature rose to 102, when antipyrin was given as by Jahn. By the time the last dose of the series was given the temperature had fallen to normal. The medicine was now given in 15 grain doses every four hours, and the temperature did not again rise. The case did well. The second case was one of encysted dropsy of the peritonæum from peritonitis, in a girl, æt. 18. The cavity was opened and drained. On the third day, as in the first case, the temperature rose to 102, when antipyrin was given as before, the temperature falling steadily to normal, at which point it remained as long as the supply of the drug held out. This patient is convalescent, but weak.

LEMON JUICE AS AN ANTIPYRETIC.—Dr. Lanchlan Aitken, of Rome, writes, in the *British Medical Journal*, very favorably of the antipyretic value of lemon juice, which he has given to advantage in cases of enteric fever, enteric fever complicated with malaria and typho-malarial fever. This remedy was first brought into notice about a year ago by Dr. Maglieri in *Il Morgagni*, who got his information from his uncle, a farmer, who had frequently used it to the benefit of some of his farm laborers, the victims of malarial affections which had resisted better known means of cure; and from his own experience in chronic malarial cachexy, and pernicious malarial fever. At the request of Professor Tommasi-Crudeli, the remedy was adopted by a large landed proprietor near Rome, and the results obtained by him, too, in severe cases of malarial infection, were very surprising, and were mentioned in a letter to the Minister of Agriculture and Commerce. In the *Morgagni* for March, 1884, Dr. Dominico Arzillo gives some details of cases in which he had used the lemon decoction with excellent effects, and writes in enthusiastic terms of the simplicity of the cure and of its superiority to quinine.

Its preparation is as follows: A freshly gathered and unpeeled lemon being taken, cut into thin slices, put in three teacupfuls of water, and boiled down to one teacupful in a clean earthenware jar; this quantity of the decoction was then allowed to stand over night in the open air, and given the first thing in the morning, after the liquid had been separated from the

rind, pulp and seeds by careful filtration and compression just before it was drunk.

The effects observed by Dr. Aitken have been as good as those of large doses of quinine. It has never seemed necessary to give the decoction prepared from more than one lemon daily; but there can be no reason why more than one draught should not be taken in the three hours if required. It was noticed that freshly plucked lemons had more apparent effect than those not quite recently gathered, a serious drawback, in the meantime, to the use of the decoction in countries where there are no lemon trees. What the active principle is, is as yet quite uncertain, although it is obvious that it is not citric acid. The alkaloid principles, hesperidine and limonine, said to be obtained from lemons, are quite unknown to medicine; and no experiments have been made to ascertain their physiological properties.

MEDICINE.

ON COBRA POISON.—Dr. R. Norris Wolfenden (*Indian Medical Gazette*), has been conducting some investigations into the chemical nature and physiological action of cobra poison. He gives credit to Dr. Wall's book on Indian snake poison as being very valuable, and refers to Weir Mitchell and Reichart, but is ignorant of the scope and character of their investigations. His researches led him to the conclusion that cobra venom chemically consists of 1. A globulin venom. 2. A serum albumen venom. 3. Traces of other albumens. 4. Salts, chlorides, phosphates and sulphates. 5. Water. He found no proteid body resembling a peptone. Morphologically the glands secreting the poison resemble parotids, and the resemblance is still more striking from the occurrence of a diastatic ferment in the secretion (which was long ago spoken of as analogous to ptyalin by Burk and others). The venom is generally thought physiologically to be modified salivary secretion, consequently we should scarcely expect to find peptone present.

Physiologically he recognizes in cobra poison two distinct venoms. 1. Cobra globulin venom. 2. Cobra albumen venom. They exist probably in different proportions in different secretions, but these two are always present. The globulin venom is destroyed by high temperatures, but the albumen venom is not so affected. The globulin venom poisons the respiratory center, producing no paralysis of muscles; the albumen venom does not effect the respiratory center, but produces marked and progressive motor paralysis. He does not agree to the generally conceived opinion that cobra venom exerts no influence upon the blood; his experiments show that cobra venom decolorizes, by driving out the hæmoglobin from a large proportion of the discs, and breaks up a large number of the white discs completely, filling the plasma with minute granules. He does not think the bacterial forms, which are present in such large numbers in cobra venom, have anything to do with the activity of the venom. When recovery takes place from poisoning with a dose of the poison insufficient

to kill, it is not improbable that a condition of blood poison may supervene secondarily. The globulin venom is slower in its action than the serum albumen and a longer period often elapses after the injection before symptoms supervene or terminate life. The globulin is very deadly, and when once the symptoms have supervened asphyxia rapidly ends the existence of the animal.

POISONING BY CANNED FOODS.—Dr. John G. Johnson, of Brooklyn, N. Y., having had six cases in his practice of corrosive poisoning, according to his diagnosis, from eating canned tomatoes, he presented a paper on this subject before the Medico-Legal Society, of New York, and the *Boston Medical and Surgical Journal* gives the following as the general conclusions of his paper:

(1.) The six cases were not cases of sickness from spoiled tomatoes. (2.) They were cases of corrosive poisoning from muriate of zinc and muriate of tin. (3.) This poisoning amalgam must be abandoned. (4.) Exemplary damages "at the discretion of the jury," will be sustained by the courts for this reckless tampering with human life in using a dangerous means when a safe one could be used. (5.) The canners have only themselves to thank for the present pause in their business, for they have persisted in this dangerous plan, knowing it was dangerous. (6.) Every cap should be examined, and if two holes are found in it send the can at once to the Health Board, with the contents, and name of the grocer who sold it. (7.) Reject every article of canned food that does not show the line of rosin around the edge of the solder of the cap, the same as is seen on the seam at the side of the can. (8.) Reject every can that does not have the name of the manufacturer or firm upon it as well as the name of the company and the town where manufactured; "standards" have all this. When the wholesale dealer is ashamed to have his name on the goods fight shy of him. (9.) Press up the bottom of the can; if decomposition is commencing, the tin will rattle the same as the bottom of the oiler of your sewing machine does. If the goods are sound it will be solid, and there will be no rattle to the tin. (10.) Reject every can that shows any rust around the cap on the inside of the head of the can. If housewives are educated to these points then muriate of zinc amalgam will become a thing of the past, and dealers in "swills" have to seek some other occupation.

EXPERIMENTAL AND CLINICAL INVESTIGATIONS INTO BRIGHT'S DISEASE.—Dr. Mariano Semmola (*Archives de Physiologie*) thus sums up the results of his study of the subject:

1. Each organism has a certain orbit of nutrient activity for the albuminoid substances as well as for the hydrocarbonaceous substances.

2. The albuminoid substances, as well as glucose, which present themselves in the circulation, in a proportion superior to the degree of activity of the orbit, are forcibly eliminated by the organism as foreign and useless substances by all the emunctories, and particularly by the urine. Albuminuria, in this

sense, constitutes a simple act of organic epuration, to which the kidneys contribute, without any necessary epithelial alteration.

3. One of the most important physiological conditions for the accomplishment of the activity of this orbit of assimilation and combustion resides in the activity of the respiratory functions of the skin.

4. When the activity of the skin is diminished or suppressed, the albuminoids which appear in the blood-serum either do not attain, or do not preserve, their necessary degree of non-diffusibility, and hence become incapable of accomplishing their biological mission. There is necessarily, in consequence of this, an elimination of the albumen by the urine, and by all the other epurative emunctories of the organism. It follows, therefore, that the formation of urea is diminished because there is a diminution in the activity of the combustion of the albuminoids.

5. The want of assimilation of albuminoids furnished by alimentation may be produced by two initial conditions, that is to say: 1st. The quantity of albuminoids introduced being more than the orbit of respiratory activity proper for each individual, and consequently there exists an albuminuria by absolute hyperalbuminosis of the serum of the blood; 2d. While there should exist a perfect equilibrium between the quantity of albuminoids ingested and the activity of assimilation proper to each organism, if, from accidental and pathological causes, a diminution of the respiratory activity of the skin takes place, naturally that equilibrium is disturbed, and the same quantity of albuminoids that was formerly completely assimilable and combustible becomes necessarily in part inassimilable, and a *relative* hyperalbuminosis occurs. In the first condition the albuminuria is accompanied by the physiological maximum of urea proper to the organism in question, whilst in the second case, with the albuminuria there is observed a diminution of the urea in proportion to the physiological mean of the twenty-four hours.

6. This chemico-molecular alteration of the albuminoids, which we cannot detect chemically with the reactions that we possess at present, is characterized by their pathological diffusibilities, which deprives them of the power of accomplishing their biological function. It is from this fact that Dr. Semmola applies the name of *hetero-albuminemia*.

7. Among the functions which exert a great influence in producing this complete chemico-biological evolution of albuminoids through the organism, the cutaneous functions must be placed in the first rank. But there are, of course, other influences, such as the liver, the ganglionic nervous system, etc., which require further and special investigation.

THE
Journal of the American Medical Association.

PUBLISHED WEEKLY.

THE EDITOR of this JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information, should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE..... \$5.00.

SINGLE COPIES..... TO CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 65 RANDOLPH STREET,
CHICAGO, ILLINOIS

SATURDAY, NOVEMBER 29, 1884.

GASTRIC DILATATION IN CHILDREN.—Ectasis of the stomach appears to have received more than usual attention of late on the part of French clinicians. It is a subject worthy of careful consideration in this country as well; for, whether the malady be more prevalent in Europe than here or not, it doubtless exists many times when our practitioners fail to detect it, contenting themselves with a diagnosis which recognizes only a symptom, not the primary lesion. This may be owing in part to the difficulty often attending its detection, and also in part to the mask the disease assumes of symptoms referable to the heart, skin and nervous system. Even when on the lookout for dilatation of the stomach in adults, few practitioners, we think, would expect to find it in young children. Yet Dr. J. Comby, in *Archives Générales de Médecine* for August and September last, presents some interesting features of the disease as studied in fifty cases which occurred in his dispensary practice. He found it associated with rachitis; not, however, as an effect, but as a cause, itself being the result of improper and excessive feeding. Although occurring in children for the most part, it may yet be found in infants at the breast as well as in those reared with a bottle. In such cases, the distension of the stomach is produced by the ingestion of a too great bulk of liquid nourishment. In other instances, alimentation of an improper kind is instrumental in its causation. The symptoms are dyspepsia, convulsions, insomnia, urticaria, eczema, bronchitis, and manifold other functional disorders. These symptoms may occur alone or together. Dr. Comby regards the prognosis as serious, since the dilatation may persist until puberty, or even until

mature years. As measures of prophylaxis he recommends that bottle-fed infants be put to the breast, and that all infants, whether nursing or not, be fed at regular intervals and restricted as to amount. Infants should not be weaned too early nor too quickly, he thinks. If ectasis of the stomach already exists, the food should consist exclusively of milk in case of infants, while older children should be allowed solid food only. Irrigation of the stomach is sometimes advisable. Dr. Comby enumerates as diagnostic points, a protuberant abdomen, tympanism, and the characteristic succussion sound. The subject is an interesting one, and though some may not be inclined to accept the author's conclusions, particularly as regards its etiological relation to rickets, it may serve to stimulate to profitable research.

BINDING OF THE JOURNAL.—In answer to many inquiries we will state that any parties who may desire it, can have the volumes of their JOURNAL bound in good strong binding suited to the size of the volume (cloth sides and leather backs), neatly lettered with title and number of volume on the back, for *one dollar per volume*. The binding is done by the Chicago Legal News Company. Volumes that are properly wrapped and labelled, sent to this office free of charge to us, we will take charge of, get bound and return them as soon as possible, for the accommodation of our readers. We have no arrangements for furnishing simply skeleton backs or binding, as is done by the publishers of a few journals, simply because no book-binders wish to prepare and keep a stock on hand without some assurance that the JOURNAL will be continued in the same city more than one year.

NEW YORK STATE MEDICAL ASSOCIATION.—The first annual meeting of this Association was held in the city of New York from the 18th to the 21st inst. The meeting was numerously attended, harmonious, and well supplied with papers of interest and value.

An excellent plan of organization for the State was adopted. We omit a part of the matter under the head of Medical Progress and some of the editorial items to give place in this number to the first half of the proceedings as furnished by our special correspondent. The remainder of the proceedings and the President's address will be given in our next number, as they were received a day too late for this issue.

DEATH OF DR. SAMUEL M. BEMISS, OF NEW ORLEANS.—This eminent and well-known physician and medical teacher died suddenly at his residence on the evening of the 17th inst. A further notice and biographical sketch will be given in our next number.

SOCIETY PROCEEDINGS.

NEW YORK STATE MEDICAL ASSOCIATION.

First annual meeting of the New York State Medical Association, held at the Murray Hill Hotel, New York, November 18, 19 and 20, 1884; the President, Henry D. Didama, M.D., of Syracuse, in the chair.

FIRST DAY—MORNING SESSION.

Report of the Committee of Arrangements.—Dr. J. W. S. Gouley, chairman of the Committee, delivered an address of welcome, and gave an analysis of the programme of the meeting, stating that fifty-four papers had been received.

Address by the President.—In it he laid special stress on the paramount importance of therapeutics in a sound medical education, and reminded his hearers that, however admirable a thing culture might be, it should not be allowed to take equal rank with the essential branches of the healing art. He strongly advised the adoption of the three years' graded course by the colleges, and drew a striking contrast between the old and new systems of medical training.

Addresses by Delegates from other State Societies.—During the session a large number of delegates from other States were introduced. Dr. Shoemaker, of Philadelphia, spoke for the Pennsylvania State Society; Dr. S. S. Clark, of St. Albans, for the Vermont Society, and Dr. Wylie for the Connecticut Society. Dr. Wm. Detmold, President of the New York County Association, also made an address.

Report of the Committee on Organization of District Associations—Dr. Gouley, chairman, reported that the Committee recommended the formation of five district associations, to be known as the first or Northern, the second or Eastern, the third or Central, the fourth or Western, and the fifth or Southern; that the vice-presidents of the parent association should be the presidents of the district associations to which they respectively belonged; and that each of the district associations should have one stated meeting each year, the number of special meetings being left to each association to determine for itself.

After some discussion the report was unanimously adopted. From twelve to fourteen counties are represented in each of the five district associations, which were afterward organized in accordance with the plan proposed. The first stated meeting of the first district association is to be held at Utica on the second Tuesday in July, of the second at Saratoga on the fourth Tuesday in June, of the third at Syracuse on the second Tuesday in June, and of the fifth at Brooklyn on the third Tuesday in September.

The address on Surgery was delivered by Dr. E. M. Moore, of Monroe county, who took for his subject the "Transfusion of Blood."

He preferred the use of natural blood for this purpose to defibrinated blood, milk, or any of the saline solutions which had been employed by others. The two great dangers to be avoided are, ingress of air into the vein and coagulation of the blood, and in order to avoid the latter it was requisite that the

period of transfusion should be short and definite. Unless the syringe, which was almost universally employed in the performance of this procedure, were held perpendicularly, air was constantly liable to be injected into the vein; and therefore he had devised a simple apparatus which obviated the necessity of a syringe, and also enabled the operator to make the transfusion in a very brief period of time. It consisted of a long narrow India rubber sac, to the lower end of which was attached a canula, provided with a rounded stiletto and Moncocque's mandril, by means of which the supply of blood could be instantly shut off. Another advantage of this instrument was that it required no lubricating, as was necessary for the packing of syringes, and by reason of which impurities might be introduced into the blood. The blood of the donor was to be received in a funnel held in the mouth of the rubber sac, and more than two ounces was never to be drawn at one time, on account of the danger of coagulation. Even less than this quantity was often sufficient, and if more were required, the operation could be repeated without withdrawing the canula from the vein of the patient.

AFTERNOON SESSION.

Dr. J. C. Hutchinson, of Kings county, read a paper on "Transfusion," in which he described a new apparatus. It consists, first, of a glass cylinder graduated in fractions of an inch and holding twelve ounces. In an opening of the metallic cap which covers its lower extremity is fitted a punch screw, and the rubber cap at the top of the cylinder is perforated by a thermometer. The cylinder is placed in a double rubber bag which is filled with hot water, but which is so arranged that the graduated scale of the cylinder can be observed. The fluid within the cylinder flows through a rubber tube, the upper end of which is secured with the punch screw mentioned, and the lower end of which terminates in a canula provided with a slip-knot, which is inserted into the vein of the patient. Dr. Hutchinson prefers the use of saline solutions to blood for transfusion, as he thinks the action of the transfused fluid is dynamic rather than nutritive. From twelve to twenty ounces of fluid should be used, and the flow should not exceed one ounce per minute.

Dr. Rochester, of Erie county, thought that the quality of the fluid used in transfusion was of more importance than the quantity, and said that in the cholera epidemic of 1849 and 1850, in New York, all the patients in whose cases transfusion with saline solutions were employed (although temporarily improved by it) eventually died.

The President said that in cholera times it used to be remarked that "salting a patient and curing a patient were two different things."

Dr. Alfred S. Carroll, of Richmond county, read a paper on "The Question of Contagiousness after Acute Infectious Diseases." As this was a matter of great practical importance, especially in regard to the return of children to school after such illnesses, he had addressed inquiries to a number of prominent medical men throughout the State, but except in regard to small-pox the replies had varied very widely. The

results of his inquiries would subsequently be embodied in a report to the State Board of Health, and he trusted that the Fellows of the Association would favor him with any data that had been noted by them bearing on this subject.

Dr. John S. Jamison, of Steuben county, read a paper on "Chronic Intestinal Catarrh," which was an exhaustive treatise on the subject. Before the part of it devoted to treatment was reached, the reader was interrupted by the expiration of the half hour which was the limit for the reading of all papers.

Dr. Edward R. Squibb, of Kings county, read a paper on "The Modern Progress of Materia Medica," in which he said that physicians did not now depend on the books for the determination of doses of medicines, but upon the physiological and therapeutical effects which they produced, that drugs were used in more concentrated forms (fluid extracts having to a great extent superseded tinctures and syrups), that fewer and more active agents were employed, and that the quality of drugs was much more closely scrutinized.

Dr. W. H. Robb, of Montgomery county, read a paper on "The Management of Criminal Abortion," in which he discussed the best methods for controlling hæmorrhage, removing the entire ovum, the prevention of septicæmia, and the restoration of the patient to health. For the control of hæmorrhage he depended on ergot and digitalis internally or hypodermically, and locally the use of the hot vaginal douche and tents introduced into the mouth of the uterus. For the removal of the ovum, in order to accomplish which it was often necessary to dilate the os, there was ordinarily no instrument so good as the finger; but it was sometimes necessary to resort to the curette, or the female blade of the blunt-hook and crotchet. Such procedures should always be followed by intra-uterine antiseptic injections.

Dr. Ely Van de Warker believed that ergot was useless as a hæmostatic upon or at the third month, and he thought steel dilators preferable to the use of tents for dilating the os uteri. He had found the blunt curette of great service in removing the remains of the ovum, and thought it sometimes of advantage to swab out the interior of the uterus with the tincture of the chloride of lime after its use.

Dr. Charles Bulkley, of Monroe county, read a paper on "Chronic Mercurial Poisoning." The case on which the paper was based was that of a patient who suffered from symptoms resembling those of arsenical poisoning, but which were ascertained to be due to the mercury used in the coloring of the hard red rubber dental plate which she wore. Since then he had met with several other similar cases, though of less severity.

Dr. R. H. Sabin, of Albany county, read a paper on "A Case of Acute Lead Poisoning, Resulting Fatally." There was probably serous effusion of the brain, though an autopsy could not be obtained. The patient, while apparently in good health, fell suddenly to the floor, and remained unconscious up to the time of death, a period of thirty-two hours.

The following papers were read by title: "The Therapeutics of Diphtheria," by Dr. J. W. Moore, of

Albany county; "Notes on Dislocation of the Hip, based on 238 cases occurring in the State of New York," by Dr. Frederick Hyde, of Cortland county; and "Intestinal Obstruction," by Dr. Avery Segur, of King's county.

EVENING SESSION.

Dr. H. E. Mitchell, of Rensselaer county, read a paper on "Errors of Refraction: the Importance of their Recognition and Correction in Early Life."

The rapidly increasing number of defective eyes in children, he thought, could be arrested to some extent, at least, if more general practitioners would provide themselves with sets of the ordinary test types, and with the optometer, which was a very simple, but useful instrument, which demands to be better known.

Dr. Austin Flint, Sr., of New York, read a paper on "The Dietetic Management of Dyspepsia," in which he maintained that dyspepsia and indigestion are distinct affections. The greater number of dyspeptics at the present day, he thought, were individuals who endeavor to regulate their diet and all the habits of life in accordance with certain rigid rules which were formerly much more in vogue than now, and especially in New England. The guides for eating should be the appetite, the palate, and common-sense. Dietetic idiosyncrasies are much less common than many believe to be the case, and the patient's experience with particular articles of food was apt to be extremely fallacious. In general, the diet which was beneficial to the healthy individual was beneficial to the dyspeptic. It was a mistake to leave the latter hungry, and food was to be taken not merely at stated intervals, but whenever the appetite craved it.

Dr. N. C. Lynde, of Erie county, read two papers, the first on "*Double Synchronous Amputations*," with a table of such operations collected from the reports of surgeons throughout the State, and the second on "The Functions of the Auricle." In this paper he claimed that the main function of the auricles was merely that of a reservoir into which the great veins emptied, and the principal part of the paper was devoted to an argument in support of the proposition that they did not contract. In the course of this he claimed that the pulse in the jugular vein was due exclusively to the contraction of the right ventricle.

Dr. Austin Flint, Jr., remarked that the views of the author of the paper were in direct variance with those of all recognized physiological authorities, and that personally he had often himself actually seen the auricles contract in animals whose hearts had been exposed. He claimed that if the auricles did not contract their walls would become atrophied, as was the case with muscles that had become paralyzed, and that direct observations on dogs (without exposing the heart), had shown that the auricles, as well as the ventricles, contracted. This was done by means of sounds which were introduced into the cavity of the heart through the jugular vein and which were provided with two rubber bags, one of which entered the auricle and the other the ventricle. It was found in this way that two-tenths of the time of the heart's whole pulsation was occupied with the contraction of

the auricles, two-tenths with the contraction of the ventricles, and the remaining four-tenths with the general diastole.

Dr. Austin Flint, Sr., claimed that the jugular pulse was due to the contraction of the right auricle, as well as to that of the right ventricle. That there was an auricular, as well as a ventricular jugular pulse, seemed to be proved by the fact that preceding the contraction of the ventricle (the time of which could be positively determined by the impulse of the heart, the first sound, and the carotid sound), a pulse could be detected in the jugular vein which could be due only to the contraction of the auricle. This, he believed, he himself had been the first to point out.

The paper was also discussed by Drs. Moore and Ross, both of whom opposed the views expressed in the paper, and Dr. Lynde then said that in a large number of cases he had plunged trocars and canulæ into the auricles of dogs, he had never succeeded in getting the blood to come through the instruments; while when the same canulæ were introduced into the ventricle a strong stream of blood invariably flowed through them; which seemed to afford conclusive evidence that the auricles did not contract.

Dr. E. D. Ferguson, of Rensselaer county, read a paper on "The Use of the Aspirator in Hydrothorax." He had seen such bad consequences, such as empyema and death, resulting from the too free use of the aspirator, that he now made it a rule never to use it in this condition except when dyspnœa or other serious symptoms supervened, and when he did resort to aspiration carried the procedure only to a very limited point. Dr. Bowditch had advised that it should not be discontinued until pain in the epigastrium or dyspnœa was produced; but he thought that it should be stopped before the occurrence of these symptoms, which indicated serious difficulty, and that more than a pint of fluid at the utmost should never be withdrawn at a time. Much evil had also resulted from aspiration of the pelvic cavity, in which the greatest caution ought to be observed, and he thought that on the whole the instrument had perhaps done more harm than good in the hands of the profession.

The paper was discussed by Drs. T. F. Rochester, of Buffalo; Flint, of New York; Moore, of Rochester, and Fifield, of Boston, a delegate from the Massachusetts State Medical Society; and Dr. Rochester read a paper on "A New Procedure in Paracentesis Thoracis."

The procedure referred to was the introduction of the finger into the opening and the separation of the ribs in those cases in which the closeness of the ribs prevented the insertion of a drainage-tube. He had used this in these cases with success.

SECOND DAY—EVENING SESSION.

Dr. Gouley proposed a plan for dividing the Association into five sections at its future meetings, and on motion the matter was referred to the Council, with the request that they should report on it at the next annual meeting.

Library in New York.—On motion of Dr. Gouley, a series of resolutions providing for the formation of

a library of the Association to be located in the city of New York, was unanimously adopted.

Dr. S. C. Allen, of Rensselaer county, read a paper on "A Case of Diarrhœa from Disease of the Pancreas."

The patient suffered from what the author of the paper termed "adipose diarrhœa," but improved greatly under treatment. The case was complicated with renal disease, and death finally resulted from uræmic coma. No autopsy was permitted.

Dr. T. Gaillard Thomas then delivered the address on Obstetrics and Gynæcology.

Having glanced at the past history of obstetrics, he said that, in his judgment, one of the greatest achievements in modern pathology had been the discovery of the agency of certain micro-organisms, classed under the head of bacteria, in the production of septicæmia, pyæmia and other similar affections. Although the obstetricians of the present day were not prepared to make antiseptic midwifery the rule whenever that art was practiced, it was highly probable that in the very near future this proposition would be accepted. To free the parturient act from the dangers of septic poison would be to save millions of lives in every generation. The germ theory had also revolutionized the treatment of that variety of septicæmia known as puerperal fever. He spoke next of the successful treatment of extra-uterine pregnancy by laparotomy, and lauded the use of electricity before the rupture of the cyst. In placenta prævia and cases of uræmia during pregnancy he advised the induction of premature labor as a sovereign resource. In the obstetric forceps he thought the only real improvements which had been made since the time of the Chamberlins were the additional length and pelvic curve added by Levret and Smellie and the tractors of Tarnier. He concluded this portion of the address with a plea for the adoption of laparo-elytrotomy in preference to the Cæsarian section or Porro's operation.

The brilliant results in gynæcology during the past quarter of a century, Dr. Thomas attributed to the bringing into the service of this department the powerful aid of surgery; although he wished it to be understood that he was a strong advocate for the great advantage of constitutional treatment in diseases of the pelvic viscera of the female. In most of the pathological conditions met with by the gynæcologist, surgical interference was often an essential to cure. Having spoken of the good achieved by Emmet's, Battey's, Hegar's and Tait's operations, he referred to extirpation of the uterus, and summed up by saying that Freund's operation of the removal of the uterus by abdominal section, on account of its difficulties and dangers, was now relegated to the past; while vaginal extirpation had conquered for itself the position of a recognized, legitimate, and even valuable procedure. After alluding to the forcible distension of the uterine canal by a divulsor, or expanding forceps, as a treatment for uterine deformities, he spoke, in conclusion, of four drugs which had recently been introduced into gynæcological practice, viz.: permanganate of potassa and the fluid extracts of the *stigmata* and *ustilago maidis*, of the *viscum album*, and of the *viburnum opulus* and *viburnum prunifolium*.

Permanganate of potash he considered the best emmenagogue which has yet been discovered.

SECOND DAY.—AFTERNOON SESSION.

The following papers were read by title: "Pyæmia and Death After the Operation for Convergent Squint," by Dr. J. J. A. Burke, of Monroe county; "Relations of Habit to Disease," by Dr. C. M. Kittridge, of Dutchess county; "Report of a Case of Nephro-Lithotomy for Calculous Pyelitis," by Dr. F. N. Seymour, Rensselaer county; "Report of a Case of Excision of the Rectum for Cancer," also by Dr. Seymour; "The Practice of Medicine of Fifty Years Ago with Comparative Position at Present," by Dr. B. L. Hovey, of Monroe county; "Notes on Peat as a Surgical Dressing," by Dr. W. S. Tremaine, of Erie county, and "A Case of Ovarian Cyst, with Operation," by Dr. T. M. Lloyd, of King's county.

Dr. Darwin Colin, of Wayne county, read a paper on "Venesection in the Convulsions of Pregnant and Parturient Women," in which he made a strong plea for this procedure, basing his opinion on a large number of cases in the practice of his father and himself, both before the introduction of the use of chloroform, ether, chloral, bromide of potassium and hypodermic injections of morphia.

In the discussion which followed, Dr. Moore, of Rochester, said he believed that recovery in these cases depended on the elimination from the system of the poison which was creating the disturbance, and that nothing was so efficient in doing this as cathartics. Since, however, the patient was liable to die before the latter could have their appropriate effect, anything that would suspend the convulsions for the time would prove of service. Blood-letting undoubtedly did this; but there were other agents which he preferred for this purpose, and the best of all, in his opinion, was ether. The inhalation of this should be kept up unremittingly until either the uterus had been emptied or the bowels had been moved by a purgative.

Dr. Thayer, of Brooklyn, referred to the use of Norwood's tincture of veratrum viride, in teaspoonful doses, as very efficient in controlling convulsions and preventing their recurrence.

Dr. C. C. F. Gay, of Erie county, read a paper on "Fracture of the Base of the Acetabulum."

(TO BE CONTINUED.)

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated meeting Nov. 6, 1884. The President, R. A. CLEEMAN, M.D., in the chair.

Removal of Uterine Appendages for Menstrual Epilepsy Recovery. DR. E. E. MONTGOMERY exhibited the specimens and read the history of the case. Sarah H., æt. 17 years, was admitted to the Philadelphia Hospital, April, 1884. She suffered from an attack of inflammatory rheumatism in childhood and began to have epileptic seizures in her thirteenth year, these were slight at first, but have recurred every month, increasing in number and violence, so that at present she is unconscious from ten days to two

weeks out of each month. There has only once been a trace of menstrual discharge and that for a single day only. There is no history of any chronic disease in the family; brothers and sisters are healthy. The patient was pale, flabby, anæmic, poorly developed and extremely nervous. The external genitals were but slightly developed, the uterus small and no special tenderness over the pelvis. Iron tonics and a generous diet were given; the bromides were not well borne. Owing to her youth and the fact that she had not yet menstruated, it was deemed best to undertake to establish the menstrual function and exhaust the antispasmodics before resorting to operative interference. The failure of all remedial measures was complete, and on September 13 the operation was performed; both ovaries and tubes were removed. No antiseptic was used about the wound. All the water used had been well boiled. Absorbent cotton was placed over the wound which had been closed with silk sutures. The operation occupied thirty-five minutes. The recovery was uninterrupted until the night of the 26th of September when she had four epileptic seizures. There were recurrences of slighter attacks during the next three nights, but they were shorter, and during the intervals she was perfectly conscious. During the first four days of October, spells of staring with momentary unconsciousness occurred, becoming less frequent and lighter. A well marked convulsion on the night of Oct. 14 was followed by from one to four convulsions daily until the 29th. But they have not been so severe as before the operation.

Removal of Parovarian Cyst, Recovery. DR. E. E. MONTGOMERY presented the specimens and related the history as follows: Mrs. A., æt. 30 years, native of England, married, never pregnant, has suffered from an enlargement of the abdomen for seven years. As it was first noticed a few months after her marriage she supposed herself pregnant. Her menses have never been interrupted, now occur every three weeks, are very slight, and have never been excessive. She suffers from severe pain the week before menstruation over the lower portion of the abdomen and through the hips. She suffers at other times from pain in the feet and legs and from a sensation of weight. The tumor has been tapped some six times. The fluid was always of a pale straw color. The largest quantity removed at any one time was 40 lbs. The last tapping was on June 27, 1884. She has had four attacks of peritonitis.

When first seen last July, two weeks after the last tapping, the abdomen was swollen and tender to pressure; fluctuation was distinct. Since that time the abdomen has increased considerably in size, presenting a prominent tumor distending the whole abdomen, nearly symmetrical, but projecting slightly to the right side, circumference at umbilicus 32 inches, distance from symphysis to umbilicus 7 inches, to ensiform 13 inches; fluctuation distinct over the whole tumor; coughing projects the whole mass forward and downward. Her general condition is good, she is quite active.

Diagnosis, a Parovarian Cyst, Plan of Operation—exploratory incision, remove the tumor if possible,

but if the adhesions were too great to permit that, then to open the sac, stitch it to the integument, and introduce a drainage-tube and thus secure obliteration of the sac.

Operation Oct. 9, abdominal wound 4 inches, adhesions universal, but generally broken up without difficulty, no ligatures were needed. The intestines were not seen, being concealed by old inflammatory deposits. The right ovary was enlarged and was also removed. The wound was closed with seven sutures, and a glass drainage-tube introduced. Salicylated cotton in a thick layer was placed over the wound. Suppositories of morphia were used to control pain which continued to a greater or less extent for two weeks, arising partly from inflammatory conditions and partly from collections of gas in the intestines. The abdominal wound discharged freely, three ounces the first day. The drainage-tube was removed on the 13th, four days after the operation, but the discharge of bloody serum, pus and flaky lymph continued for full two weeks later when the wound closed entirely and the patient was discharged.

DR. B. F. BAER presented the specimens and read the following report of a case of *Placental Polypus which simulated malignant disease of the uterus*. The patient was 35 years of age, married and had two children at full term, the last twelve years ago. She has had several abortions since, but otherwise she has enjoyed good health. Her mother died at the age of 38 of cancer of the uterus. In the early months of this year our patient first noticed that her catamenia were becoming too frequent and were attended with expulsive pains and a fetid watery discharge in the intervals. The blood loss increased in quantity and she soon began to show signs of failing health in pallor and loss of flesh. She would not permit a physical exploration until the latter part of July, when she had a violent flooding with great pain. *Examination* now revealed to Dr. R. Armstrong, of Lockhaven, Pa., whose patient she was, a healthy condition of the cervix and a normal os, but the body of the uterus was enlarged to more than double its natural dimensions, it seemed to be symmetrical and rather softer than usual. The hæmorrhage was controlled by ergot and rest. Although the grumous fetid discharge and the uterine tenesmus continued, she did not have another severe attack of metrorrhagia, probably because of her exsanguine condition and the fact that she was suffering from septic absorption. Her temperature rising as high as 104° in the afternoon, she had distinct rigors. Her abdomen was tympanitic and very tender to the touch. The physical condition of the uterus led the doctor to introduce two tents into the cervical canal on Sept. 23. They were allowed to remain 24 hours although their presence increased the violence of the symptoms. When the tents were removed, a rather soft friable mass could be felt presenting at the internal os. This led to a fear that the disease might prove to be malignant. A severe colliquative diarrhœa now set in and the patient's strength became so much reduced that nothing could be done except to administer remedies to check the diarrhœa and to prevent collapse. On the morning of the 25th, through the

kindness of Dr. Armstrong, I saw the patient, temperature 103°, pulse rapid and weak, stomach irritable, rejecting everything taken, bowels still quite relaxed. Her face presented the livid hue of malignant disease. The outlook was not favorable for an operation which would necessitate the dilatation of the cervix sufficiently to remove the diseased tissue which evidently occupied the uterine cavity, but it was the only course to pursue. Ether was administered. The uterus was found retroverted and adherent to the floor of Douglas's cul-de-sac. The cervix was rigid and but slightly patulous. In view of existing peritonitis we concluded that it was best that I should endeavor to remove the contents of the uterus without a further attempt at dilatation, fearing rupture of adhesions and increased inflammatory action, I passed the wire loop of the écraseur through the os, and by careful manipulation luckily succeeded in guiding it over the tumor and up to its attachment. Drawing upon the wire it closed around the pedicle and severed it. The tumor was seized with a vulsella forceps and delivered. The index finger could not be passed into the cavity of the uterus. The pedicle was situated on the posterior wall near the fundus. The tissues at that point were soft and friable, but the remainder of the surface of the uterine cavity appeared to be free from disease. The stump was cauterized with nitric acid, and a two-grain opium suppository placed in the rectum. Convalescence was rapid and satisfactory.

On section and close examination the specimen very much resembles placental tissue, and the microscope shows typical placental villi in its structure. It is the *placental polypus* described by C. Braun in 1851, and somewhat resembles the *fibrinous polypus* of Kiwisch who thought that these polypi might arise from long persistent hæmorrhage, a kind of apoplexy of the womb, a large coagulum forming, the upper part consisting mostly of fibrin and adhering by a stalk to the uterine wall, whilst the lower consists of red, soft coagulum having a coat of firm fibrin. Scanzoni does not admit this view. He contends that these are cases of abortion and would therefore fall under the class of placental polypi (*Barnes*). My own experience agrees with that of Scanzoni. These polypi cause profuse metrorrhagia and sometimes, as in this case, blood poisoning.

This case furnishes another strong argument in favor of the entire removal of the decidua or placenta after abortion. Who can tell how many lives are lost or in how many cases the health is undermined by a neglect of this procedure? Death would inevitably have occurred in this case if the uterus had not been emptied. The patient may suffer for months or years as a result of neglect. In this instance the fault was in the patient, for she had been properly advised by her physician. It is true that many cases escape without serious injury, but that does not prove that the principle and practice of immediate removal is not always the safe one, for here is a case where a neglected abortion had apparently passed off safely, but it almost destroyed the patient's life a long time afterward.

Malignant disease was properly suspected from the

rapid development of such grave symptoms, from the general cachectic appearance of the patient and from the sensation conveyed to the finger when touching the growth *in situ*. But when it was found that it had a limited point of attachment and that the uterine cavity was healthy at all other points this hypothesis was weakened, and when more careful examination of the specimen and investigation with the microscope showed it to contain placental villi, its benign character was assured.

DR. MONTGOMERY remarked that in cases in which partial dilatation of the uterine canal had been accomplished before the patient presented, the best instrument to continue the dilatation is the mechanical urethral dilator of Dr. A. H. Smith.

HAIR-PIN IN THE UTERUS.

DR. B. F. BAER exhibited a hair-pin removed from the uterine cavity of a patient sent to him by Dr. Pancoast, of Camden, N. J. The woman believing herself to be pregnant had tried to produce an abortion by inserting the pin by grasping the points and inserting the blunt end. The patient had obtained a view of the parts in a mirror placed upon the floor. The presence of the pin was readily detected by the uterine sound. He at first thought of dilating with tents, but, the patient being greatly alarmed and very importunate, he used the steel dilator. One point of the pin became imbedded, in its descent, in the tissues of the cervix and required dissection to release it.

DR. WHARTON SINKLER exhibited a hair-pin removed from the vagina of a patient who had tried to introduce it into the uterus to produce abortion. She had failed in her purpose and had also failed to remove it from the vagina. The doctor found the points of the pin widely separated, presenting downward and hooked into the walls of the vagina. By bringing the points close together the pin was removed without difficulty. It had been in the vagina for some time.

DR. MONTGOMERY stated that, while a student, he had seen a hair-pin removed from a vagina. It was thickly incrustated with a calcareous deposit.

FOREIGN CORRESPONDENCE.

PARIS LETTER.

PARIS, November 7th, 1884.

Dr. Régis, of Bordeaux, read a very interesting paper at the meeting of the Association Française pour l'avancement des Sciences, lately held at Blois, on the heredity of general paralysis. During a service of three years as interne at the Sainte-Anne Asylum, 318 cases of general paralysis were brought under the author's notice, and the following are the conclusions taken from his observations: Mental disorder or insanity is almost never found amongst the ancestors of a patient suffering from general paralysis, whereas cerebral affections are frequent.

This immunity is found equally among the descendants of general paralytics. These descendants are, in general, normally constituted, and if there is anything remarkable about them, it is their superior intelligence rather than their intellectual or mental inferiority. The comparative study of heredity in general paralysis and in insanity teaches that, contrary to the opinion of some authors, these two affections are not branches of the same family, and that they are incapable of engendering each other mutually. The practical deductions accruing from this fact are most important. A physician consulted about the future of the child of a general paralytic subject may now reply with some assurance that such a child is not necessarily predisposed to insanity, that all that is to be feared, by predisposition, is cerebral affections, and consequently the two critical periods of life, viz.: infancy, when there is a great tendency to cerebral accidents; and mature age, when cerebral paralysis, and even general paralysis, are more common. Moreover, if the physician is consulted as to the propriety of marriage with the offspring of a general paralytic subject, the answer may be in the affirmative, as this affection does not predispose to insanity.

A note from M. TAILLER was lately read at the Academy of Sciences on the elimination of phosphoric acid in insanity and in epilepsy, and the following is a summary of the results of his investigations:

1. In acute delirium, in acute mania, there is a notable excess in the elimination of phosphoric acid and of urea.
2. In mania with excitement, the elimination of phosphoric acid is slightly in excess; that of urea is normal.
3. In simple mania, the urine is in a physiological state.
4. In lypemania, in its acute state, or when accompanied with excitement, there is a notable increase of the elimination of urea, and a rather slight elimination of phosphoric acid.
5. In lypemania without excitement, the quantity of phosphoric acid and of urea eliminated does not exceed that of the normal state.
6. In general paralysis the excretion of phosphoric acid and of urea is in relation to the numerous morbid states which characterize this form of mental disorder.

In epilepsy, the urine, during the paroxysms or immediately after, contains a proportion of phosphoric acid notably superior to that of the average, and a feeble proportion of urea; when the paroxysms succeed each other rapidly, there is an increase of phosphoric acid and of urea; in the intervals between the paroxysms the urine is normal.

In his thesis for the doctorate, Dr. Blanc spoke in the most favorable terms of the treatment of acute abscesses by the injections of alcohol, which he observed in the wards of Professor Gosselin, at La Charité Hospital. The mode of procedure is as follows: The abscess having become soft and fluctuation evident, a puncture in preference to an incision is made. The matter is then gently squeezed out, and

about 60 centilitres, or about a pint of alcohol of 90 degrees, is injected into the cavity. The alcohol is then pressed out with the matter with which it may be mixed up, and another injection of the same quantity of alcohol is made, which is allowed to run out freely. The wound and the exterior of the abscess are then dressed with camphorated spirits or ordinary alcohol. If, on the following day, the suppuration has not stopped, another injection is made, and then a third, or even a fourth, according to the size and state of the abscess. A rather severe pain follows, and lasts for about a quarter of an hour after the injection; the site of the abscess and the parts in its neighborhood become hard and inflamed by the injections. But these phenomena disappear in a time proportionate to the size of the abscess, which is completely healed in from four to six days after the last injection. Dr. Blanc explains the *modus operandi* of the injections thus: The alcohol has a double action; it destroys the pus already formed, and prevents its reproduction by acting on the capillaries of the *parietes* of the abscess, and in provoking the secretion of plastic lymph and consecutive adhesion.

Dr. Taillefer, of Châteauneuf, in washing out the stomach of one of his patients by means of a syphon formed with an India rubber tube and a funnel, had the idea of employing the same means for washing out the bladder of another patient whom he had under treatment, but in whom he had till then employed a more complicated process with a double catheter and a syringe for the same purpose. The advantages claimed for this method are simplicity and inexpensiveness. All that is required to be purchased is an India rubber tube of about 60 centimetres long. A funnel is found in every household. This dispenses with the syringe and the double catheter. To cleanse the bladder, Dr. Taillefer begins by emptying it with an ordinary catheter, he then applies the extremity of the India rubber tube to the catheter without removing it from the bladder. He fills the funnel which is held rather below the level of the bladder. He then raises the funnel in order to allow the liquid to enter the bladder, and then lowers the funnel to let the liquid run out. In this way the patient is saved the pain which is sometimes caused by the adapting of the pipe of the syringe to the orifice of the catheter.

A. B.

BERLIN LETTER.

BERLIN, GERMANY, Oct. 22, 1884.

MR. EDITOR:

Since my last letter from Copenhagen, I have been secluded in the quiet little German town of Weimar, which is celebrated as having been the home of the most celebrated German poets, Goethe and Schiller, as well as of Herder and Wieland.

I had hoped, on my return to Berlin, to be able to give you at once a letter about the Royal University; but I find it impossible at present, because there is a great difference between the customs here and ours.

Although the University nominally opens on a certain day, the 16th of October, yet in reality the professors commence their lectures whenever they please, at times varying from the middle of October to the first week in November, so that, as yet, the University is not in working order.

Last Monday, October 20, a great feast was given in the evening in the "Central Hotel," in honor of Prof. Dr. Rudolf Virchow, who is a member of the Reichstag, and who has been a city official for twenty-five years. The great hall of the hotel was completely filled with ladies and gentlemen, and was handsomely decorated with flags, a pleasant feature being a bust of Prof. Virchow in the middle of the hall, very tastefully decorated. There were two excellent musical concerts, interluded by speeches, and followed by a dance which lasted until the small hours.

There is a report that a certain German doctor has succeeded in producing cholera in rabbits, and that his bacilli have been submitted to Prof. Koch, who admits that they are indeed "comma bacilli," and that he is now testing them by cultivation, to see if they are identical with his "comma bacilli." If it amounts to anything, and we have an authentic report, I will inform you at once.

Since the meeting of the International Medical Congress at Copenhagen, Denmark and its capital city have become much more thoroughly known, and the various people who have listened to the reports of the wonderful hospitality of the Danes in general, as well as those who had the honor to be their guests, will sincerely regret the destruction by fire on the 3d inst. of the beautiful palace called "Christiansborg," of the King of Denmark, where he and his queen so handsomely received and entertained the members of the Eighth International Medical Congress, August 15. Many works of the most celebrated of Northern European artists, Albert Thorwaldsen, were destroyed, but the Thorwaldsen Museum, which contained the most of his works, and which adjoined the palace, although severely threatened, was saved.

I am sure that all members of the Congress would have been glad to add their signatures to the following address which, signed by sixty-four members, was forwarded to the King of Denmark.

"To His Majesty Christian IX, King of Denmark:

"May it please your Majesty:—We, the undersigned, English, Scottish, and Irish members of the International Medical Congress, lately held in Copenhagen, desire very respectfully to offer to your Majesty the expression of our profound regret at the destruction of the grand and beautiful palace of Christiansborg. We very gratefully remember the honor conferred on us in that palace, where we were received and entertained with splendid and graceful hospitality by your Majesty and the members of your Royal Family. The recollection of that reception and of all the proofs of welcome which were shown to us in the City of Copenhagen, impels us to offer, and to hope that your Majesty will graciously accept, this assurance of our sorrow for the loss which your Majesty and Denmark have sustained."

N.

DOMESTIC CORRESPONDENCE.

ANSWER TO DR R. W. SUTTON.

72 LAFAYETTE AVE., DETROIT MICH., }
November 18, 1884.

TO THE EDITOR.—*Dear Sir:* In your issue of 15th inst., Dr. R. S. Sutton invites me to recall a fatal case of ovariectomy in my practice which occurred at Lansing, Mich., in January last, and of which he claims to have in his possession a certificate of death. In reply I must absolutely decline any such invitation, and must say to Dr. Sutton that any such certificate is either a gross blunder or a wicked forgery. *The simple fact is that I have never in my life performed ovariectomy at Lansing nor upon a Lansing patient any where at any time.* In the face of Dr. R. S. Sutton's repeated assaults upon my reputation for truth and veracity, I hope that I may be allowed to say here that if anything could exceed the grotesqueness of that gentleman's frantic efforts to advertise himself and his abdominal hospital it is his unwavering interest in me and my sayings and doings.

As might be expected, these devoted attentions on his part have led me to make some slight notes of Dr. Sutton. While I think that I can candidly disclaim everything like wrath, malice and envy, at the same time I must confess that the results of my study of Dr. Sutton's peculiar idiosyncrasies have not been agreeable nor flattering to that gentleman. In fact, sir, there seems to me to be strong reasons for suspecting that your Pittsburgh correspondent will have to be classed with those unfortunates who are said to have "lost the chart and missed the reckoning of rationality." This is the most charitable explanation of his persistent efforts to involve me in unnecessary and unseemly strife.

One word more; within a few days I propose to place on record some further facts and figures relative to my own recent experiences with ovariectomies performed in public amphitheatres in presence of hundreds of students, and in "cottages by the way-side," from which I venture to hope that some considerable comfort and encouragement may be extracted by that large and honorable class of American surgeons who do not hesitate to give the poor sufferer from ovarian disease the only possible chance which remains for her life, even although a special abdominal hospital and a *special abdominal operator* are beyond their and her reach, and even although they in their scientific modesty do not aspire to compare even their highest efforts with the tender mercies of "The Almighty," as Dr. Sutton audaciously did before the Obstetrical Section at Washington.

I am, etc., DONALD MACLEAN.

BOOK REVIEWS.

MANUAL OF CHEMISTRY. By W. SIMON, PH.D., M.D.
Philadelphia: H. C. Lea's Son & Co.

This book is intended for medical and pharmaceu-

tical students, and seems to be up to the average of works compiled for the same purpose.

A novel feature of the book is found in the plates colored to represent the precipitates formed in various qualitative tests, and it is possible that these plates may be of use to students who have not the opportunity of doing laboratory work.

The questions at the end of each chapter might be in place in a grammar-school text-book, but in a manual intended for colleges the propriety of appending them is much to be doubted.

A TREATISE ON PHYSIOLOGY AND HYGIENE. By JOSEPH C. HUTCHINSON, M.D., LL.D. New York: Clark & Mayard. 1884. Cloth, illustrated, 319 pages.

This school text-book has all the faults common to that class of literature. Some of the illustrations are simply for embellishment, and the text is often faulty. Besides its minor errors it has one positive evil. The lists of questions at the foot of each page and end of each chapter tempt the teacher to rely on the text-book and the parrot-like memory of the pupil rather than on a clear explanation and demonstration of the subjects taught and the due appreciation of those subjects by the student's higher mental faculties.

SURGICAL DELUSIONS AND FOLLIES. By JOHN B. ROBERTS, A.M., M.D., Professor of Anatomy Philadelphia Polyclinic, Surgeon St. Mary's Hospital. Philadelphia: P. Blakiston. Pp. 56.

This is a clever address which the author delivered before the Medical Society of the State of Pennsylvania. Without professing to go deep into scientific questions, he discusses here many minor superstitions and errors which cling about surgical practice, much in the spirit of the immortal author of "DON'T." It is doubtless true that in the routine of minor surgery more absurd and antique delusions are still in vogue than in most modern specialties. It is also true that some good physicians, who do only occasionally any surgical work, are the most hide-bound in their prejudices, and need a thorough shaking up before they will let go old notions and adapt their surgery to the present day. This little volume is both suggestive and profitable to all who look over its pages.

E. W. A.

THE EAR: ITS ANATOMY, PHYSIOLOGY, AND DISEASES. By CHARLES H. BURNETT, A.M., M.D. Second edition, revised and re-written. Calif. 585 pages, 107 illustrations. Philadelphia: Henry C. Lea's Son & Co.

The author, in the second edition, has evidently spared no pains both by careful compilation and original research, to bring the work fully up to date. The part on diseases and treatment is arranged under seven sections, considering first the examination of the patient, then the various diseases according to their anatomical location, and lastly a section on the methods of relief and education of deaf mutes and partially deaf children.

C. E. W.

A MANUAL OF DERMATOLOGY. By A. R. ROBINSON, M.B., L.R.C.R. & S., Edin. New York: Bermingham & Company. Cloth, 647 pp., illustrated. Price, \$5.00.

This admirable work commends itself to the student and practitioner by its clearness of style, its orderly arrangement, and its full and explicit directions respecting treatment.

There is a marked resemblance among modern text-books of dermatology, and while this evidently belongs to the common species, it presents marked individual characteristics. The study of the cutaneous diseases affords an opportunity to follow the minute details of the morbid processes from the commencement of the attack until its termination in resolution or permanent lesion. The author has taken advantage of this opportunity and gives his readers an insight into the histology of many of the diseases considered.

We sincerely hope that he will prosecute his plan of a more voluminous and original work, but, however necessary that may be to the specialist, we feel assured that the present publication will fully meet the needs of the general practitioner. C. E. W.

TRANSACTIONS OF THE COLORADO STATE MEDICAL SOCIETY HELD IN DENVER, JUNE, 1884. Paper, 155 pages with eight climatic charts.

These transactions show a commendable activity on the part of the profession in Colorado.

A paper by S. E. Solly, M.D., on the influence of the local climate on Bright's disease presents as its chief physiological points, the fact that the urine in that dry region is somewhat concentrated, and as its conclusions "That acute nephritis is not especially induced by the climate, but having arisen, is in its onset aggravated by it," and respecting chronic nephritis, that the tendency of the climate is toward its cure. He does not consider that either of these propositions is fully established.

The climatic charts, two for each of the four seasons of the year, 1882, show respectively the absolute humidity in grains to the cubic foot of air and mean cloudiness in tenths, for the whole country. They are issued by the society and published at its suggestion and expense by the war department and should be seen to be appreciated.

Their most salient features are given in the following quotation from the report of the society's committee: "The extremes of dryness and moisture as indicated by this actual humidity are about as follows for the different seasons. The elevated western interior as compared with Florida and the extreme south of Texas, has one-fourth as much atmospheric vapor in spring, one-third as much in summer, and one-fifth as much in autumn, as the latter, while in winter the central portion of the country from Denver north and northeast has less than one-sixth the actual humidity that exists in the moistest portions of the south (Florida)."

The sunniest portion of the United States for the whole year, is the eastern parts of Southern and Middle California, from Red Bluff south, taking in the Death Valley, where there is less than one-tenth of

cloudiness, while the cloudiest section of the whole country is in the Ohio Valley and great interior lake region, when over seven-tenths of the time there is cloudiness during the winter. It is in winter that the greatest contrast is to be noticed between the elevated interior and southwestern sections on the one hand, and the whole eastern half of our country and the northwestern corner on the other hand, bringing out into merited prominence for sunshine and as winter homes for invalids, the eastern central portion of Colorado, and much of New Mexico, Arizona and Southern California."

M. H. Sears, M.D., discussed the treatment of morphine poisoning and recommended the intravenous injection of milk. In both of the written cases which were of a desperate character, the injection was followed by improvement in the symptoms and in one case by recovery. In the successful case the patient was a male, eight ounces were injected in about 15 minutes. Some blood was allowed to escape before the milk was injected. C. E. W.

TRANSACTIONS OF THE MEDICAL AND CHIRURGICAL FACULTY OF THE STATE OF MARYLAND. Eighty-sixth Annual Session. Held at Baltimore, Md., April, 1884.

This contribution to medical literature contains very little trash. In glancing over its pages the following items have attracted our attention.

The recommendation of C. W. Chancellor, M.D., respecting the sanitary needs of the poor, expresses the hope that in time the laboring classes may be in possession of better dwellings, and recommends means for securing this and other desirable results.

A paper on "Preventable Blindness," by Samuel Theobald, M.D., particularly cautions the profession respecting the several varieties of ophthalmia, including sympathetic, and glaucoma.

F. Donaldson, M.D., respecting the influence of lung retractility, concludes that it is "not only a powerful physiological force in respiration, but that it also produces modification of a decided character in diseases of the chest." This latter is of particular importance in making a physical diagnosis.

C. E. W.

THE ELEMENTS OF PHYSIOLOGICAL AND PATHOLOGICAL CHEMISTRY. By T. CRANSTOUN CHARLES, M.D., Philadelphia. H. C. Lea's Son & Co.

For years Germany has taken the lead in the advanced study of the purely scientific branches of medicine, and the laboratories of the great universities have pushed research to an extreme scarcely possible anywhere else. The names of the men at the head of these laboratories have drawn students from all parts of the world, and these students, returned to their homes, have made the works of their teachers almost as well known there as in Germany itself.

This influence first showed itself in the translations of leading German manuals, followed in time by original works formed on German models, and embracing the results of German experience.

In physiological chemistry the books of Hoppe-Seyles, Kuchne and Gorup-Besanez have been our best authorities, and any one pretending to accurate

knowledge on the subject has been obliged to consult them.

It is an encouraging sign of the times that a book with the above title has appeared in English and that an American edition has also been issued.

In these Elements of Physiological and Pathological chemistry, Dr. Charles has given us a most excellent text and reference book. It does not in the least detract from its merits to say that throughout one perceives the influence of Hoppe-Seyles, for to successfully follow such a master is in itself no slight honor.

The volume of 450 pages is divided into four parts or books, treating of Nutrition and Foods; Digestion and the Secretions Concerned; the Chemistry of the Tissues, Organs and remaining Secretions; and the Excreta. Each book is subdivided into chapters, of which, in all, there are 98.

The information contained in these chapters is accurate, and embraces the results of the latest researches in the several departments. Methods of analysis are quite fully given where necessary, and numerous tables show the results of examinations of tissues, digestive fluids, excretions, etc.

The book can be recommended to any one wishing to obtain a clear idea of the present state of physiological chemistry.

ILLUSTRATIONS OF THE INFLUENCE OF THE MIND UPON THE BODY IN HEALTH AND DISEASE.

Designed to elucidate the action of the imagination. By DANIEL HACK TUKE, M.D., F.R.C.P., LL.D. Second American from the second English edition. Philadelphia: Henry C. Lea's Son & Co. Cloth. 482 pages.

The plan of this work is sufficiently set forth in the following, from the introductory chapter:

"Psychologically, we intend to indicate, by the title we have adopted, the design of illustrating by a considerable collection of striking cases the often admitted, but too frequently forgotten, and still more frequently neglected truth, that the state of the mind, comprising therein intellect, emotion, and volition, exerts an enormous influence for good or evil upon the body with which it is associated,—including in this term all sensations, movements, and the organic functions."

The author has carefully carried out this plan, and we have presented a mass of systematically arranged material, much of which is certainly striking enough, but some of which is of little scientific value.

Quotations from the daily press and the literary classics are very useful as embellishments, but hardly serve as sufficient data for the establishment of scientific laws. In the material collected from medical sources conditions of healthy emotion and organic disease are frequently associated in such a way as to confuse the careless reader.

In the pursuit of a subject like that selected by our author, which deals with matters extraordinary, more than usual care is necessary. Nervous patients exaggerate their symptoms. The excited attendant exaggerates his report of the case. The studious compiler arranges his material in such a way that the ardent student, led on from simple matters to those

more marvellous, is deluded as to the actual attributes of that most important of all organic phenomena, the mind, and in his turn becomes the victim of a self-propagating delusion.

Such a work should consist of a demonstration of the relations of the mind to the body in individuals who are organically sound; a consideration of these relations as affecting organic disease; and lastly, a consideration of environment and association as affecting mental conditions favorably or unfavorably, thus influencing the health of the individual. Thus we would have the physiology, pathology, and therapeutics of the mind. Such a work will require the greatest care and skill in its preparation.

The present volume contains enough of value to be of service to the careful reader, but falls far short of ideal perfection.

C. E. W.

MISCELLANEOUS.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, UNITED STATES ARMY, FROM NOVEMBER 15, 1884, TO NOVEMBER 21, 1884.

Cowdery, S. G., Captain and Assistant-Surgeon, granted leave of absence for one month. (S. O. 237, Dept. East, November 17, 1884.)

Havard, Valery, Captain and Assistant-Surgeon, granted leave of absence for four months, (permission to go beyond sea) to take effect when his services can be dispensed with at his present station. (S. O. 268, A. G. O., Nov. 14, 1884.)

Phillips, Jno. L., First Lieutenant and Assistant-Surgeon, assigned to duty at Fort Keogh, M. T. (S. O. 134, Dept. Dak., Nov. 5, 1884.)

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY DURING THE WEEK ENDING NOVEMBER 22, 1884.

Ames, Howard E., Passed Assistant-Surgeon, detached from the Greely relief steamer Bear, and assigned to special duty in New York, Nov. 17, 1884.

Bright, George A., Surgeon, detached from the Galena and placed on waiting orders, Nov. 19, 1884.

Cleborne, C. J., Medical Inspector, to duty at Philadelphia, Pa., as member of Medical Examining Boards, Nov. 21, 1884.

Du Bois, F. L., Surgeon, when detached from the Naval Examining Board, Nov. 29, is ordered to the Galena, Nov. 20, 1884.

Green, Edward H., Passed Assistant Surgeon, detached from the Greely relief steamer Thetis, and assigned to special duty in New York, Nov. 17, 1884.

Hall, J. H., Surgeon, detached from Navy Yard, Mare Island, and assigned to duty at the Naval Hospital at that yard, Nov. 19, 1884.

Hugg, Joseph, Surgeon, to the Minnesota as relief of Surgeon Wolverton, Nov. 15, 1884.

Martin, William, Assistant-Surgeon, to special duty in connection with the New Orleans Exposition, Nov. 19, 1884.

Nash, F. S., Passed Assistant-Surgeon, detached from the Greely relief steamer Alert, and assigned to special duty in New York, Nov. 17, 1884.

Simon, W. J., Surgeon, to the Philadelphia Hospital for treatment, Nov. 17, 1884.

Wolverton, T., Surgeon, detached from the Galena, and placed on waiting orders for sea service, Nov. 15, 1884.

CONSERVATIVE PROGRESS.

FIRST ANNUAL ADDRESS TO THE NEW YORK STATE
MEDICAL ASSOCIATION, DELIVERED IN NEW
YORK, NOVEMBER 18, 1884.

BY HENRY D. DIDAMA, M.D., PRESIDENT.

— The advance of science is hindered not more by obstinacy than by fickleness.

The skepticism which uses an honest crucible is a blessing; the skepticism which wields a club, and smashes old things indiscriminately *because* they are ancient, is a curse. Underneath its destructive malice is often a credulous and craven tenderness for anything which is new.

One face of Janus was emblematic of Memory, and looked benignly upon the past, with its garnered treasures; the other represented Hope, and peered eagerly into the rich possibilities and promises of the future. These faces were not mutually inimical; they were complementary; they were unity in diversity.

In medicine, bigotry and laziness sometimes call themselves conservative; opposed to these are discontent and love of novelty, which may assume the label progress; but genuine progress and enlightened conservatism work harmoniously together to perfect medical science. The one patiently tests all things; the other holds fast that which is good.

In medicine much is worthy of conservation; not a little is still moot; research is very active and confident; vast fields await exploration. Your attention is invited to a few illustrations and suggestions.

In *Pathology* the predisposing causes of disease are fairly well known by long and careful observation; but in the dazzling field of the microscope they are apt to be forgotten.

Inheritance, acquired vices, insufficient or improper or excessive food and drink, vitiated air, deficient sunlight, exposures, indolence, overwork, worry, these are predisponents which act by so impairing the resisting power that attacking foes of feeble potency are able to gain an easy victory.

Many diseases, such as eruptive, contagious and malarial fevers; pneumonia, consumption, erysipelas, septicæmia, pyæmia, and even suppuration are now quite generally regarded as the work of micro-organisms—the *contagium vivum*.

The doctrine of germs is essentially modern; although Harvey is thought to have had glimpses of its truth more than two hundred years ago. But Harvey never regarded germs as living particles, capable of prolific multiplication. He considered the emanations from a certain disease able—by what he called a seminal influence—to propagate the same disease in a healthy person.

The witty Jonathan Swift, in the early part of the last century, described a microscopic specialist whose enthusiasm is hardly eclipsed by the zeal of any modern observer. He had discovered worms in the flesh of certain diseased animals, and he published an account of his observations. His paper attracted some attention and received favorable comment. Inflated with flattery and vanity, the now famous discoverer continued to use his lens, and forthwith published the startling announcement that worms are the fountain and origin of all diseases.

In the present germ excitement—analogous to the gold fever of 1848 and the petroleum craze of later years—we are not to ignore other and well-established causes. We encourage the search for new *microzymes*—as we do prospecting for gold and oil;—we watch intently each promising indication; but we prudently reserve our credence and wait for verifications of alleged discoveries; knowing that some observers have that keen vision pointed out in the couplet:

“Optics sharp it needs, I ween,
To see what is not to be seen.”

We not only braid fadeless chaplets for the modest brows of those who unearth a new *bacillus*, whose pedigree can be established beyond question; but we bestow our admiration upon those ingenious philological microscopists, who, if they cannot diagnosticate hereditary diseases by the physiognomy of the blood corpuscle, are yet able to invent some magnificent name for the minutest pest which infests the human organism.

We urge that investigation cannot be too extensive and thorough; but we counsel that there be no premature rushing into print with generalizations; lest the observations shall turn out illusory; lest alleged causes shall prove to be but unimportant coincidences.

The reward for patient work may be slow in coming, like the flour from the mills of the gods, but it will be of excellent quality at last.

If he is worthy of national gratitude who makes two blades of unnecessary grass grow where but one had a feeble struggle for existence before, how much

more deserving of temporary immortality is he who establishes his claim to a new pathogenic *cacozyme*, be it *bacillus* or *micrococcus* or *spirillum*; especially if he can tell us what to do with it.

The specific micro-organisms of tuberculosis and splenic fever and—perhaps—cholera, have been differentiated; those of miasmatic diseases, seen as the *palmella* in Ohio by a genius of sharp optics, and as the *bacillus malarie* by Italian observers, remain to be verified. There should be little doubt of their existence, notwithstanding the incredulity recently expressed by an eminent writer who still pins his faith to the ancient notion that a poison is generated by decomposing vegetation. For while a living and developing organism will account for all the facts of origin, incubation, and behavior of miasmatic fevers, a dead poison is quite unsatisfactory and insufficient.

But the germs which cause scarlatina, measles, pertussis, etc., have thus far eluded search. It is still an undecided question whether croupous pneumonia be a germ fever, with a local expression.

The suggestions of our eminent friend and associate, who called attention to this point several years ago, are entitled to, and are receiving, consideration throughout the world. Continued observations are still needed to confirm or overthrow the proposition.

In *Therapeutics* conservative progress finds an ample field. To prevent; to guide to a favorable termination, when prevention has been neglected; to alleviate, when recovery is impossible; to delay the inevitable escape of the soul from its weary prison; these are the important duties of the physician.

A thorough knowledge of the composition and structure of the body, and of the relation of parts, is indeed of great importance. The action of organs in health, and their perverted action in disease, rightly demand the most careful study.

The foes which boldly attack the citadel of life, and the occult influences which insidiously undermine and sap the vital forces; these may well engage our earnest attention.

The fascinating analysis of our secretions and excretions, of our foods and medicines and poisons, deserves all the consideration which it receives.

The innumerable instruments of precision, which promise to substitute mathematical accuracy for vague guess, and which are too often used not to supplement but to supplant other and valuable methods of investigation, these, like the tribe of Abou Ben Adhem, will continue to increase, till they become multitudinous—if not perplexing—like the grasshoppers of the West; these rightfully challenge recognition and study, while with unappeasable appetite, they devour our substance if we attempt to add them all to our armamentarium.

But anatomy and histology, physiology, pathology and chemistry, etiology, diagnosis and prognosis; the possession of all the scopes, all the graphs, and all the meters, and the familiar and dextrous use of them; all these, interesting as they may be to the scientist, important and indispensable as they may be as preliminaries, foundations and aids to medical

skill; all these are practically worthless except as they contribute to the relief of human suffering.

“The real physician,” says Broussais, “is the one who cures; the observation which does not teach the art of healing is not that of a physician, it is that of a naturalist.”

And, paraphrasing Sacred Writ, it may be added, there remaineth therefore pathology, diagnosis, therapeutics, these three; but the greatest of these is therapeutics.

Therapeutics, then—which includes all means to prevent and manage disease—being the superstructure to which all medical ologies are but foundation stones and adornments; the very fruitage of the tree of life; the sole beneficent application of all medical science, its importance to humanity, and therefore to the physician, cannot be overestimated.

Efforts to elevate the standard of medical requirements are worthy of commendation. Owing to the fierce rivalry of schools and the facility with which incompetence secures its diploma, it has been deemed very important, by many reformers, to have the licensing power placed in the hands of an independent Board of Examiners.

Should such a Board be constituted, it may properly require a thorough preliminary training; it may be so comprehensive in its demands, and so vigorous in its examinations that no one guilty of ignorance regarding the fundamental branches of medical and other cognate sciences shall be able to gain admission to the ranks of a noble profession.

But if, in these exalted demands and these exacting examinations, therapeutics be ignored or belittled; if therapeutics be not elevated to the highest position and regarded as the one thing needful; the very vital principle without which everything else is but dead and useless science, and with which alone the physician does all his skillful deeds of benevolence; then the ordeal to which the candidate is subjected is delusive and beggarly. It may even deserve reprobation.

The object of a Board of Examiners should be to protect the community from the ravages of additional incompetency. Its action must of necessity be prospective. It cannot hope to uproot a professional ignorance, which, associated with length of years and engaging manners, has become popular and almost sacred. But it can determine the minimum amount of knowledge which must be possessed by every candidate who shall gain admission to the medical fraternity. If its examinations shall be comprehensive and searching, and at the same time not so narrow and technical as to regard an error in orthography less excusable than a gross blunder in medical practice, it may accomplish its good purpose.

But if it tithe, rigorously, the mint, anise and cumin, and neglects the weightier matters of applied medical science; if it shows partiality; allowing Vitreus Ceruleus, who believes the radiance which filters through blue glass to be the only and omnipotent remedy for all diseases; and the gushing Aquarius, who dotes on and swears by magnetized spring-water as a panacea; and the innocent Credulus who puts all his faith in faith alone; and the oily and

plausible Sinbad, who pretends to be under the guidance of disembodied spirits; if the Board allows these to shirk entirely the examination in therapeutics and materia medica to which plain, unpretending Medicus—who recognizes the importance of these sciences—is subjected; then when it puts these five on the same high level before the public, giving each the same indorsement and the same license, it inflicts a wrong on Medicus; places an unnecessary and useless burden on Ceruleus, Aquarius, Credulus and Sinbad; and perpetrates a fraud on a confiding and misled community.

To serve the public wisely and well, the Board should subject every applicant, whatever his callow crotchets, or prejudices or intentions may be, to the same examination in every branch of medical science, as understood by the vast majority of the profession. Possessing the learning requisite to pass this examination, and endowed with his credentials, the tyro should be at liberty to adopt and practice any special delusion or idiocy which his fancy may indicate, or the credulity of the public make profitable. For as he can never entirely divest himself of his useful knowledge, the community will have all the protection it is possible for an Examining Board to furnish.

Some of the general principles of therapeutics are worthy of the most careful preservation. Many of the measures employed in preventing and stamping out various so-called zymotic diseases are fairly successful; and constant research is adding largely to their numbers and potency. The importance of iodine and mercury in certain diseases; the palliative and curative effect of opium in a variety of complaints; the efficacy of Peruvian bark in miasmatic affections; the desirability and possibility of preventing and subduing high temperatures in fevers and inflammations; the wonderful results secured by certain heart tonics; the neutralizing and eliminating measures which have shortened the term of rheumatism from six weeks to six days; the undiminished power for good of ferruginous preparations in suitable cases; the occasional utility and even saving power of the once abused and now as much maligned venesection: these are merely samples of therapeutic principles and practice, whose truth is attested by countless, critical, level-headed observers throughout the whole world.

New discoveries in etiology, pathology and materia medica will modify our views and constantly increase our ability to overcome disease. They will show us when to interfere actively and when to watch and wait. And while we hold fast to well-founded principles of treatment and to remedies whose adoption has been tried, we give a hearty welcome and testing to every new measure, to every new medicine, which has a satisfactory indorsement. We are hampered by no dogma; so that while we are not seduced by utopian theories, while we make no experiments with obvious and gross delusions, and while we set our faces like flint against fraudulent pretenses and practices, we carefully consider every promising suggestion, by whomsoever made, and we gladly adopt every useful discovery, and every tested new application of old principles and remedies.

Is not this platform broad enough to afford standing and working room for every one who seeks to know and practice truth?

It is fashionable in certain quarters to decry the medical schools of our country; to censure their practice of so oiling their portals that the grossest ignorance can find an easy and welcome admission; to inveigh against their methods of teaching; and to condemn the facile, if not farcical, examinations which permit incompetence to seize a title and go forth to prey upon community.

Indiscriminate and unmixed reprobation is not only unjust; it defeats its purpose. For whatever may be the deficiencies of our great schools; however far they fall short of what they can and should be; they have excellencies which should not be ignored. They have given to the profession men renowned throughout the world for their wisdom and skill. In their corps of teachers are many whose aptness and industry and ability are unsurpassed. They afford clinical opportunities so rich and varied as to leave nothing to be desired.

If their requirements for entrance and exit have been too low, is it not because the profession have not demanded higher? If the terms have been too short, and the years required too few, and the methods unnatural and deficient, is it not because the profession have given little practical encouragement to the hearty, even if too speedily abandoned, attempts which some of the schools have made to secure needed reform?

Can it be doubted that the accomplished and devoted teachers in the schools are always ready and willing to respond to any earnest call of the profession for a higher standard?

Shall this call be made? Will those who make the demand prove their sincerity by pledging their influence, their aid and comfort, to those schools which, at whatever labor and expense, shall eliminate the faults of the present system and bring it into harmony with the teaching in all institutions of learning, and with the law of mental evolution and growth?

That brilliant results have been achieved under the prevailing system of medical teaching has not been, and cannot be, denied. Would they not have been still more brilliant and satisfactory under a better system?

The native Ceylonese, with instruments which would hardly be tolerated in an American blacksmith's shop, sits on the ground and patiently fabricates jewelry and filigree, which are marvels of exquisite delicacy and beauty.

Retaining his present artistic taste and skill, how much more and better work could he do with the perfected instrument of his civilized brother.

The superiority of the graded system of medical training is not universally acknowledged. At least one prominent teacher and one good medical journal openly profess not simply a contentment with the present unnatural system, but an admiration for it, and a desire to have it conserved. The attempts to reduce chaotic elements to order, they denounce as impracticable; and they kindly predict and counsel their early abandonment.

Proposed reforms always provoke some opposition. The attempt to introduce into Mexican farming such modern implements as the steel plow, the cradle, the reaper and thresher, is earnestly combated by many of the native workers. They not only adhere to the sickle and to the old one-handed Palestine plow—an iron-shod stick which barely scratches the soil—and to the threshing-floor, where oxen and mules tread out the grain, but they insist that this clumsy system is the better. They hill their corn, as our own farmers did fifty years ago. They use a hoe in the operation. But the hoe has no handle, and the native partly creeps and partly jumps, like a kangaroo, from hill to hill, as he goes through the field. Still he loves and reveres the old ancestral implement. He denounces the handle as a device to promote laziness; and he asserts that with a primitive hoe in each hand he can do more and superior work. It was only by compulsion that these earnest Mexican conservatives could be brought to use wheelbarrows on the public works. They preferred to carry their loads of stone and dirt on their backs and heads. And such was their devotion to the ancient method, that at first they actually shouldered wheelbarrow, dirt and all, and then vociferously condemned the new notion as a fraud and nuisance.

Honest differences of opinion should be treated with respect and tenderness. And since these differences exist regarding medical education, it may not be unprofitable briefly to compare and contrast the antique system with the modern.

Most of you know, from personal experience, that in the large majority of medical schools in this country, the student, at the very outset, is expected and required to hear lectures on all the branches taught—the most advanced as well as the elementary—every day. Although not usual, the occurrences to be described are by no means impossible. An ingenuous youth, full of zeal, industrious, ambitious, but with scant knowledge of the elements of the most moderate education, is received without question at the grand old conservative college. He matriculates. He attends a lecture on anatomy,—the first he ever heard of this important subject. He is delighted. He enters the laboratory and listens with pleasure and profit to the professor of chemistry. Truly, he says to himself, the ways of wisdom are ways of pleasantness, and all her paths are flowery walks of peace.

He hastens into the surgical department. The lecture is introductory. But in a few days, and while his knowledge of anatomy is still limited to an awful admiration for the suspended skeleton and for the tray of disarticulated bones on the table, the subject of the lecture is aneurism.

The bright description, the lucid explanation make the whole subject interesting and satisfactory. The eloquent professor describes the operation for ligating the radial artery in its lower third: "Hold the hand supine; make an incision two inches long on the radial side of the *flexor carpi radialis*. The integument and aponeurosis being laid open, the artery is at once brought into view."

This is all clear enough to you, learned Fellows,

because you have received sufficient anatomical instruction.

But the fresh pupil whom we are considering—one of us perhaps—whose hopes but a few days ago were radiant and towering, becomes perplexed and disheartened, if not disgusted; because he has no knowledge of what radial may mean; whether aponeurosis is an animal or vegetable; or whether the *flexor carpi radialis* be a bone, nerve or sinew, situated on the crown of the head or sole of the foot.

After the wearisome—wearisome because incomprehensible—incomprehensible because the student has not been prepared to understand it—lecture on surgery is ended, the still plucky pupil ventures into the room where the professor of the art of medicine is showing how insufficiency of the tricuspid valve, by obstructing the onward flow of blood in the *vena cava*, may cause congestion of the portal system and then gastric catarrh, hæmorrhage and albuminuria. He does not doubt the truth of the demonstration. But it loses all its beauty and force because the poor fellow has not the slightest notion of what tricuspid, or any other valve, may be, or where the *vena cava* or portal system is located.

In the obstetric department, the same failure to comprehend the lecturer results from the same want of preparation. But the rules of the school require attendance on all the lectures. And so, hour after hour every day is wasted, by an earnest and ambitious student, in listening to what he cannot understand, and so neglecting the studies which are prerequisite.

The short winter course is passed, and the student emerges in the early spring, with a head full of jumbled and meaningless words, with muddled ideas of medicine, obstetrics and surgery, and with insufficient knowledge of anatomy, physiology and chemistry, *because* the time which should have been devoted to these fundamental studies has been frittered away in a dazed attendance on lectures he had never been prepared to understand. The next winter he goes through exactly the same course but he is now better able to comprehend the teaching.

In *building a dwelling house*, you prepare a plan—first consulting the good wife regarding the fitness of things—and then you go ahead decently and in order. You lay the foundations deep and broad and strong. You carry up the superstructure carefully and gradually, so that no cracks nor flaws shall afterward appear. You put on the roof; finish the rooms honestly, without veneer or graining, and wait a sufficient time before you move in with your family.

You do not jumble all together, working an hour on the turret, another on the trench for the cellar walls, and still another on window sills and hard finish and joists and rafters.

If you were to *train for an athlete*, you would not unwisely overstrain your sinews the first day by doing work beyond your ability. You would begin with light weights and moderate walks, increasing the labor each day as the muscles became developed and strong.

In his attempt to *make an accomplished musician*, the wise teacher first trains the fingers and wrists of

the pupil, and requires much practicing of the exercises and scales, till all the fundamentals are thoroughly mastered.

He does not allow the aspiring youth to practice the rudiments in the forenoon, and then, in the afternoon, murder the symphonies of Beethoven, or attempt to render the brilliant lunacies of Wagner, at the very outset of his career.

If it should be proposed to *evolve a mathematician* out of raw material, we would not ask the candidate the first day to solve the problem of the hare and hounds, nor to listen to a demonstration of the 12th Proposition of Euclid.

We would begin with the simplest examples in addition and subtraction, and then advance through the higher and still higher departments, till at length, like Verrier, the fully developed candidate could discover and locate a planet by pure mathematical calculation.

In *training a child* to be a *linguist*, we begin with the simplest form of speech and lead him on, by precept and example, till he can speak with the tongues of men and of angels, and have charity besides. It would be unnatural, and therefore unwise, to allow him to waste time at the start in listening to the sounding brass of Cicero's orations, or the tinkling cymbals of Xenophon's fables.

If in every other department of human industry the natural development plan is pursued without opposition or question, why should medical education be the marked exception? Why, if we wish, as we ought, to *utilize to the utmost, the time and talents of a medical student*, should we not take him step by step—for that is what the graded course means—through anatomy and physiology, histology and chemistry up to surgery and practice and obstetrics?

Why should we have him fritter away the scant but precious hours of his first course of lectures in listening to what he cannot by any possibility fully comprehend? Would not this be doing what ought not to be done, and leaving undone what ought to be done?

The natural system of medical education is no longer a beautiful and dreamy speculation. It has been fairly tested, and it has been found efficient. Those who know it best give it the heartiest approval. The requirements for matriculation are, or should be, more and more exacting every year. The written and oral examinations are frequent and thorough. The yearly and final ordeals are very trying and severe; but the students who have brains, application and faithfulness always come through triumphantly. Even those whose natural capacity is not the greatest succeed remarkably. Under a natural system their mental growth is rapid and astonishing. At the last they seldom fail because their time has been husbanded and properly employed; because their studies have been interesting and delightful inasmuch as they have been thoroughly comprehended and mastered, every step of the way.

Here are two pictures. Do they not represent the prominent differences in requirements and results between the ancient, but still prevailing system, and the modern one.

In one case; no preliminary examination; only two short courses of lectures required, the second identical with the first; the novice required to attend lectures on every subject every day, neglecting preliminary work because the time which might have been devoted to it has been worse than wasted in hearing learned talk which he was not prepared to understand; valuable clinical and laboratory opportunities; no examinations to advance to higher grades, for there are no grades; a final examination which is so superficial in many instances as to be little better than a farce, and whose meshes are large enough to let mediocrity and inferiority, as well as the superiority, which is always present, pass through with greatest ease.

In the other case; preliminary examinations which require a certain, even if insufficient, preparation; three years of training at the college, the novice beginning at the beginning; all his time employed in hearing and doing what he can and should understand; his capability and progress tested by frequent oral and written examinations; his advance from grade to grade checked if his fitness be not established; valuable clinical and laboratory opportunities; searching yearly examinations; and a final examination, which, although of great severity, does not, except in rare instances, result in rejection, because the student has been educated in a way which accords with Nature and does not violate it.

Of these two systems, judge ye which is the better.

And yet the difference between the old system and the new is greatly one of arrangement. A change from one to the other can be effected with as little commotion as was noticed when twenty discordant and puzzling computations were consolidated into the present admirable system of standard time.

No more teachers would be required; no better lectures could be delivered, or would be needed. The labors of the professors would be considerably increased because the total length of the lecture season would be more than doubled, but they would hardly be conscious that a radical change, amounting to a revolution, had taken place. But the students, who are to be the physicians of the future, and the confiding patients of these physicians would derive incalculable benefit.

Would not the adoption, by all the schools of this country, certainly by those of this State, and especially by the three prominent ones in this medical metropolis, of the natural system, with the honest and vigorous enforcement of its entire demands, secure a practical elevation of the medical standard, so much yearned for; deserve the support of the profession; and restore a confidence which has been seriously impaired? Would not this adoption protect community to the greatest extent possible from incompetence, and render unnecessary, so far as legitimate medicine is concerned—the only medicine about which we have any solicitude—the proposed State Board of incongruous Medical Examiners?

And now, Fellows of the A-sociation—good fellows and patient, one and all—I thank you for the very great and, of course, unsought honor—for it would not be an honor if I had sought it—you have

conferred in choosing me to be your first presiding officer. I confidently count on your kindly forbearance and your generous assistance.

I congratulate you that our first meeting begins so auspiciously; that the promised material for our coming three days' scientific festival has never been surpassed in richness or variety.

I cordially invite each and every one to contribute to the success of the feast.

APHONIA DUE TO CHRONIC ALCOHOLISM. PARALYSIS OF THE LATERAL CRICO-ARYTENOIDS.

BY ETHELBERT CARROLL MORGAN, A.B., M.D.,
WASHINGTON, D. C.

Read to the Section of Ophthalmology, Otology and Laryngology of
American Medical Association, May 8, 1884.

There is no morbid condition involving the vocal organs possessing a more varied pathogeny than paralysis of the lateral crico-arytenoid muscles, the functional aphonia of pre-laryngoscopic authors.

No disease is more doubtful in its amenability to therapeutic measures, the restoration of voice in some instances following the introduction of the laryngoscopic mirror; in others baffling all our resources. That motor disturbances of the muscles under discussion resulting from fright, mental emotion, anæmia, chlorosis, dysmenorrhœa, intestinal irritation,¹ rheumatism,¹ syphilis, diphtheria, hysteria, and reflex influences do occur is a fact generally admitted and frequently observed by the laryngologist.

Lead,² arsenic,³ phosphorus, opium,⁴ and belladonna,⁵ have all been accredited with having caused palsy of the various laryngeal muscles. These cases, however, are greatly scattered throughout literature, and occasionally lack important details. "The influence of certain substances taken in poisonous doses is exerted upon the nerves and muscles of the larynx as well as other parts, and loss of voice is a circumstance to be witnessed after using some of the powerful narcotics, antimony, mercury, arsenic, and other poisons of an exhausting character."

"These agents act slowly . . . causing a palsy similar to wrist-drop."⁶

Though analogically we may be warranted in establishing an alcoholic laryngeal paralysis, I am aware of but few precedents in the form of recorded cases.

Hamon,⁷ in recording an instance of what he designates "aphonie alcoolique," takes occasion to

say: "Alcoholic aphonia is an affection rarely observed, and it is doubtless for this reason that medical treatises are silent upon this subject."

Whilst prolonged indulgence in alcoholic stimulants not infrequently terminates in loss of voice and imperfect articulation, dependent upon central paralysis, there is also evidence that the loss of voice may occasionally originate in defective peripheral innervation.

I am only too conscious of the great difficulties enshrouding this entire question of pathogenesis in paralysis of the laryngeal muscles in the affection under consideration.

Ziemssen¹ says, "It cannot be determined whether or not the toxic paralyzes of the vocal cords are to be regarded as central paralyzes of the glottis."

Cohen² in describing paralysis of the lateral adductors says, "The cause of these paralyzes is sometimes involved in great obscurity."

The exposure, muscular relaxation and lowered vitality accompanying and resulting from chronic alcoholism, doubtless assist in producing the motor laryngeal trouble.

A few of the ancient writers on medicine clearly allude to the modification of voice during intoxication. Thus Hippocrates³ in his article on Aphonia remarks:

"*Si quis ebrius ex improvviso mutus fiat, convulsus moritur, nisi febris corripuerit, aut ubi ad horam qua crapula solvuntur, pervenit locutus fuerit.*"

Morgagni⁴ mentions alcoholism as a cause of aphonia, and speaks more particularly of the central lesions giving rise to this trouble.

G. Andral⁵ says: "Nervous aphonia is sometimes noticed after hysteria is developed during drunkenness, and may be caused by both opium and belladonna."

There is a common phrase used in Germany expressive of the deleterious influence which alcoholics exert upon the vocal organs—"Er säuft sich die Kehle ab."

Bierbaum⁶ records the history of a man suffering with mania à potu who was aphonic. This case, however, was evidently due to central influences.

Examples of loss of voice have fallen under my care during a number of years past, which have clearly pointed to alcohol as the "*fons et origo*" of the laryngeal palsy, and consequent phonetic deficiency.

These patients were not periodic, but to the contrary habitual imbibers, and as a rule, only discontinued their protracted debauch when bed-ridden.

The clinical history and data in my first case are as follows:

CASE I. A military gentleman of fine physique and 30 years of age was referred to me by Dr. William M. Mew, U. S. A.

The patient had neither pain, cough, nor thoracic trouble, but exhibited a dull appearance of visage,

and the general evidence of a protracted dissipation, which he admitted.

He could scarcely speak in an audible tone, and stated that the voice commenced to weaken eighteen months previous.

He had been compelled to relinquish his company, as the puerile voice rendered proper decorum among his men an impossibility, for they could not hear his commands.

The laryngoscope revealed a moderately congested pharyngeal and laryngeal mucous membrane, no erosions, hypertrophies, nor inter-arytenoid thickening.

Upon attempted phonation the vocal bands were incompletely approximated, and much phonetic leakage occurred.

The treatment instituted consisted in enforced abstinence from all alcoholic stimulants, the internal administration of thirty minims of tincture of nux vomica thrice daily.

Sprays of an ethereal solution of iodoform 2.30 gms. to 21.00 gms., as well as ammonium chloride 1.60 gms. to 32.00 gms. of water, were administered on alternate days, morning and evening.

Improvement followed, and the patient said that his own children were frightened at his voice on returning after four weeks' absence from home.

In six weeks the voice was completely restored, and he was discharged from medical treatment and rejoined his company.

I learn that he has been more temperate, and that his voice is still good two years after treatment.

CASE II. M. C., aged 32, white, to whom I was called on the morning of March 30, 1884, was my second case.

The messenger stated that the patient was experiencing suffocative attacks, and desired my aid immediately.

On arrival I found my patient in a state of nervous excitement. He said in a whisper, devoid of vocal sound, that he had habitually drank alcoholics to excess; but having recently indulged more freely than usual, developed aphonia, insomnia and nervousness.

A laryngoscopic examination showed a normal mucous membrane—no hyperæmia, inflammation or ulceration. The vocal bands, however, failed to approximate during phonation, and on inspiration the same bands evinced indisposition to proper abduction.

A careful physical exploration of the thoracic organs demonstrated the absence of all disease other than slight cardiac hypertrophy, and his intellect, hearing and vision were normal. He had never had syphilis, rheumatism, or any laryngeal inflammation.

The patient said that on a previous occasion he had lost his voice for ten days, during an exacerbation of alcoholism.

My treatment in this case comprised abstinence from alcohol, the administration of a purge of calomel and rhubarb, followed by nervous sedatives and hypnotics. I pencilled the larynx with a pigment of zinc chloride, endeavoring to arouse the torpid muscles.

The patient slept well during the next forty-eight hours, took nourishment, and improved in voice but slowly.

I finally employed faradisation and nux vomica with the best result, as the power of complete phonation was regained in ten or twelve days.

Here are two instances of aphonia existing in patients having normal sight, hearing, and perfect intellectual faculties, patients free from chronic catarrhal laryngitis and the evidence of syphilis or rheumatism.

The removal of the alcohol in one, and the employment of either an excito-motor stimulant or faradisation in the other, resulted in entire restoration of voice in these patients.

The rapid improvement in my cases, and line of treatment, excludes intracranial influence as causing the aphonia.

Hamon¹ says: "It is totally unnecessary for alcoholic poisoning to be pronounced in order that aphonia may be produced." This statement is in accord with my own observation, and is verified by my cases.

Alcoholic aphonia is, in my opinion, more common than the scanty literature would suggest.

The voice, as Broue² judiciously observes, is the hygrometer of sobriety.

Recalling, then, the many causes involved in the production of paralyses of the lateral crico-arytenoids, and the uncertainty of our knowledge on the entire subject, may I venture to add alcohol to the list of toxics occasioning paralysis of the laryngeal muscles?

At least let alcohol be assigned to the same category as lead, arsenic, antimony and opium, there to remain subject to future scrutiny and additional clinical observation.

TREATMENT OF UTERINE DISPLACEMENTS.

BY AUGUSTUS P. CLARKE, M.D., CAMBRIDGE, MASS.

Read before the Gynecological Society of Boston, Nov. 13, 1884.

Perhaps in no other department of gynecological practice has a subject been more thoroughly considered than that of the treatment of uterine displacements, and although much has been achieved in this direction by the study, still there remains much diversity of opinion in regard to the propriety and method of such treatment. From the earliest times physicians have recognized the discomforts of uterine displacements, and have sought in some manner to rectify them, and for such relief a great variety of devices have been used. The ancients made use of medicated pessaries, which they distinguished into astringent, opiate, aperient, emollient, etc. The solid pessaries are composed of cork, ivory, wood, gum elastic, sponge, caoutchouc, silver, lead, zinc, copper, glass and other peculiar substances, and often coated or concealed by soft rubber or other protective, as the peculiar symptoms, or as the fancy of the operator might dictate. Indeed it would seem that a physician can hardly be considered a good gynecologist until he has devised or approved of some special form of a pessary. Without attempting to wade

¹ *Gaz. d'Hop.*, Par., 1860, xxxiii, p. 222.

² *Hygiene Philosop. d' Artistes Dramatiques*, Par., 1836, ii, p. 109.

through the history and description of these several singular contrivances, I would state that the main design in theory, at least, in the treatment of uterine flexions is to place the unimpregnated uterus of a woman, otherwise healthy, in such a plane or position in the pelvis that the circulation of that organ shall be unobstructed. This is the important point in the treatment that should not be lost sight of, if we are to succeed at all in properly selected cases. Another important point in correcting a displacement or prolapse is not to elevate the uterus above the normal health line, for when the elevation is too great, the symptoms of prolapse or displacement will remain unrelieved, and the cervix be liable to become eroded, and a leucorrhœal discharge take place. The enlarged and flabby condition of a retroposed uterus has often been ascribed to subinvolution of that organ, but this condition of hypertrophy is often found in nulliparæ who present themselves for treatment for retroflexion. I can recall cases of retroflexion occurring in nulliparæ when the cervical canal was patulous and when the mucous membrane of the lips protruded, presenting the appearance of ectropion.

Such cases are usually attended with a cervical discharge producing more or less excoriation, and often vaginitis. The uterus at first, and more especially the fundus, is retroflexed, and if the symptoms remain unrelieved, that organ becomes more and more prolapsed. In this condition the uterus is often extremely sensitive, and the adjacent parts, particularly the ovaries, become the centres of hyperæsthesia. In such a case as this the retroflexion is not the sole cause of this perverted sensibility—but it is owing to the changed relations of the body, fundus and cervix to each other, and the necessary strain upon the uterine ligaments and the production of venous stasis in the parts, by the pressure on the walls of the blood-vessels at the preternatural curve or angle formed by the flexion. In recently produced cases, by sudden violence a good deal of hæmorrhage often takes place, but this is not owing to congestion, as is sometimes ascribed, but to the obstruction in the circulation as stated above. Authors are accustomed to speak of different degrees of retroflexion. Thus, the first degree is where the uterus has a slight bend backward, and the second is where it has a more marked flexion. The third degree is where the fundus is so much bent backward as to have the two extremities of a semi-circle nearly touch each other. Sims used to state that the normal position of the unimpregnated uterus is on a line parallel with one from the umbilicus to the tip of the coccyx, this to be determined by the introduction of the uterine probe or sound. Any deviation from this position, which constitutes an angle less than forty-five degrees, is, as a rule, not to be considered as abnormal. The symptoms of uterine displacement are numerous. One of the most common is uterine dyskinesia, or painful and difficult locomotion. This symptom may occur with either variety of flexion, and become so aggravated as to acquire the title of reflex paraplegia. In such a case the power of locomotion is greatly diminished, and the action of the muscles is deficient. According to

a more recent view by Dr. C. J. Nixon (*Dublin Journal of Medical Science*; JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, vol. iii, p. 408), the dyskinesia or paraplegia is the result of an ascending neuritis or phlebitis which extends from the primary source of the disease of the uterus to the spinal cord, or the occurrence of a descending neuritis commencing in the sacral plexus, and extending downward along the sciatic nerves.

I have now under treatment a young lady unmarried, who has suffered greatly from uterine dyskinesia as a result of a retroposed uterus in the second degree, and whom I have greatly relieved by paying close attention to the uterine displacement. In her case the local application of tannin and glycerine continued for several weeks, coupled with good tonic constitutional treatment, has in a great measure relieved her distressing symptoms and enabled her to walk again as heretofore. The glycerine, according to its well-known action, abstracts fluid from the thickened and œdematous parts, while the tannin by its astringent power gives support to the vaginal and uterine walls. In another case I have used alum instead of tannin, in accordance with the plan of Robert Bell, M.D. (physician to the Glasgow Institution for Diseases of Women, *Retrospect*, part 89, page 165.) According to this author the tampon when saturated with a solution of alum in glycerine and applied in flexions or versions acts in three different ways; 1. as a support; 2. as a depleting agent; and 3. as an invigorating agent to the uterus and vagina. That this agent by its styptic powers reduces the arterial supply, and by its astringent property induces contraction of the muscular fibres, and thus materially assists in the expulsion of the venous blood. It has another advantage in being a cleanly application; it coagulates the catarrhal discharge and thus prevents its decomposition and the excoriation and vaginitis consequent on profuse and acrid discharges. Under this treatment papillary ulceration speedily disappears and hypertrophy of the cervical tissue greatly diminishes. I have recently had a case of a multipara, aged forty years, who had been a great sufferer from a retroposed uterus of the third degree. She had suffered much from hyperæsthesia extending to the left ovary, she had also suffered from cellulitis. The uterus could not easily be replaced, owing to firm adhesions. There was a good deal of unhealthy discharge, she had had an unfaithful husband. I tried a great variety of pessaries, but she experienced no benefit from their application. Indeed, it was with much difficulty that a pessary could be adjusted, as the uterus was held so firmly by the adhesions. This lady suffered much from cystitis, owing to the pressure of the cervix and body of uterus upon the bladder. As this woman had a very fair perinæum, I was advised to try tampons of glycerine and tannin. The applications were to be made every day or two, while the patient was in the recumbent position. These tampons were applied with gentle pressure at first, and each succeeding one was applied with more and more pressure, when at length the adhesions gradually gave way, and the uterus could be raised higher and higher toward the normal health line.

The hyperæsthesia and vaginitis finally disappeared, and the leucorrhœal and vaginal discharges ceased, and the mucous follicles about the cervix became atrophied. These medicated tampons were continued for some time after her more distressing symptoms had yielded.

In another case I used alum instead of tannin, as recommended, which is more cleanly, besides it gave equal if not better satisfaction. Following is the formula: glycerine, 320 grammes; alum, 40 grammes; acid carbohc, if deemed necessary, 8 grammes; water, q. s. and a tampon of absorbent cotton saturated with the mixture is to be placed well up in Douglas's pouch, the other larger one behind the cervix and acts as support of the smaller of the two. This treatment is applicable to the bladder symptoms of anteversion or anteflexion, as a rule one tampon is sufficient (Retrospect, part 84, pages 201-2). I recall another case of retroflexion which occurred in my practice about a year since, where a similar treatment was so far successful that the patient could dispense with the use of a pessary without inconvenience. Before she came under my care she had worn several kinds without material benefit. In another case where the retroversion was dependent upon a subinvolution the application of the medicated tampons, and small and repeated doses of ergotin, in pills three centigrammes, three times a day with gentle laxatives, effected a thorough and speedy recovery. In another case where I freshened the edges and closed an old ruptured perinæum for rectocele, I employed medicated tampons as a preparatory treatment. This case did well but a Hodge pessary was afterward necessary for a long time. In an old and troublesome case of prolapse, where there was a very fair perinæum, occurring in a Swedish lady, I succeeded quite well with the tampon but a good sized Hodge pessary afforded her great comfort.

Cases of anteflexion with or without cystocele are often quite troublesome and difficult to relieve. The following case came under my care: Miss H., unmarried, aged 16 years, had suffered for some years more or less from an affection of the bladder. She suffered from symptoms simulating calculus of the bladder. Her suffering at length became so severe that medical attendance was imperative. This lady suffered from bradysuria, and the urine contained a copious sediment of mucous or white corpuscles. A thorough exploration of the bladder demonstrated that there was no calculus, but that the uterus was sharply anteflexed or bent upon itself like a joint of a finger when closed. The uterus, while the patient was under ether, was replaced by means of a uterine sound. Considerable pain and constitutional disturbance followed the operation, but this soon subsided. This patient at the time was seen in consultation by one of the most distinguished surgeons of Boston, who advised against the use of a pessary in this particular case, relying upon general treatment and occasionally restoring the displaced organ, but contrary to his advice a Hodge pessary was fitted and applied with seeming benefit and relief to the patient. This was by the advice of a specialist in this line of work.

This case I have had under observation and care for the past six years or more, and though the patient was undoubtedly relieved by the hot uterine douches at first continuously and systematically employed, yet I have had some doubts whether the pessary has been of that particular benefit which it at first seemed to promise. For I cannot forget what J. Matthews Duncan has said (Retrospect, part 87, page 206)—that a kindly doctor makes an amiable patient anxious to please him and ready to express a sense of relief which may not be real. Our patient was all this; a highly amiable lady, trained with great care, and anxious to please, and undoubtedly ready to express a sense of relief which may not have been real, without having a desire to be untrue. This young lady, contrary to the advice of *Punch* to the young man, not only contemplated marriage, but recently has become a wife to a sturdy Saxon. The writer of this paper has not lost his interest in the case, but still has his lenses properly focused, in order to see, not only what is to be the outcome of this case, but further, to ascertain who had the sounder opinion—the distinguished surgeon or the presuming specialist. One practice, however, that was at first offered, that of replacing the uterus from time to time by the probe or finger, does not receive the sanction of J. Matthews Duncan. This, he says, has no other effect than to irritate the organ, for the displacement immediately recurs after the probe or finger is removed. Duncan further, speaking of the use of pessaries, says he has never used one on any ground whatever in a virgin, and as to the benefit of pessaries for anteflexion, he expresses no belief, but remarks, if they do good, it is not by keeping the uterus straight; it is by diminishing or preventing further descent of that organ. He remarks he has never used an anteversion pessary, and that he has no idea or intention of so doing, as he has never seen any benefit from their use. Matthews Duncan, in the same part (87, page 282), speaking of minor displacements of the uterus, says we may have these displacements without the symptoms, and the symptoms without the displacement, and until we know better than we know now that the symptoms are dependent on the displacement, he advises us to leave the displacements alone.

Now after reading carefully the above article, I cannot but feel that the author here referred to fails to distinguish a pathological condition of the uterus from a normal physiological one. According to the statistics of Dr. Vedeler (Archiv für Gynäkologie, retrospect, part 86, p. 196) who examined 3,012 women, found 18 suffering from prolapsus. Of the remainder, in 15 per cent., the position of the uterus was normal, it was anteverted in 12 per cent., retroverted in 10 per cent., anteflexed in 54 per cent. So that of 3,012 women of the menstrual age, and of all conditions, the uterus was anteflexed in more than half of the number. Of the whole number 466 were virgins, 749 nulliparous, 322 were from 2 to 3 months pregnant, and 1,465 were mothers. In healthy nulliparous women the normal position was found in 9 per cent. only, and anteflexion 71 per cent. In nulliparous women who complained of pelvic symptoms

the normal position was 15 per cent. and anteverted in 56 per cent. In about 75 per cent. of healthy women who are nulliparous, the uterus was in a state of anteversion or anteversion, while a similar position of the organ was found in 70 per cent. of such women who complained of uterine suffering, and the so-called normal position was found in 8 per cent. only of such women in health, but in 13 per cent. where they suffer from uterine disease. Emmet early recognized that versions may exist an indefinite period without causing disturbance, and it is only when the circulation is obstructed that discomforts arise. I have a patient who has had a marked retroversion for the past eight years at least, and who has not had the slightest inconvenience from the displacement. In her case there is no impediment to the uterine circulation. I can also recall several cases of well-marked uterine displacement where no untoward symptoms have occurred. It is only in retroversion and in prolapse that mechanical means are of use. For this statement we have the authority of Emmet. As for anteversion¹, that is for the most part the normal condition of the uterus, and it is only where we have prolapse or descent of the organ that vesical disturbances occur. The descent causes traction downward on the neck of the bladder or along the anterior wall of the vagina, just as retroversion causes the dragging of the neck of the bladder upward. Now in order to relieve the bladder in consequence of the anteversion we must correct the prolapse of the uterus as we do in cases of vesical disturbance arising from retroversion. This was the condition in the case of my patient suffering from the effects of the anteversion already referred to when a Hodge pessary was employed to elevate the uterus without regard to the flexion of that organ.

The same end is sought to be compassed by a new method of treating the severer uterine prolapses by operation on the round ligaments (by William Alexander, M.D., F.R.C.S., England; Surgeon to the Liverpool Work-house Infirmary). Hence we see, from a therapeutic point of view, why, before the advance of gynecology, the term prolapsus uteri was employed to embrace all that is comprised in the several terms that now denote uterine displacements. The operation devised by Alexander is not limited to cases of prolapsus uteri as such, but it has been resorted to with success in cases of retroversion, attended with descent of the uterus. Cases of cystocele, with prolapse of the vaginal wall, where there are no adhesions, may be slightly benefited by the operation, but where there are old adhesions this operation should not be undertaken. Drs. Campbell, Adams, Lediard and others have had recourse to this operation with success. Dr. Knowsley Thornton (Retrospect, part 82, p. 281), speaking of uterine displacements, says it is the descent of the uterus and the dragging on the ovaries and broad ligaments, with consequent interference with the functions of the bladder and bowels, that lead patients to seek our aid. For extreme cases, where there is no descent,

but where mechanical obstruction exists in the cervical canal, he resorted to graduated sounds for their relief. This practice I have myself adopted, in several instances, for some years past, with quite good success. In such a case now, I make use of rapid dilatation as being more satisfactory. In regard to stem pessaries, Thornton believes them to be often of incalculable mischief. He believes those who take out pessaries, as a rule, do infinitely more good, and infinitely less harm than those who put them in. The writer of this article remembers once to have heard the late Dr. Atlee make the remark that he was often consulted in cases where he removed a pessary, but rarely in a case where he deemed one necessary. The advice contained in the above remarks, in regard to the use of pessaries, strikes every one as being somewhat sweeping, but perhaps was aimed at the practice of the cranks in the profession, who often can not discriminate between a case of simple retroversion and one requiring the aid of this valuable instrument. Besides the means above referred to, cases have been relieved by other modes of practice. Dr. Evory Kennedy (late Master of the Dublin Lying-in Hospital, *Med. Press and Circular*, Sept. 25, 1872), makes mention of an obstinate case of procidentia cured by the actual cautery.

After the uterus was placed *in situ* the actual cautery was then applied about an inch and a half from the vulva round the surface of the vagina for the extent of about half an inch. The cicatrix formed by the eschar prevented the descent of the os. In my early practice, I remember treating a case of old and obstinate prolapsus uteri by industriously applying for several days, for the profuse leucorrhœal discharge, a strong solution of nitrate of silver to the protruding cervix. The uterus I had previously restored, but a violent inflammation ensued, that resulted in such firm adhesions I was never afterward able to distinguish clearly between the cervix and the fundus of that organ. Suffice it to say that the patient finally recovered from all her distressing symptoms, and regarded her case as having been most skillfully treated. In the same paper we find reported a case of procidentia vesicæ treated by a vaginal mould. A cast of the vagina was taken in wax, with the bladder restored to its natural position. A plaster of Paris mould was made from it, from this a caoutchouc instrument was moulded. This the patient wore with great comfort and convenience. Dr. James Dunlop reports a case of artificial occlusion of the vagina for the cure of prolapsus uteri. In this case, a strip of mucous membrane an inch and a half wide was dissected from half an inch below the meatus on one side to the corresponding point on the other. The raw surfaces were brought together, and kept together by means of quilled sutures. This patient was dismissed as having recovered. (*Med. Times and Gazette*, Feb. 26, 1876), Dr. Protheroe Smith speaks of having used a pelvic band in the treatment of uterine versions. The main feature of his appliance is that it forms an artificial skeleton, and so supports all the chief *points d'appui* by which the complicated muscular systems engaged in the acts of expulsion harmonize and effect their purpose. As regards the choice

¹Since finishing this article I find just published in the Boston *Medical and Surgical Journal*, vol. cxi., p. 394, October 23, 1884, the fact alluded to by Dr. Fildes that in fetuses and young infants the uterus is anteverted and bent to the left.

of pessaries, Gaziel's air ball or air ring is often of benefit. I have mentioned having used Hodge's pessary; this I have found as good as any. Otto's spiral pessary I have often used, it is useful in cases of a temporary treatment. Graily Hewett's ring pessary is highly praised by many. It consists of a copper wire ring coated externally with gutta serena or soft rubber. The wire is of various diameters, and can be moulded into any shape the case may require. It is suitable for cases of anteversion, retroversion and prolapse. Thomas's anteversion and retroversion pessaries are often of benefit—I have used both with seeming advantage. From time to time many surgical operations of a heroic nature, such as the removal of the cervix, the entire uterus, the narrowing of the vagina, have been undertaken for the relief or cure of obstinate cases, but no operation is more satisfactory, in properly selected cases, for the relief of the distressing symptoms connected with uterine displacements, than the one undertaken for the restoration of a ruptured or deficient perinæum to its normal dimensions.

MEDICAL PROGRESS.

MATERIA MEDICA AND THERAPEUTICS.

EPILEPSY AND BROMISM. BROMIDE OF POTASSIUM.—Prof. Germain Sée, in *La Semaine Médicale*, discusses this subject at considerable length. He considers first:

What is the part played by the potassium and the bromine in bromide of potassium? Since the investigations of Traube the effect of the potassium salts, particularly of the nitrate, upon the heart has become recognized. The heart, after a short period of excitement, undergoes a certain degree of inhibition with diminution of the blood pressure; hence the conclusion that all the salts of potash constituted the true therapeutic method. But experience has shown that the chlorate, nitrate, and iodide of potassium are all perfectly inert in the treatment of epilepsy. It is therefore proven that potash in general, no matter in what dose it is given, does not possess the slightest therapeutic influence in epilepsy.

Another view of the action of bromide of potassium is to divide its physiological action into two parts, recognizing on the one hand its effects upon the brain, the spinal cord and the skin as of a special nature, and on the other, its effects upon the circulation, respiration and heat, as of a general nature and alkaline in its origin. The latest researches of Krosz show that in man the whole action is due to the bromine, while in animals the amount of bromine that can be taken as bromide of potassium without producing the slightest effect is enormous.

A third view not only removes all curative properties from bromide of potassium, but gives to it a baneful influence upon the heart, an intoxication of the heart. Here the effects of the bromism are attributed to the potassium, and another alkaline base is sought

for, to replace the potassium, in order to avoid the dangers that might result from its constant use for months and years.

It is this theory that has given us bromide of sodium, bromide of ammonium, and the combining of the two with the inevitable bromide of potassium. The poly-bromides, notwithstanding their complex effects, are now very much in vogue on account of this potassiophobia. The ordinary dose of 6 grammes of bromide of potassium introduces but 2 grammes of potash into the system. Under other circumstances the stomach has never made the slightest objection to this amount. The $1\frac{1}{2}$ grammes of potash to every 100 grammes of potato has never been suspected to possess a sedative action or injurious effect. To produce effects equivalent to 5 grammes of bromide of potassium, it is necessary to carry the dose of bromide of sodium to 10 or 15 grammes. So, to avoid a very uncertain danger, the risk is run of producing bromism. Injections of bromide of sodium into the blood of animals produces convulsions as with the potash salt. Bromide of ammonium is still more exciting, so that the three salts combined present no advantage over the bromide of potassium, which plays the third part in the poly-bromic mixture.

Absorption and dose. The bromine is readily and promptly absorbed by all the mucous membranes; in a few minutes it appears in the urine; it is true that it takes only two or three days to be thoroughly eliminated, therefore there is an imperious necessity for continuing its action without interruption; to omit a day occasionally or to diminish the dose is permissible, but to stop it altogether is dangerous. Professor Sée has seen patients where, the drug being stopped for several days in succession, convulsive attacks have recurred after an interval of a year or eighteen months. The bromine is eliminated in great part by the kidneys, very little by the salivary glands, still less by the stomach, and these organs are but little influenced by the drug. The respiratory mucous membrane and the skin, on the other hand, are deeply impressed by the elimination of bromine. The pharyngeal mucous membrane becomes the seat of a painful rasping sensation and of a very pronounced pallor, due to local ischæmia—and with a dose of 5 to 6 grammes the uvula becomes more or less completely anæsthetic. Voisin considers this a sign of saturation of the system—and as produced when 10 or 12 grammes have been taken, but individual characteristics in this respect differ so greatly that poisoning might occur before this symptom presents itself.

Woillez has tried to anæsthetize directly the palate by means of strong bromide gargles, but without success,—nor has touching the parts with the bromide itself proved efficacious. The bronchi become frequently the seat of marked irritation, from the passage of the bromine through the secretory glands; this bromic bronchitis results in a little irresistible cough, dry, or with but little expectoration, and is one of the most serious obstacles to the proper treatment of epilepsy. In one case the patient could never take more than one and a half grammes on

account of this cough. A combination of the bromide with morphia or atropia nullifies the effect of the bromide. There is no species of cough—that of whooping-cough, of hysterical cough, or of tuberculous cough, but what is aggravated by the use of this remedy.

With the skin there is shown the effects of slight bromism and of grave bromism. In the first there is acne, which appears early and which has its seat of selection on the face and chest. Arsenic given with the bromide seems to relieve this symptom. The kidneys are not modified but the urine contains an increased amount of chlorate of potassium, which leads to the supposition of an alteration of base and transformation in the blood into bromide of sodium. The salivary glands are often irritated to the production of an abundant and dangerous salivation, contributing not a little to the emaciation of patients. The gastro-intestinal mucous membrane is but little influenced; if pain is produced upon taking the salt, a freer dilution with water will act as a corrective. Neither dyspepsia nor constipation will follow its use.

The bromine is a vaso-constrictor. There are two principal useful qualities in bromide of potassium; the first is its vaso-constricting effect, the second its depressing influence on reflex action in general, and on the excitability of the cerebral cortex in particular. An attack of epilepsy commences with anæmia, resulting from the excitation of the vaso-constrictor nerves; the bromide is powerful against this transitory condition, but the attack continues and terminates by the hyperæmic condition which provokes vaso-dilatation; it is by its antagonistic or vaso-constrictive action that it proves efficacious, but not thus alone, it is also an energetic depressor, or so to speak, destroyer of the reflex excitability of the cortex cerebri, and of the cortex of the medulla, by means of which it prevents the onset of an attack, as well as arrests its evolution. Is there another vascular drug which can be compared to this. Ergot, which is also a vaso-constrictor, stimulates markedly the reflex action. Belladonna is a vaso dilator and stimulates the reflex action. Curare is of no comparison, it acts injuriously by paralyzing the vessels; while the nitrites of amyl or sodium have but an ephemeral effect and are impracticable from their toxic qualities.

The bromine restrains the exaggerated excito-motricity in epilepsy. Clinical cases as observed by several authors leave no doubt of this fact, but a recent experiment made by Albertoni furnishes a physiological proof which seems to be irrefutable and markedly applicable to epilepsies of cortical origin. In electrifying the cerebral cortex as exposed by the trephine, Albertoni produced partial and general convulsions; on administering 2 to 3 grammes of the bromide to the animal the electric excitability of the cortex diminished considerably, and became more marked as the use of the drug was prolonged; it seemed as if a resistance to the propagation of the stimulus to the psychomotor centres was developed by the brain saturated with bromine. This was then a true excito-motor paralysis, which was the more striking, as voluntary motion was intact. After dis-

continuing the use of the bromide, the brain regained its former excitability, and the electric stimulus recovered its convulsive force. Under the same conditions neither belladonna, atropia or curare acted other than to increase reflex sensibility.

Serious bromism. In his description of this, Prof. Sée details the same train of symptoms as given by various authors. He notes that the general decay is shown by a marked elimination of phosphoric acid and of urea, and has seen death from pneumonia in three cases, which he attributes to the excessive use of this drug. For its relief, he recommends a total cessation of the use of the drug for a considerable period, never to return to doses which have provoked cutaneous, respiratory or nervous bromism.

Mode of using the bromide. Here Prof. Sée adds what he considers as a complement and indispensable commentary to Hammond's work. The efficacy of the bromide rests almost exclusively in the depressive influence which this drug exercises upon the reflex action of the medulla and spinal cord. Therefore everything which might counteract this influence, which might stimulate the morbid excitability of these nervous centres, should be severely proscribed. Epileptics should be denied the use of alcoholic and vinous drinks, beer and carbonized waters; alcohol and carbonic acid gas stimulate markedly the excito-motor functions of the medulla. Coffee and tea, by virtue of the caffeine, produce habitually the same result. In smoking, the nicotine, by exaggerating the vascular action of bromine, by tetanizing the arterioles of the nervous centres, annihilates the useful effects of bromine. Violent gymnastic exercises, hydrotherapeutic remedies, particularly sea-bathing and cold douches, exercise injurious effects upon the attacks. It is the same with physical pain, moral emotions, and generic excitations. All active medication is proscribed, as purgatives, emetics, revulsives, cauterization, and particularly blood-letting.

Auxiliary means. Iron, particularly the tartrate of iron and potassium, 1 gramme per day, Fowler's solution of arsenic, 12 drops per day, sulphate of quinine, cod-liver oil and a residence in the country, moderate physical exercise and moderate mental labor. A proper use of the brain tends to prevent an exaggerated action of the medullary excito-motor power. The bromide does not depress intellectual force, which is generally normal between attacks, and sometimes highly developed. Cæsar, Mahomet and Petrarch were epileptics.

PILOCARPINE IN DISEASES OF THE EYE.—Dr. Caro (*Giomale Internazionale di Scienze Medice, Recueil d'Ophthalmologie*) has published six cases of eye disease treated by the subcutaneous injection of pilocarpine. The diagnoses were: 1st, choroiditis exudativa, with opacity of the vitreous body; 2nd, exudative choroiditis; 3rd, posterior sclero-choroiditis; 4th, serous retinitis; 5th, serous retinitis, with consecutive opacity in the vitreous body; 6th, serous retinitis. A cure was effected in the first, fourth, fifth and sixth cases. In the second there was a very marked amelioration at the time of publication, and the disease had been completely arrested in the third.

Dr. Boucher comments on this with observations made at the clinic of Dr. Galezowski. In one instance a woman presented herself with some slight disturbances of vision. She was frightened because she thought it was a reappearance of an optic neuritis for which she had been treated, at the clinic, two years previous, with subcutaneous injections of pilocarpine. There was nothing there. On the ophthalmic examination, it was difficult to appreciate that the nerve had at that time gone through a period of inflammation, the only remaining evidence being a slight suffusion of the papillary borders. The patient asserted, however, that at her first visit to the clinic the sight of the left eye was almost completely gone. Recently Dr. Boucher saw a case of double optic neuritis, with a prominence of the optic nerve equal to + 8 diopters, yield to the action of pilocarpine, and the vision become reëstablished to a very satisfactory extent. He is perfectly satisfied of the value of pilocarpine in eye diseases, where there is an exudation or transudation to be reabsorbed.

Dr. Caro carried his injections generally to the number of sixteen, using each time a solution containing two centigrammes of hydrochlorate of pilocarpine.

THE ACTION OF CHLORAL IN ALBUMINURIA.—Burduzzi (London *Med. Record*) in 1878, noticed the good effect of chloral in albuminuria, recently confirmed by Dr. Wilson in the *Brit. Med. Jour.* His case in 1878 was that of a lady, suffering from insomnia in the last months of pregnancy, with dyspnoea, from general oedema of the legs and hands, and with highly albuminous urine, in which he ordered 2 grammes of chloral to be taken in two doses every evening. This treatment was continued for about twenty days with very good effects; sound restorative sleep was not only obtained, but the oedema disappeared, and the quantity of albumen in the urine was notably diminished. Labor followed in due course, and was in every respect normal, and the puerperium was free from any complication. Since then Burduzzi has always prescribed chloral in the last month of pregnancy, when there is much oedema, and the urine is scanty and albuminous, as a prophylactic against eclampsia. In a man, 45 years of age, affected by simple nephritis, chloral in doses of 3 grammes a day procured great relief in a short time, and the albumen almost entirely disappeared from the urine. In the so-called physiological albuminuria, chloral is also useful, as the author shows by the case of a man, in whose urine albumen was almost constantly present. Burduzzi points out the need of more exact studies of the action of chloral on the renal tissue.

SURGERY.

ON THE TREATMENT OF ERECTILE TUMORS BY ELECTROLYSIS.—Dr. Delore (*Gazette Medicale de Paris*) gives the preference to electrolysis in the treatment of erectile tumors, because, 1st, it is precise in its operation—that is, it does not attack the

healthy parts; 2d, it is sufficiently powerful to destroy the vessels and vascular cavities which have undergone a morbid development; 3d, the resulting cicatrix is comparatively slight. With a fine needle of gold the smallest and most delicate vessels can be reached. He calls attention to the fact that many surgeons do not make a proper distinction between the galvano-cautery and electrolysis. In electrolysis it is the electricity which decomposes, and not the heat; it is a disintegration of the tissues, more or less energetic, but still a decomposition. The acids which are electro-negative are developed at the positive pole, and the bases at the negative pole. At the positive pole an ebullition is produced, resulting undoubtedly from the discharge of carbonic acid; at the same time the erectile tissue becomes pale and blanched. This is due partly to the electric contraction of the vascular walls, and partly to the electric cauterization. At the negative pole the cauterization is less, hence the necessity for changing the needle of the positive pole more frequently. The success of electrolysis depends upon the use of an apparatus that acts with regularity, and Dr. Delore gives the preference to the Chardin apparatus, which acts by the aid of the bichromate of potash; the pile is in enameled porcelain of two compartments, and the liquid is in the lower compartment, while the zinc and carbon elements are in the upper; it acts when resting on its side, and has special openings for the discharge of gas to prevent the breaking of the porcelain.

Mode of Operating.—The operation being painful, an anæsthetic is desirable, except in children at the breast. The patient being placed in a suitable position, the two needles are introduced into the tissues, when bubbles of air are seen to disengage themselves from about the positive pole, and the needles are surrounded by a whitish aureole, which is due in part to the cauterization, in part to vascular contraction. Attention is first paid to the peripheral vessels, or those which are supposed to nourish the angioma. The needle is left *in situ* as long as it is desirable to sustain a rapid and energetic action; when the surface becomes completely white, it is removed. The object is not to destroy all the vessels definitely, as that would result in a complete eschar of the tumor, but rather to produce cicatricial islets as small and as numerous as possible, so that their retraction may exercise the stenosis and anastrophic action on the adjacent vessels. The operation lasts about five minutes. Often when the needle is removed rapidly from these sinuses or blood cavities, blood flows freely from the puncture; it is well then to remove the needle slowly, and with a twisting movement to assist in coagulating the blood.

Some little time after the operation the pallor of the surface of the nœvus extends, and the circulation is reëstablished at all points where the electrolytic cauterization has not been effective. At these points a crust forms, swelling results, and in strumous subjects suppuration ensues. It is only in the case of large tumors that a slight febrile reaction is noticed. At the end of eight or ten days the swelling diminishes sufficiently to allow the operator to examine the

results of his work. Generally, at the end of fifteen days it is preferable to operate a second time, if necessary.

MEDICINE.

ON THE SPECIFIC GRAVITY OF THE ENCEPHALON.

—Dr. Morselli, in the *Annales Médico-Psychologiques*, gives the results of experiments made upon forty-four cases of insanity, and finds that the specific gravity of the encephalon of the insane is generally greater than that of the healthy. The cerebellum and medulla oblongata of the insane possess a greater proportionate density than the cerebral hemispheres, compared to the healthy. In the warmer seasons of the year the cerebrum, and especially the cerebellum, are increased in their specific gravity. The specific gravity of the cerebrum and cerebellum in small brains of inferior weight is generally greater in proportion. The cerebrum and cerebellum of the female insane possess a less specific gravity than of the male insane, as in health, but in the insane it is less pronounced. In the male the specific gravity of the encephalon attains its maximum between thirty and forty years of age, in the female between twenty and thirty years. Mental alienation in general, and particularly in middle age, elevates the specific gravity of the encephalon. The greatest density is shown in epileptics and alcoholics; the least in phrenæsthenia and paralytic dementia. The chronic forms of consecutive dementia and of symptomatic delirium coincide generally with a specific gravity which is superior to that in the acute and typical forms of mania and of melancholia. The specific gravity is diminished in the chronic and degenerative secondary forms, extremely elevated in those which are dependent upon alcoholism or epilepsy. A marked elevation of specific gravity occurs where there is compression of the cerebrum by exudations, tumors, etc.; it is lowered in atrophic periencephalitis, diffused encephalo-myelitis, and where there is no compression exercised. The symptomatic insanity of acute diseases (lungs, kidneys, skin), shows an increase in the specific gravity; the insanity which results from the alterations of somatic consumption, and is chronic, as in cardiopathy, caseous or tuberculous pneumonia, shows a diminution of the specific gravity of the encephalon. The density increases when there is a cerebral hyperæmia, and diminishes with anæmia. Induration of the cerebellum and medulla oblongata produces a lowering of the specific gravity; it is elevated in softening and œdema. (*Jour. de Med.*)

REFLEX ACTION OF THE DIGESTIVE ORGANS UPON VISION.—Dr. Rampoldi (*Annali di Ottalmologia Recueil d'Ophthalmologie*) describes several cases illustrating the reflex action of the digestive organs upon the visual apparatus, one of which is particularly striking. It is the case of a young girl, twenty-two years of age, who was taken suddenly with complete blindness of the left eye, followed three days later by a very decided amblyopia of the other eye. The patient had suffered for two years from tænia

solium. An external examination of the eyes showed a mydriasis of the left eye, which was so marked as to appear as if atropine had been instilled repeatedly. The pupil was completely motionless to light. The pupillary dilatation was less on the other side, where a feeble reaction to light persisted. Visual acuteness was 0 on the left, greatly reduced on the right. On ophthalmoscopic examination ischæmia of the whole of the fundus of the eye, with increase in the size of the veins, was determined. The patient complained of lancinating pains at all the points of emergence of the branches of the fifth pair of nerves, and even at the point of emergence of the occipital nerve. Servellani's tænifuge (?) was administered. After two or three days there was marked amelioration of vision, which returned to its normal state in about five days. But the worm was only partly expelled.

THE IMPORTANCE OF OSSEOUS LESIONS AS A DIAGNOSIS, AND IN THE TREATMENT OF HEREDITARY SYPHILIS.—Dr. Somer (*Zeitschr. f. Geburtsh. und Gynækol.; Arch. der Tocologie*) gives under this head his observations in the examination of 43 foeti. The first question which he tries to answer is: Is the syphilis of bone an absolutely characteristic condition, to be met with in all cases of hereditary syphilis? May it not give rise to errors of diagnosis? *The characteristics of non-syphilitic bone.*—If a longitudinal incision of the bone be made, there is seen between the bone and the cartilage a delicate straight or slightly undulating line. It is so delicate that microscopically it appears as a simple line, and not as a special layer, with a low power this line is decomposed into a series of little bony projections, very fine, very numerous, crenated, and penetrating into the cartilage. This is the line of ossification. Above this line are seen the cartilage cells arranged in longitudinal series, this is the preparatory layer.

The characteristics of syphilitic bone.—The line of ossification forms a large layer, which carries absolutely irregular processes into the cartilaginous substance. In the bone are found islets of cartilage; in the cartilage, osseous plates in course of destruction. The epiphysis is either completely detached or there are deep clefts in the bone above the limit of ossification. By a low power, instead of the regular series there are great masses of cartilage cells, irregularly disposed, or in vertical series.

He divides his cases into three categories:

1. *The bone gives the perfect alterations of syphilis.* 21 cases. In all the spleen was enlarged. Of the fathers 11 were noted. One was not syphilitic, but his wife was syphilitic from her first husband, and she had two syphilitic children, the offspring of the second, 10 of the fathers had chancres, 3 ten years previously, 3, five years previously, 4, three years previously. Of the mothers 13 were, so to speak, healthy, and had never been under treatment. Four had been infected by their husbands, and four independent of the marriage state. The bones gave the perfect alterations of syphilis. The spleen and liver were always enormous in size. It made no difference in these cases as to the degree of the disease as to

whether one or both parents were infected, whether the primary chancre dated back one or ten years, whether there was or was not treatment, whether there were or not secondary symptoms, whether the child was too large or small. A number of the children were dead before the thirtieth week. The mothers could give no reason for the death of the children, or the premature delivery. In calculating the period of pregnancy, it was always more advanced than the weight of the foetus would indicate.

2. *The bone presents syphilitic alterations, but they are not marked.* In one case of twin pregnancy, one of the children was macerated, with an enormous liver and spleen, and osseous alterations. The other child was fresh in appearance and showed nothing microscopically which could indicate syphilis. The mother said she had always been well and had already four living children.

In another case of twin pregnancy, both children presented enormous livers and spleens. One of these children was macerated, the other was fresh. In the last, the osseous lesions were so minute as hardly to exist. Nevertheless the child was syphilitic as it presented the bullæ of pemphigus on the skin, or abscess of the thymus and the microscopic alterations of the liver and spleen. In five other cases the spleen and liver were enormous. In these 9 children, three were born living but died in a few hours. These cases present a great analogy to those of the preceding category and presented simply the same disease to a limited extent.

3. *The bone appears normal.* There were 13 cases, in one the child was manifestly syphilitic, two others gave much enlarged spleens and livers. Ten others were born in a macerated condition but not syphilitic. The non-syphilitic foetus differs in appearance from the syphilitic. It is more mummified, seems dried up, is brown and often covered by a sort of yellowish or cinnabar-reddish pigment. The syphilitic foetus is œdematous, flesh-colored, with a disagreeable odor. From this he concludes that a normal appearance of the bone in a macerated foetus, does not exclude the possibility of syphilis. The development of the liver and spleen allows of the conclusion of the existence of syphilis, notwithstanding the fact that the bone gives no proof. In the non-syphilitic foetus we frequently find some particular defined circumstance which will explain the death of the foetus, and the size of the foetus corresponds to the period of pregnancy, which is not the case in the syphilitic foetus. Finally, in the case of a syphilitic foetus the placenta presents a weight which is relatively too great in comparison with the weight of the foetus.

In answering the question: Can there not exist normally, sometimes, osseous alterations like those of syphilis? Dr. Somer has examined the bones of 21 embryos furnished from premature deliveries, caused by placenta prævia or induced delivery. He has never found anything analogous to that which exists in syphilis. Moreover, in the majority of cases the visceral alterations of syphilis coincide with the osseous alterations.

Finally, in concluding his article, he decides positively in favor of paternal syphilitic influence, as

equal to that of the maternal syphilis, and he counsels anti-syphilitic treatment in all cases where women abort frequently even when there is no trace of syphilis.

ANATOMY AND PHYSIOLOGY.

THE INNERVATION OF THE PYLORUS.—L. Oser (*Centralbl.; Jour. der Med. Wissenschaften; Jour. der Med.*) has been conducting a series of experiments on curarized dogs, in the laboratory of Prof. v. Basch of Vienna. He introduced into the pyloric constriction, after twenty-four hours of feeding, through the stomach or duodenum, the myrographic forceps, in connection with the registering apparatus of von Basch, which shows the curves of contraction and relaxation.

Whether the vagi or splanchnic nerves were divided or left intact, it was found that the pylorus was the seat of contractions, differing in intensity, which succeeded each other in an irregular manner.

The excitation of the vagi nerves in the neck produced constantly a contraction of the pylorus, the intensity of which was in direct relation to the degree of excitation. The contraction sometimes followed immediately after the stimulus, sometimes it was marked by a longer or shorter interval of in some instances as much as seven seconds. The contraction was sometimes followed by a second one, resulting from a single excitation.

Excitation of the splanchnic nerves in the thorax, caused a cessation of the spontaneous contractions of the pylorus. The effect of a stimulus to the splanchnic was to develop progressively; it attained its maximum between the first and second minutes which followed the application of the stimulus, when the pylorus passed into a state of absolute repose and presented its maximum of dilatation, after which the influence of the splanchnics ceased gradually. Following this were new spontaneous contractions, feeble in the beginning, but at the end of three minutes they had regained their primitive intensity.

If the vagi nerves in the neck, and the splanchnic nerves in the chest were stimulated simultaneously, the inhibitory action of the latter showed itself only by a diminution of the intensity of the pyloric contractions. The maximum excitation of the splanchnic nerves, does not paralyze completely the effects of even the most feeble excitations of the vagi nerves. It is only when this simultaneous excitation is arrested that the effects of the splanchnics are fully manifested, after which, as has been stated, reappears the spontaneous contractions of the pylorus. If the vagi nerves are stimulated at the moment of manifestation of the effects of the excitation of the splanchnic nerves (period of complete repose), either no result follows, or but a feeble contraction is noted, and the action of the stimulated vagus nerve is shown only when this period of repose caused by the splanchnic nerve has ceased.

The left splanchnic produces this action with a sensibly greater intensity than the right splanchnic.

Journal of the American Medical Association.

PUBLISHED WEEKLY.

THE EDITOR of this JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information, should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE..... \$5.00.

SINGLE COPIES..... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 65 RANDOLPH STREET,
CHICAGO, ILLINOIS

SATURDAY, DECEMBER 6, 1884.

THE INTERNATIONAL MEDICAL CONGRESS OF 1887.—The General Committee for the organization of the next International Medical Congress, consisting of twenty-five members, held its first general meeting in Washington, Nov. 29, 1884. Fifteen members were present and answered to the roll-call, viz.: Drs. J. R. Chadwick, of Boston; A. Jacobi and T. F. Rochester, of New York; J. M. DaCosta, S. Wier Mitchell, and I. Minis Hays, of Philadelphia; W. C. Van Bibber and C. Johnson, of Baltimore; J. S. Billings, U. S. A., J. M. Browne, U. S. N., and S. C. Busey, of Washington; N. S. Davis and H. A. Johnson, of Chicago; W. W. Dawson, of Cincinnati, and Geo. J. Engleman, of St. Louis. Dr. J. S. Thomas, of Savannah, Ga., also arrived to attend the meeting, but was, unfortunately, confined to his hotel by sickness. The absent members were: Drs. Austin Flint and L. A. Sayre, of New York; Geo. C. Shattuck, of Boston; H. F. Campbell, of Augusta, Ga.; T. G. Richardson, of New Orleans; D. W. Yandell, of Louisville; R. A. Kinloch, of Charleston, S. C.; L. C. Lane, of San Francisco, and R. P. Howard, of Montreal. The Committee was permanently organized by the election of Dr. Austin Flint, Sen., of New York, President; Drs. Alfred Stillé, of Philadelphia, H. I. Bowditch, of Boston, and R. P. Howard, of Montreal, Vice-Presidents; Dr. J. S. Billings, U. S. A., Washington, General Secretary, and J. M. Browne, U. S. N., Washington, Treasurer. An Executive Committee of seven members was appointed, consisting of the President, General Secretary, and Treasurer, with Drs. S. C. Busey, of Washington, Christopher Johnson, of Baltimore, I. Minis Hays, of Philadel-

phia, and A. Jacobi, of New York. A Finance Committee of five members was directed to be appointed by the President, subject to the approval of the Executive Committee. A liberal basis of representation for the election of delegates to the Congress by the various medical society organizations in this country, was adopted; and the work of the Congress facilitated by the establishment of eighteen Sections. The selection of officers of these several Sections was not completed, but left in the hands of the Executive Committee. If the error of selecting these mainly from the few large cities of the Eastern and Middle States is not committed, we think the preliminary work of organization will have been placed on a good basis, with a fair prospect that the proposed Congress will receive the enthusiastic support of the profession of the whole country.

THE ABSENCE OF FREE HYDROCHLORIC ACID IN STOMACHS DILATED FROM CARCINOMATOUS STENOSIS OF THE PYLORUS.—It is often difficult to differentiate between simple ectasis and other chronic disorders of the stomach, notably dilatation due to stricture of the pylorus from carcinoma. Here much, as regards prognosis, depends upon the differentiation of these two conditions. The diagnosis is rendered tolerably certain by a palpable tumor, pronounced cancerous cachexia, rapid emaciation, etc. There arise cases, however, in which the problem is by no means easy of solution, and hence, in Germany, where dilatation and cancer of the stomach appear to be not very uncommon, the subject of their differential diagnosis possesses great practical interest. In 1879, Dr. Van der Velden announced in the pages of the *Centralblatt f. d. Med. Wiss.*, page 664, that free hydrochloric acid is wanting in the ejecta of stomachs rendered ectatic in consequence of carcinomatous stenosis of the pylorus. The significance of this if found to be a fact, is at once apparent. To test this point, Dr. Kredel has conducted an elaborate series of investigations in thirty-six cases of gastric ectasis presented for treatment at his medical clinic in Giessen. His results are published in the *Ztschr. f. Klin. Med.* vii, page 592, and recapitulated in the *Centralbl. f. d. Med. Wiss.*, page 665, September 20, 1884.

Seventeen were cases of simple dilatation of the stomach, while nineteen were diagnosed in life as cancer of the pylorus with stricture and consequent ectasis. The reagents used in the detection of free hydrochloric and lactic acids were "tropæolin," (a red dye) "methylviolet," (a blue dye), and according to Uffelmann's method the carbolate of the chloride of iron (*Eisenchloridcarböl*). This last test is

said to be both delicate and accurate, since a solution of the carbolate of the chloride of iron is turned from amethyst-blue to yellow by lactic acid when only of the strength of $\frac{1}{20}$ of one per cent., while hydrochloric acid of same strength changes the solution to a steel-gray color: If this latter acid be present in larger amounts, it completely decolorizes the solution. When both acids were suspected to be present at the same time, a speck of fibrin was subjected to the digestive action of the filtered portion of the vomited matters, this action being delayed if hydrochloric acid was absent. In every one of the seventeen cases of simple ectasis this acid was found to exist, the tests for its presence being frequently repeated through a number of months. It is interesting to note that in one case presenting extreme anæmia with consumption, in which the post-mortem examination revealed a circular ulcer of the stomach as the cause of the gastric disorder, that in this case the acid in question existed in the stomach notwithstanding the patient's having been supported by nutrient enemata. On the other hand, hydrochloric acid was not found in the nineteen cases of carcinoma with two exceptions to be referred to presently. The diagnosis was confirmed in five of these cases by an autopsy, whereas in the others all doubt was removed by the development of a palpable tumor, the cancerous cachexia and additional concomitant symptoms. In one of the five cases examined after death, hydrochloric acid appeared for one month, after having been wanting in preceding investigations; and during the month of its reappearance, the improvement in the patient's general condition was very perceptible. One other case, where, however, no post-mortem was obtained, also presented the acid for a limited time with visible amelioration of symptoms.

On the whole, therefore, the results of Dr. Kredel's researches are highly satisfactory, and go to verify Dr. Van der Velden's proposition. The two exceptions mentioned may be really regarded as equally confirmatory, since the reappearance of this normal acid of the gastric juice lasted for but a month. Dr. Kredel considers this subject one of great diagnostic and prognostic import. It is full of interest in many respects. It suggests two questions, viz.: Is this acid wanting in all cases of carcinoma ventriculi, whether located at the pylorus or elsewhere? How does the existence of carcinoma achieve the disappearance of the acid? Furthermore, the marked improvement associated with, and probably occasioned by, the reappearance of the acid is of practical interest as affording a hint for the medicinal treatment of these unfortunate cases. We trust some may be found

among our countrymen who will emulate our German colleagues in their patient, painstaking investigations in this field.

NEW YORK STATE MEDICAL ASSOCIATION.—The very general interest felt by the profession in the progress of re-organizing the profession in the great State of New York in harmony with the society organizations of other States and of the Nation, has caused us to leave out some items intended for this number to make room for the proceedings of that Association, the address of its first President, and the letter of our New York correspondent. All our readers will be gratified with the marked success that characterized the recent meeting, and we hope all will give particular attention to that part of Dr. Didama's address relating to the relative importance of the study of therapeutics and the practice of medicine.

SOCIETY PROCEEDINGS.

PROCEEDINGS OF THE NEW YORK STATE MEDICAL ASSOCIATION.

(Continued from No. 22, page 610.)

This fracture, he thought, was more common than was generally supposed; but its positive diagnosis was very difficult, if not impossible, and the object of the paper was to call attention to the danger of too much manipulation, as uncomplicated cases would get well without any treatment except rest. He presented a specimen in which the fracture extended in three directions and involved the os innominatum.

Dr. J. G. Orton, of Broome county, read a paper entitled, "A Case of Tubal Pregnancy, at Full Term, of Fourteen Years Standing—Autopsy." A spontaneous opening was formed into the rectum about four inches above the anus, and most of the bones of the fœtus had been withdrawn by this means when the patient died of diarrhœa, which was then epidemic in the neighborhood where she resided.

Dr. Nathan Bozeman read a paper on "A Case of Tubal Pregnancy, Considered in relation to Rupture of the Tube, Diagnosis and Treatment." The cyst ruptured on the 13th inst., but as the case was mistaken for one of pelvic hæmatocele by the attending physician, it was more than a week after the rupture that laparotomy was performed by Dr. Bozeman. The enlarged tube was removed and the hæmorrhage effectually controlled, but the patient died thirty-three hours after the operation.

Cases of extra-uterine pregnancy were referred to by Drs. Isaac E. Taylor, Arnold, Ross, Newmann and Squibb.

Dr. Charles S. Bull, of New York, read a paper on "Hydrochlorate of Cocaine in Ophthalmic Sur-

gery, in which he referred to its effects (1) in producing anæsthesia of the sensory nerves of the cornea and conjunctiva; (2) on the pupil and (3) on Accommodation. The drug he considered of inestimable value in the relief which it afforded the ophthalmic surgeon from the thralldom of ether and chloroform.

Dr. Mitchell spoke of the value of bromide of ethyl as an anæsthetic in ophthalmic surgery. Anæsthesia could be produced with it in two or three minutes, and he believed it was perfectly safe for short operations at least.

SECOND DAY—EVENING SESSION.

Dr. Frederick W. Putnam, of Brown county, read a paper on a "Case of Dislocation of the First Phalanx of the Thumb Forward."

This he considered a rare accident, as he had been able to find but few cases recorded in the medical literature of this country.

Dr. John P. Gray, Superintendent of the State Asylum, at Utica, read a paper on "Insanity—Preventive Measures."

He believed that there were a large number of cases of insanity which could be prevented if at the very outset they receive proper hygienic and medicinal treatment and were surrounded with proper mental influences. For sleepless conditions he considered wholesome food and tonics, with bathing, suitable exercise, etc., much better, as a rule, than hypnotics and narcotics, which might be productive of much injury.

Dr. Stephen Smith, of New York, read a paper on "Excision of the Knee in Preference to Amputation in Certain Deformities of the Leg."

This preference was founded both on the comparative safety of the operation, as shown by statistics, and the unquestionable advantage in point of usefulness, of a leg with an ankylosed knee-joint over a stump. The paper was discussed by Dr. S. W. Gross, of Philadelphia, and Dr. Moore, of Rochester.

Dr. George T. Harrison, of New York, read a paper on "The Curette—Its Place and its Power in Uterine Therapeutics."

While many authorities were opposed to the use of this instrument, he believed it to be one of great value when resorted to with discretion, and he discussed the conditions in which its employment was called for, and the best method of employing it in appropriate conditions. For the removal of almost all soft growths within the cavity of the uterus, as well as the retained membranes, or other remains of the products of conception after abortion, it was of good service.

Dr. Frederick S. Dennis, of New York, read a paper on "The Relations between Tuberculous Joint Disease and General Tuberculosis."

He read the history and presented the specimens from a case in which he performed amputation for disease of the wrist-joint which was characterized by the presence of bacilli tuberculosis, and the patient afterward died of acute miliary tuberculosis. There could be no doubt, he thought, at the present day of the tuberculous origin of joint disease in a large number of cases, and he believed that tuberculous affections always spread from local foci.

Dr. Gross fully confirmed Dr. Dennis's views, and thought that an early operation was always demanded to save the patient from general tuberculosis. The disease was at first purely local, but was auto-infectious, and he thought that the analogy between it and cancer was almost perfect.

Dr. Wm. T. Lusk, of New York, read a paper on "The Management of Breech Cases in which the Lower Extremities are extended upward Parallel with the Body of the Child."

When the feet could not be reached by the hand without resorting to force, and it was impossible to hook the finger in the groin, the resort to instruments often became necessary. For this purpose he preferred the forceps to any other, especially with the tractors of Tarnier, and he did not believe that with proper care there was danger of doing the child any injury. After the forceps in point of usefulness he placed the fillet, and then the blunt-hook. If the child was believed to be dead the best instrument to use was the cephalotribe.

Dr. Thomas H. Manley, of New York, read a paper on "Women as Midwives," in which he advised the establishment of schools for the proper training of midwives, since statistics showed that one-third of the wives of the workingmen were never attended in their confinements and there was great room for improvement in the women now generally engaged in the work.

THIRD DAY—MORNING SESSION.

Dr. Flint offered resolutions, which were unanimously adopted, tendering congratulations and thanks to Mr. Andrew Corrigan for his gift of \$50,000, to establish a pathological laboratory at Bellevue Hospital Medical College, and to Mr. Wm. H. Vanderbilt for his gift of \$500,000 to the College of Physicians and Surgeons.

Election of Officers.—The following officers for the ensuing year, proposed by the Committee on Nominations were unanimously elected: President, Dr. John P. Gray; Vice-Presidents, Drs. W. H. Robb, of Montgomery county; J. G. Orton, of Binghamton; H. C. Green, of Buffalo; and J. C. Hutchinson, of Brooklyn. New members of the Council: First District, Dr. Wm. Gillis, of Franklin county; Second District, Dr. R. C. McEwen, of Rensselaer county; Third District, Dr. Frederick Hyde, of Cortland county; Fourth District, Dr. Darwin Colvin, of Wayne county; and Fifth District, Dr. J. W. S. Gouley, of New York county. President Gray appointed Dr. S. S. Purple, of New York, member of the Council at large.

Dr. Austin Flint, Sr., of New York, delivered an address on "Medicinal and Non-Medicinal Therapeutics," in which he painted with pleasant satire the pharmaco-maniacal doctor, who was carried away with every new remedy that was advertised in the market, and his opposite extreme, the skeptical doctor, who did not believe in drugs at all. Much more, however, could be accomplished without the aid of medicines than was generally supposed, and though it was now much harder to withhold these than to give them, he thought the time was approaching

when patients would be content to accept the physician as a general counsellor, and not feel aggrieved because he entrusted them to the healing power of Nature when drugs were likely to be harmful rather than beneficial. In speaking of non-medicinal agents, he dwelt for some time on the use of alcohol, which he regarded as a very valuable agent in disease, not only as a stimulus, but as a food, a germicide, and an apyretic. He also spoke of the phrase "catching cold" as something of a bugbear handed down from the past. The prejudices against fresh air and ventilation in the sick-room, which Sydenham was the first to combat, still continued to a certain extent, but it was well to remember that but few diseases really proceeded from cold, and especially that a fever patient never catches cold. In conclusion, he spoke of the beneficial influence which the physician could bring to bear on the mind of the patient, and said that a reliable work on mental therapeutics was a desideratum in medical literature.

Resolutions of Sympathy for Professor Sayre.—Dr. Gouley having announced that on account of illness Dr. L. A. Sayre would be unable to give the demonstration at Bellevue Hospital which had been set down in the programme, Dr. Flint offered resolutions, which were unanimously adopted, to the effect that the Association tendered to him its deepest sympathy on account of his prolonged illness, with the earnest hope of his speedy recovery. A vote of thanks was passed to Dr. Gouley for his indefatigable services on behalf of the Association, and in making the present meeting such a success; after which a brief address by the President-elect, Dr. Gray, who was introduced by Dr. Didama, was made.

AFTERNOON SESSION.

Dr. Gaston Griswold, of New York, read a paper on "False Albuminuria." This, he said, included two classes of cases: *First*, those in which the urine does not contain albumen, but a precipitate resembling albumen under ordinary tests; and, *second*, those in which albumen is present in the urine, but does not come from the kidney. The substances giving precipitates resembling albumen were the phosphates, mucus in excess, uric acid, peptones, and resinous drugs like copaiba, and he described in detail the means of differentiating them from albumen. Albumen in the urine not coming from the kidney might be due to blood, pus, and prostatic or spermatic fluid.

The following papers were read by title: "Commonsense *versus* Hypothetical Medication in Treating Chronic Diseases," by Dr. Jonathan Kneeland, of Onondaga county; "Cerebral Epilepsy," by Dr. C. F. Macdonald, of Cayuga county; Report of a Case of Gunshot Wound of the Stomach—Recovery," by Dr. John H. Hinton, of New York; "Stretching of Nasal and Supra-Orbital Nerves in Ciliary Neuralgia," by Dr. C. E. Ross, of Chemung county; "Organic Disease of the Brain not a Constant Factor in Insanity," by S. T. Clark, of Niagara county; "Supporting the Perinæum in the Act of Parturition," by Dr. Jacob Hartmann, of New York.

Dr. Samuel W. Smith read a paper on "The Early

Use of the Knife in Nævus of the Cavernous Angioma Variety as Contrasted with other Modes of Operation for Removal." He preferred the knife (with which he had also accomplished excellent results), as he had seen two cases in young children which nearly proved fatal from pyæmia, after operations with needles.

Dr. E. G. Janeway, of New York, read a paper on "Abscess of the Liver." The difficulties of diagnosis and the methods of treatment were illustrated by seven cases which he had met with during the past year. Four of the patients recovered and three died. Three were operated on, and in one instance the abscess opened spontaneously. In the etiology he thought traumatism was a more frequent factor than was generally supposed, and that it was very likely to be overlooked.

Dr. J. Lewis Smith read a portion of an elaborate paper on "Diphtheritic Croup." In the treatment he relied principally on inhalations of turbid lime-water to which $1\frac{1}{2}$ per cent. of liquor potassæ had been added. He also spoke well of a new solvent for fibrinous exudations, tripsin, which was largely contained in *extractum pancreatis*, and he advised that the pancreatic extract should be added to the alkaline inhalations. Time did not permit him to speak of the bichloride of mercury.

Dr. J. P. Garrish, of New York, said he had obtained excellent results with the latter, giving five drops of a solution containing one grain to the ounce every hour to a child two years old, and Dr. Moore had been very successful with the insufflation of bicarbonate of soda, and Dr. Rochester had used with success insufflations of one part of iodoform to two of bismuth.

Dr. Austin Flint, Jr., of New York, read a paper on "Typical Cases of Diabetes Mellitus not before Reported."

These were additional to the fifty cases a report of which he had read at the last meeting of the American Medical Association; and which had been published in the JOURNAL of the Association of July 12, 1884. In one the prognosis was bad, as the patient for a year when the disease was at its highest had indulged in the inordinate use of sweets, and the case was also complicated with renal difficulty. In the other three the sugar had at once disappeared under the use of anti-diabetic diet and Clemens's solution of arsenite of bromine, and had never reappeared. The ages of the patients varied from 15 to 59 years.

Dr. T. W. Ross, of Chemung county, read the report of a "Case of Rupture of the Uterus," in which the entire fœtus (a full grown child at time), membranes and placenta escaped into the abdominal cavity; constituting the second case of the kind on record, so far as he had been able to discover. Specimen exhibited.

Dr. R. B. Bontecou, of Rensselaer county, exhibited a patient who constituted a "Case of Conservative Surgery." The man had received a gunshot injury of the shoulder-joint. Resection had afterward been performed, as much of the periosteum as possible being left, and several inches of the humerus had afterward been restored by nature.

Dr. J. W. S. Gouley, of New York, read a paper on "A Case of Ligature of the Primitive Iliac Artery for Diffuse Aneurism of the External Iliac Artery." The patient died on the 19th day, of pyæmia, and Dr. Gouley regretted that he had not applied a second ligature and opened the sac, in which case he thought the man's life would have been saved. The case was discussed by Drs. Moore, of Rochester; Fifield, of Boston, and Nancrede, of Philadelphia. The Association then adjourned.

In the evening the Fellows residing in New York county entertained the Association at a banquet at the Murray Hill Hotel, and on the day following, after seeing the exhibition of bacilli and surgical cases and operations at Bellevue Hospital, went on an excursion to the hospitals and other institutions on Blackwell's, Ward's and Randall's Islands.

CHICAGO GYNÆCOLOGICAL SOCIETY.

Regular meeting of the Chicago Gynæcological Society, at No. 535 Washington Boulevard, the President, H. P. Merriman, in the chair.

Dr. Edward Warren Sawyer opened the discussion on the "Treatment of Abortion." Dr. Sawyer called attention to the frequency of the interruption of pregnancy before foetal viability. Madame La Chapelle says abortions are as frequent as labors at full term. The experience of the profession opposes this generalization. In his own practice, extending through a period of ten years, he had only seen from forty to forty-five abortions. As illustrative of the wonderful conservation and care of nature in these cases, he had never met with a fatal case in his own practice, and had seen but one fatal case in the practice of his medical brothers. This fatal case was complicated by cellulitis and pneumonia.

As to causation, abortions are divided into two classes: (1) those occasioned by natural processes; (2) those induced by accidental or intentional violence. The former class usually terminate favorably; the latter class are the *bête noir* of the physician. It is a matter of medico-legal interest, that in abortions resulting from natural processes, *i. e.*, fatty degeneration of the decidua, the ovum and decidua are expelled, as a rule, in an intact condition, while in criminal abortion, the product of conception is expelled in a more or less mutilated state. When the ovum has been mutilated, the embryo is extruded from the cavity of the uterus, before the foetal envelopes and decidua, and is frequently lost. Moreover, the embryo, so late as the fourth month, may be completely aborted. The absence of the foetus cannot be regarded in the differential diagnosis of abortion, molar pregnancy, or intra-uterine fibroids. Two distinct courses, as to the treatment of abortion, have been adopted by the profession. The radical method of immediate evacuation of the contents of the uterine cavity, and the plan of patient waiting have been, in turn, defended and opposed. Dr. Sawyer has followed the expectant mode of treatment. He waits and allows

nature to effect the expulsion of the product of conception. He has waited as long as one week. He has been encouraged in this line of treatment, by the fact that he has never seen any untoward consequence in the cases managed in this manner. He enjoins absolute rest in the horizontal position, and the exhibition of quinine and alcohol, as required. Local treatment, apart from the vaginal tampon, is limited to vaginal injections of chlorinated soda. He has never noticed hæmorrhage or inflammatory action as the result of this course of action. He objects to the removal of the whole or part of the product of conception from the uterine cavity, because, (1) it is a painful procedure, involving the use of ether, and predisposing to hæmorrhage from uterine inertia; (2) an assistant is necessary; (3) the amount of unavoidable injury to the genital tract is considerable.

In conclusion, Dr. Sawyer exhibited an unusual specimen. The specimen consisted of an intact, amniotic sac, enclosing a five months' foetus, with filamentous insertion of the umbilicus cord. Separation had occurred between amnion and chorion, the chorion, placenta, and decidua remaining within the cavity of the uterus. He had been called to see the woman, five months advanced in pregnancy, who was suffering from uterine contractions and hæmorrhage. After a brief interval the specimen presented to the Society was expelled. Noting the intact condition of the amnion, Dr. Sawyer paid no further attention to the mass, told the woman to fear no more trouble, and went home. Next morning, upon visiting his patient, he was informed that one hour after his departure, under renewed hæmorrhage and uterine contractions, another mass was expelled. The second mass proved to be the chorion, placenta and decidua. A medical friend, Dr. Albert G. Paine, had observed a strictly similar case.

DISCUSSION.

Dr. W. W. Jaggard said separation between the amnion and chorion was relatively infrequent during the sixth and seventh months, but was not uncommon prior to that period. In regard to the treatment of inevitable abortion when the ovum was expelled in an intact or mutilated condition, and decidua or portions of the foetal membranes remained within the uterine cavity, it was necessary to regard the natural history of the condition. This condition had been appropriately termed by Breslau "incomplete abortion." The terminations are briefly:

(a) Spontaneous elimination of that portion of the product of conception remaining within the uterine cavity, as the result of retrograde metamorphoses, accompanied by intermittent hæmorrhages and uterine contractions.

(b) Sometimes, though seldom, hæmorrhage ceases entirely, and the patient is apparently well. This interval varies from a few days or weeks to months. Suddenly hæmorrhage and pain occur and the intra-uterine mass is expelled. This retention, with a long interval of rest, is noticed when the placental or decidual attachments are intact. That this act constitutes the termination of the labor, so to speak, is apparent from the facts, that the milk secretion is usu-

ally established at this time, and the reductive metamorphosis is instituted.

(c) More frequently the retained decidua or placenta undergoes suppurative or ichorous changes, as the result of which systemic infection is liable to occur despite the thrombosis of the uterine sinuses, and the proliferative change in the uterine mucosa.

(d) The retained placenta or decidua may become converted into placental or fibrinous polyps—conditions which always require operative interference. All four terminations present sources of danger to the mother. From this glance at the natural history of the condition, for the elucidation of which Spiegelberg deserves especial recognition, the weight of evidence lies in favor of the so-called radical treatment. Empty the cavity of the uterus at the earliest possible period. The plan recommended by Dr. Mundé, in the February number of the *American Journal of Obstetrics*, 1883, was worthy of high commendation. One finger within the uterus, one hand on the fundus was preferable to instruments, when equally effective. The subsequent treatment was one of extreme importance.

Whenever the cavity of the uterus is invaded by the finger, or any instrument, it must be irrigated by some antiseptic solution. Two per cent. solutions of carbolic acid, or one to two thousand of the bichloride of mercury, are efficient in the destruction of conditions favoring decomposition and sepsis. After irrigation of the cavity of the uterus, it was a good plan to introduce within the uterus a *bacillus* of powdered iodoform, weighing at least six grammes. Symptoms of iodoform intoxication rarely, if ever, followed the exhibition of this quantity. Ten grammes are usually required to produce toxæmia.

Dr. Philip Adolphus said that abortions were more frequent among multiparæ than primiparæ. In the way of prophylactic treatment, he thought women ought to sleep by themselves during the time corresponding to their menstrual periods. Among the upper classes in Europe, it is customary for man and wife to sleep in separate beds. He thought it an excellent plan. When abortion was inevitable, the treatment must be symptomatic. To arrest hæmorrhage, plug the cervix, not the vagina. Use tupelo, or laminaria tents, not those composed of sponge, for obvious reasons.

Use these tents. When fetor is noticed, empty the uterine cavity. For this purpose, either finger or curette might be employed.

Dr. D. T. Nelson said the dangers from abortion were (1) hæmorrhage, (2) sepsis, (3) inflammation. Rest and opium were not sufficient. He could not rest until the uterine cavity was empty. He had no sympathy with the expectant plan of treatment. The manner of emptying the uterine cavity was of importance. If the cervix was dilated, or dilatable, the cavity should at once be cleaned out with the finger. If the cervix was not dilated, nor dilatable, the cervix ought to be plugged in the manner indicated by Dr. Adolphus, with tupelo or laminaria tents. If the cervix was partially dilated or dilatable, and the uterus fixed, give an anæsthetic, relax the spasm, and proceed as in the first case. He had no fear of ether

predisposing to uterine inertia. In dissecting off the placenta, it was advisable to glove the finger tips with the amnion. In the early months, when the ovum was attached near the cornua, it was necessary to bear in mind the possibility of irregular contraction, and the inclusion within either cornu of a bit of the placenta. The cornua must be thoroughly explored. When he employed intra-uterine irrigation—by no means an invariable method of treatment—he used a $\frac{1}{2}$ per cent solution of carbolic acid, or a dilute solution of ordinary table salt. The solution must be hot, 110° to 120° F. Hot water, in the absence of carbolic acid or salt, was effective as a cleansing agent, and as inducing uterine contractions. Dr. Nelson had had no experience whatever with iodoform, but regarded it as superfluous in all cases.

Dr. Wm. E. Clarke was more afraid of hæmorrhage and sepsis than of inflicting injury upon the genital tract. He always emptied the uterine cavity at the earliest possible period.

Dr. T. D. Fitch did not consider Dr. Sawyer's specimen a rare pathological occurrence. He had seen the same separate at the same time frequently. He agreed with Dr. Nelson in treatment. Still, when the cervix was not dilated he was disposed to pursue the expectant line of treatment. At the time of the occurrence of abortion the uterus was in a physiological condition; operative interference at a later period was attended by increased risk, as the uterus was then in a pathological state. Usually he found the placenta and membranes detached within the lower segment of the uterus. As he had a large hand with short fingers, he employed the placental forceps of Hodge, Dewees, Elliott and Roler. Once in the country he used an ordinary pail bail, with the rough edges filed off. He was not in favor of intra-uterine injections. The vaginal douche was sufficient.

Dr. Wm. H. Byford said that abortions were more frequent in large cities than in the country. Madame La Chapelle's estimate of the frequency of abortion was not exaggerated when applied to large communities. In the country he thought one abortion to three labors at term represented a fair average. Abortion was never a physiological process, although abortions from disease of the ovum were attended with less danger than those resulting from morbid uterine changes. In disease of the ovum, the circulation was impaired, the embryo perished, and expulsion followed with the minimal degree of hæmorrhage, pain and sepsis. When the cause of abortion was external violence, or decidual endometritis, danger in each of these three directions was increased. The specimen exhibited by Dr. Sawyer, was of rare occurrence at so late a period; it was comparatively common during the early months.

As regards the prophylactic treatment, he had observed two clinical facts in connection with the habit of abortion. Where uterine contractions were the prominent symptoms, abortion could be arrested in many cases by absolute rest and opium. Where hæmorrhage was severe, all attempts at arresting the process were usually futile. This was especially true during the first three months. At a late period even

when hæmorrhage was slow, abortion might be arrested.

In regard to the treatment of inevitable abortion, he had never seen the time when champions of the expectant and radical courses of action did not exist. The treatment must be governed by the consideration of the individual case. In any case, the patient must be carefully watched. He had never seen a case of abortion terminate by immediately fatal hæmorrhage. The acute anæmia, however, might induce a condition which would render the woman more susceptible to sepsis, or any intercurrent disease. He feared sepsis and metro-peritonitis more than hæmorrhage. He was conservative as to operative interference. Let nature do what she can; only in case of failure on her part, interfere. The finger was preferable to any instrument. Then it was not necessary to insist upon the removal of placenta or membranes with mathematical accuracy. If the placenta was grasped by an irregularly contracted uterus, cut off the free portion, allow the rest to lie in the uterine cavity. If two-thirds of the placenta were removed, and the uterus well contracted, the case was to be considered in a safe condition. In event of sepsis, remove all the intra-uterine mass.

Dr. John Bartlett stated that in his practice abortions were as frequent as labors at term. The product of conception was usually expelled in its integrity. When abortion was inevitable, two conditions were required before operative interference was justifiable: (1) Dilatation of the canal of the cervix to the extent necessary for the passage of two fingers; (2) the separation between decidua and the uterine mucosa must be more or less complete. Until these conditions were present, the vagina ought to be tamponed. For a tampon he was in the habit of employing bits of cotton, tied on a string, in the manner of the kite-tail.

He had seen two cases in which the placenta had remained for a long period of time within the uterine cavity without causing symptoms. The retention in one case lasted through a period of three months; in the other case the period was four months. As to the length of time the tampon could be left *in situ*, he had adopted Dr. DeLaskie Miller's rule of allowing it to remain twenty-four hours. He had frequently tamponed through three days. The colpeurynter of Braun was a useful tampon. No tampon was effective when the hæmorrhage was not of a passive character, and uterine contractions were severe.

It was necessary to diagnosticate between placenta prævia and abortion. Placenta prævia implied simply an *error loci* of the ovum. It was included between the ring of Baudl and the external os. Dr. Bartlett had never seen a case of abortion terminate fatally from hæmorrhage.

Dr. A. H. Foster had seen one case of retained placenta, in which the retained mass gave origin to no serious symptoms for a period of four months. The importance of subsequent treatment of the puerperium was urged.

Dr. E. C. Dudley referred to the dangers of cervical laceration, and subinvolution, in consequence of

abortion. The best method of applying the tampon, was by means of Sim's speculum.

Dr. C. W. Earle occupied the middle ground between the expectant and the radical methods of treatment. He did not agree with Dr. Mundé.

Dr. H. P. Merriman, after indorsing Dr. Byford's remarks on the ætiology of the condition, said that he did not like to use ergot in these cases, as it caused irregular contraction of the internal os, imprisoning the placenta, without favoring its expulsion. He produced uterine contraction by dilating the os, and then followed the expectant plan of treatment.

Dr. E. W. Sawyer, in closing the discussion, said that he had observed abortion in the lower animals, and concluded nature required little interference. He then briefly sketched the line of expectant treatment which he was in the habit of recommending.

Dr. John Bartlett then exhibited some casts of the pregnant and non-pregnant uterus for the purpose of class illustration. The idea is an extremely ingenious one and will receive attention at an early period.

The Society adjourned to meet Dec. 19, at the residence of the President, Dr. H. P. Merriman, No. 1350 Michigan avenue.

Subject for the discussion, "Extra-uterine Pregnancy;" to be introduced by Dr. Wm. H. Byford, by a paper "On a Case of Interstitial Pregnancy."

W. W. JAGGARD, M.D., *Editor*.

2330 Indiana avenue, Nov. 22, 1884.

FOREIGN CORRESPONDENCE.

BERLIN LETTER.

BERLIN, November, 1884.

There seems to be a somewhat divergent opinion among professors and students as to the necessity of matriculation. On the whole, however, it is better to do so, as it gives one a much greater license and independence. To this end a *passport* is absolutely necessary. A *diploma* will not suffice. As preliminary to the ordeal one must go to the *Registrar*, and obtain a ticket which permits him to appear before the Rector in the Senate Chamber, at a certain hour upon a certain day. At the hour specified he presents his passport, and his credentials are issued upon payment of 18 marks. His student card is sufficient guarantee to the police, as his passport is retained by the Academy until the close of the semester.

The academy exercises surveillance over all of its students, none of whom can be arrested for cause or confined by the police, as the college provides cells for imprisonment. Among very many papers received upon matriculation, is the "Anmeldungs-Buch des Studirenden," etc., in which the student enters the list of studies he may wish to follow, the other columns being devoted to the Quæstor's financial entry, to the number of the student's seat in the auditorium, the signatures of the Docent, date of announcement, etc., etc. For the list of lectures, the hours, and places where such lectures are held, the student must provide himself with the "Verzeich-

niss der Vorlesungen" which can be had at any book store for a few pfennigs. Having selected and entered such studies as he desires, he will next apply to the Janitor for a ticket (Karte zum Belegen der Vorlesungen in der Quæstorei), which gives him the privilege of paying to the Quæstor, or Treasurer, upon a certain day, the small fixed sum for the public lectures which he has elected. For private courses he must apply directly to the professor himself. In Gynæcology, Dr. Landau gives an excellent course (private) at 40 Lottringer Street, 2d floor, on Tuesdays and Saturdays, from 11-1 o'clock. Price, 50 marks.

He has lately had an exceedingly interesting case of hysterical hemianæsthesia, the notes of which he has consented to give me.

Dr. Martin holds private clinics for medical men on Elsasser street, No. 85, but as the number is limited, it is necessary to secure a seat sometime before the beginning of the term. His lectures for students are held in the same building from 1 to 3 o'clock. Dr. Schroder's clinics are in the hospital on Artillerie st. Dr. Gusseron has clinics on obstetrics in Charite and on Ziegel street. Drs. Veit, Hoffmeier (Asst. to Dr. Schroder) and Dr. Wyder, give Gynæcological clinics. Dr. Mayer on Puerperal Fever. Indeed, the opportunities for the gynæcologist in Berlin are probably greater than in any other city in Europe. Dr. Hirschberg is extremely popular among the eye students. He has his clinic on Karl street, and his command of English, together with his geniality and courtesy, attract students from all nations to his rooms. Dr. Schweigger's clinics are also well attended. Dr. Wolf and Dr. Fritsch give clinics in special pathology. And that *αναχ αυδρωγ*, Virchow, continues to draw his hosts from among all ranks. For operative clinics upon eye diseases, for gynæcology, for general pathology and electro-therapeutics, the university of Berlin offers large inducements to the student. For the obstetrician, Vienna and Munich are probably better, while Heidelberg and Strassburg are celebrated above all other places for special pathology and histology. It will take at least a month for the student to get settled, both as to living arrangements and clinics. For the system is complicated and clinics are held in all parts of the city. Without a good knowledge of German one can make very little, if any, progress. A great mistake is in attempting too much, or in the endeavors to accomplish certain aims within a given period altogether too short for its consummation. A man can learn very much here if he goes about it systematically, and manages his courses advantageously. The chances for original research and laboratory work are very good.

At the Medical Society meeting, Nov. 5, Prof. Virchow presiding, Dr. Behrend exhibited some rare forms of pigmentary skin disease. Dr. Friedlander discussed a paper on Diphtheria, which had been read at a previous meeting. He thought that pepsin had little or no influence upon the course and severity of the disease. Prof. Virchow lectured on a "Rudimentary Tail" before the Anthropological Society. A wonderful man he must be who can cope so successfully with so many diverse subjects, including politics.

A man may eat pork here in comparative safety. At the slaughter houses every pig is numbered and so is the pen in which he is placed. Twenty-four sections of this animal all bearing his number are examined by experienced microscopists, male and female, who have been employed for years in this routine and have become wonderfully expert. It requires practice to detect trichinæ readily—and I saw some very beautiful specimens—any doubtful case is referred to the microscopist in charge. It would seem to be impossible for diseased pork to escape detection.

Dr. Gusseron tells me that there are about 1,200 cases of labor a year at Charite, and about 800 outside of the hospital which are attended by the students under the direction of his assistants; at the polyclinic, No. 51 Luisen street, under the direction of his 3d assistant, and which has special direction over the ambulance system, there are treated over one thousand gynæcological cases annually. I saw two cases of acephalous monsters, one of premature delivery, due to syphilis, and one of spontaneous delivery of a fœtus with rachitis and hydrocephalus. There was one woman, with a contracted pelvis, in whom labor was being induced. In a previous confinement the cephalotribe was used. There was also a case of Emmet's operation well on to recovery, two ovariectomies, one laparotomy, and four amputations of the vaginal portion of the cervix, all convalescing. Dr. Gusseron has removed the uterus through the vagina with very fair results, but Freund's operation is never resorted to. He thinks we operate too often in the United States. His private clinic from 9 to 10 is very enjoyable, and the one from 3 to 4 is always crowded.

He showed me with evident satisfaction a room devoted to cases of puerperal septicæmia, which at the time was *empty*. As a fair sample of daily work for the gynæcologist we will take Saturday, Nov. 8. From 9 to 10 in the morning at Charite, there were dressings made to Emmet's operation, to two perineal lacerations, and to the stumps remaining from amputations of vaginal cervixes. First of all, before the dressings were removed, the external genitals were washed with carbolic water; then after removing the dressings, the vagina was washed out with the same antiseptic; iodoform powder was blown from the insufflator over the parts, and iodoform gauze tampons packed in. These dressings were all attended to by an assistant. Dr. Gusseron then removed both ovaries for papilloma. The room was thoroughly permeated with the carbolic spray, the arms and hands of the assistants were washed in a bichloride of mercury solution, and all instruments were kept in carbolic water. Dr. Gusseron had made his diagnosis the previous day and its direct confirmation by the operation was flattering. He used about seven ligatures on both sides. The operation was completed within the half hour. There are so very few persons allowed to be present at these clinics that they are very valuable as affording rare opportunities of observation.

From here the student will go to Dr. Landau's clinic at 40 Lottringer street, which commences at eleven. Dr. Schroder's clinic is at 10 o'clock in Artillerie street, but that can be had daily, while Dr.

Landau's are only held twice a week. Here we find two cases of metritis, two cases of uterine catarrh, two cases of uterine hæmorrhage, one case of anteversion with parametritis and specific inflammation of the ovary, one case of laceration, and of vegetations in the uterus. The number of students is limited to so small a number, that each man can make his own examination. Dr. Landau believes largely in uterine injections and uses saturated solutions of iodoform with alcohol, and strong tincture of iron much more frequently and boldly than is our habit at home. He also uses pyrogallic acid in ectropion of the cervical mucous membrane, and believes that the operation for laceration of the cervix is performed far too frequently in the United States. These clinics are among the most popular given in Berlin. Dr. Martin's clinics are so thoroughly known and admired, that it is difficult to join a class. But his instruction is perfect, and the opportunities for personal observation unsurpassed.

After this there are two private clinics on Gynecological Diagnosis, and a lecture from 4 to 5 by Prof. Gusseron, another private course in the evening from 6 to 7, on minor gynecology. Dr. Schroder has operations almost every day, and his auditorium is so crowded that only a few can see what is going on. Dr. Welch, late of New York, and now of Baltimore, has gone to Munich for special work with Dr. Koch's former first assistant. Dr. Lucien Howe, of Buffalo, has been working up the subject of the action of cocaine. H. R. B.

LONDON LETTER.

LONDON, November, 1884.

Mr. Elliott, vice-chairman of the Islington Board of Guardians, at a meeting of that body stated that on making inquiries the other day he found that at the Western Hospital of the Metropolitan Asylums' Board there was only one patient under treatment, whilst the officers' salaries, uniforms, etc., of that single hospital were costing the rate-payers £4,000 a year. Since then two other fever patients had been admitted, so that the hospital was now being kept open for three patients, at the cost of about £80 a week. Several members remarked upon the great extravagance of the Asylums' Board and waste of the rate-payers' money, in keeping the hospital open at such an enormous cost for two or three patients.

Dr. S. Rabbeth, senior Medical Officer of the Royal Free Hospital, in Gray's-inn road, died in that institution on Monday night, in consequence of a too-zealous devotion to a patient. On Friday week a child, aged four years, who was an in-patient suffering from diphtheria, it was found necessary, for the purpose of saving life, that tracheotomy should be performed. This was done by Dr. Rabbeth, and the obstruction not being removed, it then became necessary that some one should suck the matter through the tube. Dr. Rabbeth at once volunteered. The effect was that he relieved the patient very much for a time, but the child subsequently sank and died.

Dr. Rabbeth some days afterward was taken with symptoms of diphtheria, and in spite of all treatment he gradually got worse and expired. Dr. Rabbeth was only in his twenty-eighth year, and was greatly respected.

Much has been heard during the last two or three years of the deleterious effects arising from the combustion of our open stoves, and remedies have been ardently sought in the smoke-abatement question. Probably, however, few have realized the beneficial action of the rain as a washing agent of the London air. During the last two years the Meteorological Council, through the coöperation of Dr. W. I. Russell, lecturer on chemistry at St. Bartholomew's Hospital Medical School, have been carrying out a series of experiments, having for their object the thorough examination of London rain. The principal impurities in the rain of our large towns are known to be sulphates and chlorides, and the amount of these salts present in the London rain has been systematically determined by Dr. Russell, and in a few cases other impurities have been looked for. Three principal stations were used for collecting the rain—one in the city at St. Bartholomew's Hospital, another at Upper Hamilton Terrace, in the northwest of London, and the third at Hackney. The rain collected at St. Bartholomew's was always more or less dirty from soot floating in it, and disagreeable to taste. The results at the three stations show that city rain contains twice as much impurity as that collected at the suburban stations, and that the impurities at all the stations are in the same proportion. If the city rain is diluted with very nearly an equal bulk of water, it agrees with the rain collected in the suburbs. But although the amount of impurity at the three stations differs largely, it varies but very little with regard to the composition. It was noticed that when the impurities were high or low at one station, they were similarly affected at all stations. The experiments indicate that the summer rain is more impure than the winter rain.

The total amount of salts at St. Bartholomew's was nearly three times, and at the other two stations nearly twice as much, in the summer as in the winter six months, and there is in the summer at each station an increase in the amount of sulphates over the chlorides. Dr. Russell attributes the principal cause of the increase of impurity in the summer to evaporation, and he considers the most probable explanation of the increase in the proportion of sulphates in the summer to the decomposition of animal and vegetable matter. The impurities are found to be much greater in specimens chosen at the early stage of a rainfall than after rain has been falling for some time, clearly showing the purifying effect of a good down-pour. Experiments were also made with samples collected near Fordham, in Sussex, and on Dartmoor, which show the amount of sulphates to be immensely less than the case of London rain. Dr. Angus Smith several years ago attributed the large proportion of sulphates over the land to vegetable and animal decomposition, and thus pointed out why it was that sulphates should increase as we leave the sea. Dr. Russell gives it as his opinion that London

rain carefully collected is never acid, as is generally supposed, but if the rain is collected in an open vessel and left exposed for a considerable time, then the water will always be acid, the acidity arising not from being washed directly out of the air, but from acid washed out of the soot so abundantly present in London air. The experiments also show that a trace of arsenic is to be found in London rain, or rather in London rain and soot.

The French Railway Companies have made arrangements to run through carriages from Calais to the various health resorts along their Mediterranean coast. So that invalids leaving England will go right through from Calais without the necessity of changing stations in Paris.

Dr. Russell Reynolds delivered the Harveian oration to the Fellows and members of the Royal College of Physicians this year. Sir William Jenner presided. Dr. Reynolds said it was not of the "unavailing tears" that were shed nearly 230 years ago over Harvey's grave that it behooved him now to speak, but rather of the fact that nearly three centuries had passed since he became part of their college, and that only last year its Fellows repaired to his grave in Hempstead to do honor to his memory. Now they sought to do homage to the life of Harvey, looking at it in its three-fold aspect of moral, mental, and active energy. Harvey's work of discovery, like all great discoveries was not unprepared. He broke the shell, and there burst forth a new thing, a new thought, a new generalization. Harvey reaped much that he had not sown, but he sowed much that others after him might reap. Dr. Reynolds referred at length to the works of Harvey; to his forecasts in the matter of disease, to his suggestion that the force which converted sterility into fertility was one that pervaded the whole body, and might last almost indefinitely, to his writings on the circulation of the blood and its local variations; to his observations on the mysteries of generation, and to his character and conduct generally. The college he said by this annual oration, handed down to coming generations the memory of him from whom they had learned so much, and to whom their debt of gratitude was larger than they perhaps as yet could know. Dr. Reynolds concluded by saying that so long as the circulation was a recognized fact of science, his work would live.

G. O. M.

DOMESTIC CORRESPONDENCE.

NEW YORK, November, 1884.

The first annual meeting of the New York State Medical Association was an unqualified success in every way, and the inauguration of the noble project under such propitious circumstances certainly argues well for the future usefulness and prosperity of the Society. It was a notable gathering of representative men from all parts of the State, and there were in actual attendance nearly 250 out of a membership of 440, while there were also present delegates from the adjoining States, as well as from Massachusetts,

the District of Columbia, the Province of New Brunswick, and the medical service of the Army and Navy. The Pennsylvania State Society was particularly well represented, and in the delegation from it were included a number of the most distinguished names in the profession in the city of Philadelphia. The amount of solid work accomplished at the meeting was remarkable, and a large number of the papers presented, as well as the discussions which some of them elicited, were of a very high order and permanent scientific value. Out of a total of fifty-four papers on the list, thirty-six were read by their authors, and the rest read by title. That the occasion was not merely one of social junketing, is shown by the large number of hours taken up by the sessions, by far the greater part of which were devoted to scientific work. Thus, on the first and second days of the meeting there were three sessions, lasting from 9:30 to 12:30 in the morning, from 2 to 5:30 in the afternoon, and from 7:30 to 10:30 in the evening; while on the third and last day there were sessions of equal length in the morning and afternoon, though none in the evening.

After all this close and continuous application to business, the Association was prepared to enjoy to the fullest extent the handsome banquet which was provided for them at the close of the meeting by the Fellows residing in New York. Among the guests at the entertainment were the Commissioners of Charities and Correction of the city, and on the day following, after the members of the Association had seen an exhibition of the various bacilli and some cases and operations of Professor Dennis at Bellevue Hospital, the Commissioners placed a steamboat at their disposal, and took them on an interesting excursion to the hospitals and other institutions on Blackwell's, Ward's and Randall's Islands, in the East River.

During the meeting, as will be noticed by a reference to the proceedings, it was unanimously resolved to at once commence the formation of a library for the Association, to be located in the city of New York, and to be paid for and maintained by voluntary contributions. In advocating this measure, Dr. Gouley, to whom the conception of the project was due, spoke of the desirableness of the Fellows residing in different parts of the State feeling that they had a home in New York, the headquarters of the Association, just as the non-resident members of a London club felt about their club in town, and it was proposed that such a home for the Society should be established in connection with the library. They would have to begin, of course, in quite a humble way, he said; but in the course of time it was hoped that a commodious fire-proof building would be secured, and to this end he advised that one-half of the money subscribed to the library should be put into a sinking fund. He mentioned that there was already a nucleus for a library in the Transactions of various Societies which had been presented to the Association, and that the use of forty medical journals would be furnished free of expense. Furthermore, he announced that several hundred dollars had been promised, and that he had every reason to be-

lieve that a suitable room for present needs would be gratuitously offered for the library.

As soon as Dr. William Gillis, of Franklin county, heard of the project, he said he would present between forty and fifty volumes of either the London or the *Edinburg Medical Journal*, whichever would be most acceptable; so that already the good work is progressing.

The successful organization of the Association with such a large and distinguished membership, and the brilliant results of the first annual meeting, are due to a very great extent to the energy and indefatigable labors of Dr. Gouley, who for many months has devoted by far the greater part of his time to the rallying of the profession throughout the State to the defense of the National Code of Ethics, and it was, therefore, a well-deserved compliment that the Association paid in tendering him the only vote of thanks that was given to any one connected with it during the meeting. It is probable that at the meeting next year it will be necessary, on account of the large number of papers that will be presented, to divide the Association into two or more Sections for the better accomplishment of its scientific work, sufficient time being thus secured for discussion; and a proposition to that effect will be reported on by the Council at the beginning of the session.

On one of the days of the Association meeting there occurred the most notable event of the fashionable season in New York, viz.: the marriage of the daughter of Mr. William Astor, and the mother of the bride commemorated the happy event in a very graceful way by treating all the inmates of Bellevue Hospital, or at least all who were able to partake of such solid viands, to a sumptuous dinner of roast turkey, fricasseed chicken, and all the vegetables of the season, with a dessert of plum pudding and mince pie. Another event of immediate interest which took place at the time of the meeting, was the laying of the corner-stone, with appropriate ceremonies, of the first crematory located in the vicinity of New York. The structure is being erected at Mount Olives, within a short distance of Long Island City, across the East River, and it will be seventy-two feet in length by forty feet in width; the materials of which it is built being marble and brick, and the design that of a modified Greek temple. In the body of the building, on the ground floor, will be the chapel and offices, and the basement will contain, in the rear, the furnace, which will be constructed chiefly of fire-brick, and will be adapted to coke, with a regenerator. The incinerating chambers will consist of retorts, which will exclude all fuel and flame from contact with the body and from which the volatile products of the incineration will be carried into the furnace for re-combustion, no smoke being visible or odor perceptible during the process. The basement will also contain a *refrigidarium*, where bodies may be kept for an indefinite period when desired, a *calidarium*, for cases of possible suspended animation, the high temperature of which will induce speedy evidences of life or death, as the case may be, an *ediculanium*, or urn room, and also a room for making autopsies in cases where this may be required. Twenty dead

bodies are already awaiting incineration here, and it is expected the crematory will be completed by February next.

The correspondence between Mr. William H. Vanderbilt and Dr. John C. Dalton, President of the College of Physicians and Surgeons, on the occasion of Mr. Vanderbilt's magnificent gift to that institution, has only just been published. In his letter the donor says: "The health, comfort, and lives of the whole community are so dependent upon skilled physicians, that no profession requires more care in the preparation of its practitioners. Medicine needs a permanent home where the largest opportunities can be afforded for both theories and practice. In making up my mind to give substantial aid to the effort to create in New York City one of the first medical schools of the world, I have been somewhat embarrassed as to the manner in which the object could be most quickly and effectively reached. It seems wiser and more practical to enlarge an existing institution, which already has great facilities, experience and reputation, than to form a new one. I have, therefore, selected the College of Physicians and Surgeons because it is the oldest medical school in the State and of equal rank with any in the United States." With the letter to Dr. Dalton was inclosed the deed of twenty-nine city lots purchased at an expenditure of \$200,000 and a check for \$300,000 for a building fund. It is not often that a member of our worthy but not ordinarily opulent profession has the opportunity of holding in his hands the equivalent of half a million of dollars.

P. B. P.

NECROLOGY.

BEMISS, SAMUEL MERRIFIELD, M.D., of New Orleans, La., born in Nelson County, Ky., Oct. 15, 1821, died suddenly at his residence, New Orleans; Nov. 18, 1884. He was the son of Dr. John and Elizabeth (Bloomer) Bemiss. The father of the subject of this notice was a native of Massachusetts, but of Welsh extraction, and the mother a native of the State of New York. His ancestors were solid, substantial people, and some of them noted for their zeal in the cause of liberty in the American Revolution. His parents were among the early emigrants to Kentucky, and became thoroughly identified with its people, and the doctor partook fully of their generous traits and open-hearted hospitality. After receiving a fair academic education under the care of private tutors, Dr. Bemiss began the study of medicine in the office of Dr. Samuel Merrifield in the village of Bloomfield, Ky. He then attended lectures at the University of New York, where he graduated M.D. in 1846. He at once began to practice in Bloomfield, Ky., but in 1853 removed to the city of Louisville. His ability and learning had already attracted attention, and in 1858 he was elected to the chair of Clinical Medicine in the University of Louisville. His reputation increased with this enlarged field of his labors, but in 1862 he joined the Confederate cause and received an appointment as surgeon in the army.

He served with distinction in the armies of Virginia and Georgia and other places to the close of the war. Returning to his home in Louisville, he was installed in the professorship of Pathology and Physiology, a position which he held with increasing fame until 1866, when he was elected to the chair of Theory and Practice in the University of Louisiana in New Orleans, where he continued to lecture to the day of his death. Dr. Bemiss was gifted with close powers of observation, was a careful and zealous student, and from the time he became a resident of New Orleans, set himself to a comprehensive study of the diseases incident to it and its locality. His researches into the history and peculiarities of yellow fever were careful and untiring. In 1878 he was chairman of a commission of medical experts to study yellow fever as it appeared in the Southern States. In connection with Dr. Jerome Cochran, of Mobile, and others, he traveled from place to place where the disease had prevailed, and collected a vast amount of valuable information upon the subject. In December, 1878, he was appointed on a commission created by Congress, and placed under the direction of the Surgeon-General of the Marine Hospital Service. The result of this inquiry was published by the Marine Hospital Service in Washington. So thoroughly had he become acquainted with the epidemic in the South, that when the National Board of Health was organized under an act of Congress in 1880, Dr. Bemiss was named as one of its members, and served with it to the time of his death. The doctor early identified himself with medical organizations, and was a valuable contributor to their discussions and their literature.

He was a member of the Kentucky State Medical Society, of which he was Treasurer and Secretary; the College of Physicians and Surgeons of Louisville, of which he served as Secretary and Vice-President. Dr. Bemiss held the office of State Registrar of Kentucky for some time. A member of the American Medical Association since 1857, attending also in 1858, '59, '60, '69, '70, and 1879, and served this body both as Secretary and as Vice-President. In the eleventh volume of its transactions may be found a valuable paper by him on the subject of the results of marriages of consanguinity, and in the same volume a paper on "Stomatitis Materni." He has not only been a frequent and an esteemed contributor to medical journals, but has been counted with the editorial staff as senior editor of the New Orleans *Medical and Surgical Journal*. He was a good writer and an interesting lecturer. Oct. 16, 1840, Dr. Bemiss was united in marriage to Mary Frances, daughter of Eli Lockert, of Clarksville, Tenn. This union was blessed by six children, who, with their mother, survive to inherit the good name which the esteemed citizen and skilful physician won for himself and leaves as an imperishable legacy to them. The medical faculty of the University of Louisiana, in special meeting, passed appropriate resolutions of respect to the memory of their late associate, Prof. Bemiss, as did the Medical Association of New Orleans. The death of Dr. Bemiss is mourned by the people of New Orleans as a public misfortune.

J. M. T.

IN MEMORIAM.

Tulane University of Louisiana, Medical Department, New Orleans, November 18, 1884.

At a meeting of the Medical Faculty of the Tulane University of Louisiana the following resolution was offered by Professor S. E. Chaillé, M.D., and passed unanimously:

Resolved, That the Faculty of the Medical Department of the Tulane University of Louisiana suffered a most deplorable loss on the evening of the 17th instant by the sudden death of Professor S. M. Bemiss, M.D., a colleague beloved for his great tenderness of heart, his sensitive sympathy for the sorrowing, his prompt and cheerful services to the needy; for his hospitality, generosity and fidelity; a colleague honored for his distinguished ability and exceptional learning; for his devotion to duty so conspicuously shown during four years of war and eighteen years in the service of this University; for his many sacrifices of policy to principle; for his manly courage in assailing wrong and maintaining right, and for his charity to all, with malice for none.

When his cultured brain ceased to act and noble heart to beat his country lost one of its most valuable citizens, his patients one of America's ablest physicians, his friends a strong supporting hand in the hour of need, and his much loved wife and children a husband and father, whose great affection and self-sacrificing devotion honored them and ennobled him.

T. G. RICHARDSON, M.D., Dean.

BOOK REVIEWS.

LECTURES ON DISEASES OF THE RECTUM. Delivered at Med. Dept. Univ. City of New York. By J. WILLISTON WRIGHT, M.D., Professor of Surgery. New York: Bermingham & Co. 1884. Pp. 170. (Price \$1.25.)

These lectures were reported stenographically in the *Medical Gazette*. They are now reissued in book form, making a convenient small work of reference. They are not put forth with any claims of originality, probably, but may be said to contain a good compilation of recent opinions and modern practice in the treatment of surgical affections of the rectum and anus.

E. W. A.

TRANSACTIONS OF THE INDIANA STATE MEDICAL SOCIETY. Indianapolis: 1884. Cloth, pp 382.

In his able address the President, Dr. S. E. Munford, after a review of the present relations of the profession to society and a consideration of its philanthropic position, particularly as shown in the department of sanitary affairs, proceeds to the consideration of the gross wrongs unwittingly perpetrated upon the learned and honorable in the profession by society, which, through its nebulous belief in any loud-mouthed rascal (the phraseology is our own, and is lacking in that scholarly refinement so noticeable in the address), robs the faithful and modest student both of pecuniary success and honorable distinction.

The remedy proposed by the doctor is the one so universally advocated, namely: the better education of the profession.

There is much of interest and importance in the proceedings, but the general tone of the President's address directs attention to the class of subjects that appeared to awaken exceptional interest. This is due to the fact that the profession are very poorly protected by law in Indiana, which is consequently invaded by quacks of all descriptions.

C. E. W.

BRAIN EXHAUSTION, WITH SOME PRELIMINARY CONSIDERATION ON CEREBRAL DYNAMICS. By G. LEONARD CORING, M.D., New York: D. Appleton & Company. Cloth, 234 pages.

We will attempt to briefly summarize this charmingly written book. The law of the correlation of forces makes it evident that the functional activity of the brain is dependent upon the liberation of force by the decomposition of the organic matter supplied to that organ. Hence interference with this decomposition through the direct diminution of the supply as in compression of the carotids, or indirectly, either through failure of the organs of alimentation or from deviation into other channels, as in great muscular development, or through diminished functional activity of the brain tissue such as results from mental overwork, will lead to a diminution of its power. This latter condition, to which those previously mentioned may be accessory, constitutes brain exhaustion.

It is also shown that the rational hygiene of the emotions is important to the health of the individual, and that the power of memory serves as an index of the functional condition of the brain. Worry constitutes a prominent factor in the etiology of the disease.

In the diagnosis it is necessary to differentiate from the early stages of several forms of insanity, and it would appear to us that the differentiation is not so easy as this treatise would lead one to believe.

In treating the general causes that predispose to this condition, the author considers at considerable length the peculiarities of American society and the prevailing faulty system of education.

The principles of treatment are founded upon improved hygiene, the employment of the recuperative power of sleep, and the fact that in animal food is found the best form of nutriment for the exhausted brain. These general measures may be supplemented by a judicious use of drugs.

The volume is written by one who has had abundant opportunities for informing himself as to the practical side of the subject considered, and it is sufficiently popular in its style to be of interest to most general readers.

C. E. W.

THE ELEMENTS OF PHYSIOLOGICAL PHYSICS. An Outline of the Elementary Facts, Principles and Methods of Physics; and their Application in Physiology. By G. MCGREGOR ROBERTSON, M.A., M.B., C.M. Cloth, 528 pp. 219 wood cuts. Philadelphia: Henry C. Lea's Sons & Co.

The title of this work sufficiently explains the na-

ture of its contents. It is designed as a manual for the student of medicine, an auxiliary to his textbook in physiology, and would be particularly useful as a guide to his laboratory experiments, if he should have occasion to try any.

It will be found of great value to the practitioner, particularly the general practitioner of fair education in physics and physiology, but who has become a little rusty. For instance he may be going to purchase a microscope and to sharpen up a bit on the principles of optics, or he is to write a paper on the relation of presbyopia and procreation, and would like to remember a little something about the physics of the eye. Here in very short space he will find the very facts and principles that he has forgotten.

The book is of particular value in its explanation of the subject of electricity. The denseness of the ignorance of the majority of medical men, even of those who are constantly using the battery, as to the nature and properties of the agent employed, is perfectly astonishing to those who have an opportunity of conversing with the purchasers of such instruments.

It is not light reading by any means. It is a carefully prepared book of reference, concise and accurate, and as such we heartily recommend it.

C. E. W.

HANDBOOK OF THE DIAGNOSIS AND TREATMENT OF SKIN DISEASES. By ARTHUR VAN HARLINGEN, M.D. Philadelphia: P. Blakiston, Son & Co. 1884. Cloth, 282 pages. Two colored plates.

This book is most full in the consideration of those diseases which are particularly common or painful. It presents a large number of prescriptions, and its contents are arranged alphabetically, thus making it at once useful to the practitioner and of ready reference.

MISCELLANEOUS.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, UNITED STATES ARMY, FROM NOVEMBER 22, 1884, TO NOVEMBER 28, 1884.

McKee, Jas. C., Major and Surgeon, leave of absence extended one month. (S. O. 273, A. G. O., Nov. 20, 1884.)

Goddard, C. E., Major and Surgeon, assigned to duty at Fort Yates, D. T. (S. O. 138, Dept. Dak., Nov. 15, 1884.)

Loring, L. Y., Captain and Assistant-Surgeon, assigned to duty as Post-Surgeon, San Diego Bks., San Diego, Cal. (S. O. 135, Dept. Cal., Nov. 19, 1884.)

Taylor, A. W., First Lieutenant and Assistant-Surgeon, relieved from duty at Fort Omaha, Neb., and ordered for duty at Fort D. A. Russell, W. T. (S. O. 101, Dept. Platte, Nov. 19, 1884.)

Wilson, Geo. F., First Lieutenant and Assistant-Surgeon, granted one month leave of absence, from Nov. 20 (Vancouver Bks., W. T.). (S. O. 180, Dept. Col., Nov. 18, 1884.)

Wales, Philip G., First Lieutenant and Assistant-Surgeon, now at Ft. Cœur d'Alene, I. T., ordered for temporary duty at Vancouver Bks., W. T. (S. O. 179, Dept. Col., Nov. 17, 1884.)

ORIGINAL ARTICLES.

THE THERAPEUTIC ACTION OF THE NATURAL MINERAL SPRINGS OF CRESSON UPON THE MUCOUS MEMBRANE OF THE NOSE AND THROAT.

BY DR. CARL SEILER,

Instructor in Laryngology and Lecturer on Diseases of the Upper Air Passages, at the University of Pennsylvania.

Read in Section of Ophthalmology, Otology and Laryngology of the American Medical Association, May, 1884.

During a short sojourn at Cresson Springs, last summer, I became acquainted with the mineral springs of the place; and having observed their therapeutic value on some persons staying there, I resolved to give the matter a thorough test. It was an easy matter to obtain a sufficient quantity of the waters for trial during the winter, and the following remarks will give a *resumé* of the results of numerous trials as well as a few hints as to the proper use of mineral waters in general.

The following analyses of the iron, alum and magnesia springs at Cresson, were made by Professor F. A. Genth, of the University of Pennsylvania, for the State Geological Survey, in 1875.

One gallon of 231 cubic inches contains:

	Iron Spring.	Alum Spring.
Sulphate of Ferric Oxide	= trace	33.38970 grains.
" Alumina	= 1.60466	21.20498 "
" Ferrous Oxide	= 23.47923	16.25273 "
" Magnesia	= 22.58007	27.69855 "
" Lime	= 48.91824	40.20179 "
" Lithia	= trace	0.04693 "
" Soda	= 1.64331	0.70398 "
" Potash	= 0.32405	0.42622 "
Chloride of Sodium	= 0.04063	0.02336 "
Bicarbonate of Iron	= 5.03471	3.74756 "
" Manganese	=	trace "
" Lime	= 3.52946	trace "
Phosphate of Lime	= 0.02914	1.86794 "
Silicic Acid	= 1.20832	
	108.39182	145.56374
		Magnesia Springs.
Sulphate of Lime	=	0.10912 grains.
Chloride of Magnesium	=	0.55962 "
" Calcium	=	1.30444 "
" Sodium	=	1.22974 "
Bicarbonate of Iron	=	0.01753 "
" Manganese	=	trace "
" Magnesia	=	0.41434 "
" Lime	=	0.02252 "
" Soda	=	1.42582 "
" Potash	=	0.20671 "
Phosphate of Lime	=	0.00408 "
Alumina	=	0.00876 "
Silicic Acid	=	0.91455 "
Nitrous Acid	=	trace "
Carbonic Acid (free)	=	0.66390 "
		6.88113 "

There are at Cresson three springs: One a very strong iron spring, which, according to the analyses made by the Pennsylvania State Survey, ranks with the best so-called steel springs of Europe; a ferruginous alum and a weak magnesia spring. These waters I used on a number of patients suffering from chronic catarrhal inflammation of the upper air passages, in the form of spray applied locally to the diseased mucous membrane and the iron and magnesia waters internally with proper regulation of the diet of the patients.

Thus I found that the ferric alum water had a decided tonic and stimulating effect in those cases of atrophic nasal catarrh, which were complicated with pharyngitis sicca and chronic laryngitis, and that the beneficial effect of the local applications was very soon apparent to the patient. In these cases selected for trial no other treatment was used, so that there should be no error possible in determining the therapeutic value of the application.

The iron water I found to have no very decided effect upon these cases, but to be of great value in cases of follicular pharyngitis and in the milder forms of hypertrophic nasal catarrh, as well as in cases of ordinary simple chronic laryngitis and bronchitis. The water is sufficiently alkaline to soften the secretions and to cleanse the mucous membrane.

The magnesia water locally applied gave no results whatever, and I very soon desisted in using it for topical applications, but found it a valuable adjuvant in the treatment of patients suffering from lythæmic inflammations of the mucous membranes of the upper air passages. In these cases the patient was directed to drink the water freely, and its slightly diuretic effect soon became apparent.

The iron spring also is somewhat diuretic in its action, but it is chiefly valuable as a tonic particularly in cases with feeble digestion.

The local applications were made in all these cases in the form of sprays, either with the hand atomizer or with the steam apparatus, and were not repeated oftener than once a day.

Artificially prepared solutions of iron and ferric alum which I used in a number of cases similar to those which were treated with the natural waters, did not have the same effect, and this fact strengthened my belief that it seems impossible to manufacture an artificial mineral water in the laboratory of the chemist which is equal in its value to that produced in Nature's laboratory.

Almost all the European authors on diseases of the lungs and upper air passages lay great stress upon the

value of the natural mineral waters in the treatment of these disorders, and advise their patients to go to one or the other of the many watering places on the continent. In America, on the other hand, although we have mineral springs of equal and even greater therapeutic value than are found in Europe, yet the medical profession at large does not seem to recognize the fact, and they are little patronized with the exception of a few, where, however, the waters form the least attractions, as for instance in Saratoga.

This may perhaps find an explanation in the fact that, in this country everything being free, the patients at these watering places are left to their own choice as to the quality and quantity of the water they are to drink, and are not in the least restricted as to their diet, which as a rule is either altogether insufficient in quality, or sumptuous beyond reason. In Europe, however, the effects of the different mineral springs are well known to every educated physician, and when he sends a case to a watering place it is not a random patient which perhaps he is anxious to get rid of for a time, but he selects that mineral spring which is most suitable for the disease from which the patient is suffering. At the springs there is also a physician appointed permanently by the company or State owning the ground, who has made a study of the therapeutic action of the mineral waters, and who directs every patient as to which of the waters, if there are more than one spring at the place, he is to drink or use, how much, and in what form, whether internally, by local applications, or in the form of baths, and finally gives careful directions as to diet and exercise compatible with the use of the mineral springs.

We cannot expect that change of air and the indiscriminate use of a mineral spring alone should produce these marvelous effects which we so often hear about as having been produced by this or that German spring unless we combine hygienic measures with our therapeutic agents. As soon as the medical profession and their patients realize this important fact, our valuable mineral springs will cease to be a mere pretext for our fashionable patients to spend a few weeks at a watering place, and will become what they ought to be to-day: valuable adjuncts in the treatment of most chronic diseases.

The mineral springs of Cresson, viewed from this standpoint, will, I have no doubt, soon be recognized as extremely valuable in the treatment of all catarrhal affections of the mucous membranes, which is enhanced by their situations and surroundings. They are located near the summit of the Alleghanies at an elevation of 2,300 feet above the level of the sea, and within a few miles of the celebrated Horse Shoe curve of the Pennsylvania railroad, thus affording a moderately high altitude with a moderately dry climate, one that is eminently suited for catarrhal diseases. The hotel accommodations are excellent and the place is free from many of the objectionable features of other more fashionable watering places, such as drinking saloons, gambling hells, race courses and the like, which aside from the bad moral effect must necessarily materially interfere with the needful

rest free from excitement, so necessary with treatment of most chronic diseases.

Unfortunately I was not able to test the virtue of Cresson waters in the form of baths, but when we compare the analysis with that of other springs similar in their chemical constituents we will find that also in that form they must be valuable in many of the disorders due to nervous debility which so frequently show themselves in inflammation and neuroses of the larynx and nasal cavities. As a matter of course, springs of this kind properly used will exert a beneficial effect upon catarrhal inflammations of other portions of the mucous membrane, but as my line of work lies in the direction of laryngology and rhinology, I could not well investigate the therapeutic action of these waters further than I did, namely, upon the mucous membrane of the upper air passages.

SOME REMARKS ON THE FEEDING OF SCHOOL CHILDREN.

BY LOUIS W. ATLEE, M.D., PHILADELPHIA.

Read in Section on the Diseases of Children of the American Medical Association, May, 1884.

From the beginning of all things the weak have been subservient to the strong, both mentally and physically. That the vigor of its people goes to make the greatness of a state is well illustrated in the history of the Roman people, who lost their supremacy in proportion as they destroyed their once famous physical abilities by sensuous indulgences.

It behooves us to see that this coming generation is endowed with the bodily vigor to fight successfully the never-ceasing battle of life; for upon our shoulders is thrown this responsibility.

The subject to which I wish to draw your attention is one that of late has been most thoroughly sifted in England, where a remedy for the evil has been happily suggested. Every actively engaged practitioner in a large city, must have been struck by the number of children brought to his office, whose pale thin faces, but bright eyes, are so characteristic of active minds and bodies insufficiently nourished.

The daily life of these little ones will be found to be much as follows: After a breakfast comprised at most of a very little bread with some tea or coffee, off they go to school to exercise their quickly developing brains till two o'clock, with perhaps an intermission of one half-hour. During this long period of six hours' strain on their mental and physical powers (being often required to stand up during recitation), very few take any nourishment to sustain them, and if they take any, it will be some miserable trifle, such as cake or fruit. Thus is the health of our children broken, and if attention is not soon given to their worn out appearance or complainings, they will either sink under some sickness that in health would have been safely passed over, or the foundation will be laid for an existence made miserable by many ills.

I cannot do better than repeat the words of Sir Henry Peak, in the *Lancet* for Aug. 4, 1883: "The education system is not overworking children, but they are underfed. Do not reduce the lessons, but increase the quality and quantity of the food."

That good feeding is necessary for brain nutrition does not need to be demonstrated or even argued at length.

The brain is part of the body, and it must be evident that the position in which education places the brain of undeveloped children, is that of a highly exercised organ urgently requiring food and finding none or very little. These children are growing, and all or nearly all the food they eat is appropriated to the grosser and bulkier parts of the body to the starvation of the brain.

If the brains were not stimulated by intellectual work they would be left simply undeveloped. As it is, they struggle for food with the other organs of the body, and every part of the organism is reduced to a condition favorable to disease. Other things being equal, a growing child with a hungry brain is worse off both in mind and body than a dullard.

If the organ of mind was not at work it would not be so urgent in its demand for food, and even a poorly fed child might grow in body generally; but being mentally active and underfed, it can neither be healthy in brain or muscle.

This is a matter of great moment, and ought to be carefully considered by all who have the care of the young. Brain nutrition makes a larger demand on the supplies than general nutrition, and requires that its special needs receive immediate attention.

I have now fulfilled my intention, that of directing your attention to this important question, and sincerely hope that it may be the means of leading others, much more competent than myself, to give a thorough elucidation of this subject.

RAW FOOD EXTRACTS.

B. N. TOWLE, M.D., CHARLESTOWN, MASS.

Read in the Section on Hygiene of American Medical Association,
May, 1884.

Molescott's dictum is suggestive, "Without phosphorus there is no thought;" so without nutrition there is no life.

Life may be defined as an aggregation of molecules possessing the properties of respiration, circulation and nutrition. Each of these properties being necessary to all forms of life, the perfection of that life relies upon the completeness of the conditions on which these properties depend. Either of these properties being imperfect or vitiated, the perfection of the organization is impaired, and the life jeopardized.

Pure air in abundance must be supplied. A perfect circulatory system to convey the pabulum to the remotest atom of the organization, and a fluid bear-

ing on its bosom nutritive material suited to the wants of the most delicate tissues is a uniform necessity to health and vigor. From the food the blood is fed, and from the blood the various tissues are built up, therefore the blood of a healthy animal contains all the nutritive material necessary to the production of a perfect organization. If the blood is deficient in pabulum for any tissue, the organ to which that tissue belongs becomes disordered, and the whole system suffers from mal-nutrition and wasting disease, the unavoidable consequence.

Persons suffering from tubercular consumption or chronic disease of any of the vital organs, may be fed on the most nutritious food, and it may be prepared in the most approved ways known to the culinary art, and taken in quantities sufficient to nourish them, and yet they grow thin continually with food in their stomachs, because of a want of power to digest certain elements of it, as starch, sugar, fats, or the albuminoids, and the tissues to be fed by those elements starve, and the whole system is thrown into disease.

It matters but little whether it be faulty diastatic action and the starch not perfectly changed into digestive sugar, or whether it be imperfect peptones and the albuminoids not properly digested, or insufficient action of the pancreatic and liver ferments on the fats, the patient suffers all the same from mal-nutrition.

For faulty diastatic action we have no practical remedy. Soda will relieve the acidity of the stomach, and aid in forcing along the remaining starch to be acted upon by the pancreatic juice.

Pepsin and hydrochloric acid will, in some cases, aid slightly the digestion of the albuminoids, but aids for pancreatic insufficiency in the way of artificial pancreatic ferments, every attempt is worse than a failure. All artificial digestive ferments, when absorbed as such, are poisonous.

Sulph. ether is a direct stimulant to the pancreas, and it increases its secretion and assists in the emulsification of the fats of the food, and is invaluable in the treatment of consumptives where both starch and fats are not well digested.

It may be truthfully stated that all chronic wasting disease is the result of indigestion, or attended with it; and that the great result to be accomplished first, and without which all efforts will fail, is to correct this defect.

Nervous debility and neuralgia are often the results of nerve starvation. They are now, more than ever, the dread of every intelligent physician, and the terror of all business men. The weary hours of pain, and the sleepless nights of those suffering from nervous diseases, are but the beseechings of an exhausted nerve for food.

Hungry and starved, they make their wants known by the pain they set up as their only agonizing cry, and no medication will give permanent relief until the hunger is satisfied.

Having these facts before us, in which direction does medical science point us? Surely there is but one rational plan, and that is in the direction of food suited to the digestive condition of the sufferer.

Our research then must be to find a more easily

digested and assimilated food. Observation seems to sanction the fact that vegetable food elements are more readily assimilated by persons of feeble digestion than are the animal food elements, and especially when they have undergone the digestive process in the stomach of an ox or sheep. The blood of these animals, when healthy and fat, must contain all the food elements in a state of solution most perfect and freed from all indigestible portions, and hence in a form more easily assimilated than any other known food.

I have used blood food or raw food extracts for more than four years in a large number of cases, and in no case of mal-nutrition has it failed to give relief.

I have given it to patients continuously for months with singular benefits, especially in complicated cases of dyspepsia attended with epigastric uneasiness arising from innervation, and in cases of nervous debility of long standing.

The sudden and full relief this food affords patients who have a constant faintness at the stomach, even immediately after taking food, shows how readily it is assimilated. The faintness is a form of hunger, and is the cry of the tissues for food, not quantity but quality. A food that the famishing tissues can appropriate and thrive upon. Raw food is equally adapted to lingering acute diseases. I have used it in the troublesome sequelæ of scarlatina, when there was exhaustion from abscesses in the vicinity of the carotid and submaxillary glands, and in protracted convalescence from typhoid fever with marked advantage.

The cases that I especially value it in are laryngeal consumption and nervous exhaustion, in which cases there is always more or less derangement of the digestive tract, such as pain in the stomach, constipation, eructations of gases, distress after taking food, etc.

Raw food should be taken with each meal, the patients taking such other food as they can readily digest, in quantities suited to the individual cases. It adds much to the nutrition of the patient, overcomes the constipation, subdues the nervousness by increasing the strength, and is just the amount added which is required to secure success.

Intelligent prescribing of drugs implies, first, a knowledge of the power of the drug over certain forms of diseased action; second, a clear understanding of the nature of the disease to be treated, then the dose pushed until the work is accomplished. The same is true of nutrition. Nearly enough will not satisfy. The full meal only satiates. Raw food added to the ordinary meal of invalids very often accomplishes the full meal, and is the satisfying portion.

The therapeutic test of any remedy is its clinical results, and not pathological theories, and therefore I will add a few cases in which I have used it successfully.

CASE I. Mrs. A., aged 28 years. This patient had been failing for six months. When I first saw her she had a sore throat, cough, free expectoration of a glairy mucus, pain and tenderness through right lung just below the clavicle, debility, emaciation, fever,

and night-sweats; pulse, 100; temperature, 99½; appetite poor and food distressed her; had hæmoptysis twice. An examination of the chest revealed a dullness below the right clavicle with diminished respiratory murmur, with moist crepitations over top of both lungs.

Treatment.—Hypophosphite of soda and inhalations of oil perii sylvestris for two months, with but little or no improvement.

Raw food was added, and in six weeks she gained twelve pounds, and was able to resume her home duties.

CASE II. Miss B., aged 22 years. First saw her in 1880. Symptoms—a coarse harsh cough; free expectoration of cell mucus; pain in left side through to shoulder; throat dry; loss of appetite; diarrhoea and constipation alternating; fever at night; pulse, 110; temperature, 100; considerable emaciation and great weakness, constantly taking colds and having fresh attacks of pleurisy.

She had been treated by her family physician seven weeks with no improvement.

Blisters to the side and raw food were advised, and in five weeks she was able to resume her work in a shop.

CASE III. Mrs. H., aged 55 years. This patient had nervous exhaustion from over-work and the loss of a daughter. She was very much reduced, not able to walk on the street. Great nervousness, sleepless nights, head confused, and troubled days, often affirming that she should be insane. No appetite, food distressed her, constipated and great mental depression, often wishing to die. The whole list of nerve tonics and sedatives were tried and failed. I put her on raw food, and she at once began to mend and in six months was well.

CASE IV. Miss M., age 22. For the last five years this patient has been a constant sufferer from cancrum oris. For weeks at a time her cheeks and tongue have been one mass of ulcers. Whole days the saliva would flow continuously from her mouth. Appetite very poor, with a burning pain in mouth and stomach after taking food, and an intolerable faintness when the stomach was empty. For four years she had been suffering in this way until not able to wait upon herself. One year ago I advised raw food, and she has continued it until the present time. She now has very little trouble from the canker and is quite well and strong, able to share the care of her household.

CASE V. Mr. F., aged 30 years. Bright's disease of three years' standing. Symptoms: Uræmic vomiting; frequent epistaxis; sallow, milky complexion; great thirst; good appetite, but food often came up as soon as swallowed. I saw him, and advised mineral water and raw food, which he was able to retain, and improved on it for a time, but finally died. This case showing that raw food could be retained on the stomach when other food was rejected.

CASE VI. Mrs. A., aged 30 years. Had been treated in a distant city ten years for dysmenorrhœa with contracted os uteri, attended with hysteritis, but no improvement. Her menses had not returned but three times for the year.

Raw food was prescribed, and in forty days her menses returned and continued regular afterward, and in three months she was able to take a position as bookkeeper in a large establishment, where she still remains.

PALLIATIVE MEASURES IN RUPTURED EXTRA-UTERINE PREGNANCY.

BY W. W. JAGGARD, M.D.,

ADJUNCT PROFESSOR OF OBSTETRICS, CHICAGO MEDICAL COLLEGE.

Read before the Chicago Medical Society, Dec. 1, 1884.

An editorial bearing this title and appearing in the *New York Medical Record*, of Oct. 25, 1884, contains the following statement:

"There is no palliative measure for a ruptured extra-uterine cyst; there is no expectant treatment; and there is no other way known to medicine by which a woman in this condition can be reasonably expected to survive, save by the prompt use of the knife, and there is no reason for thinking that she would die if this be resorted to in time."

The object of this paper is to offer a protest against this *ex cathedra* mode of settling a question, in regard to which there is room for considerable latitude of opinion. Dogmatism, offensive and unphilosophical under all circumstances, attains its acme of arrogance when applied to rules of practice in medicine and surgery. Certainly, the use of the universal proposition, in the assertion just quoted, is both in bad taste and positively erroneous. In the ensuing discussion, attention is limited to the consideration of tubal pregnancy, because of its most frequent occurrence, and usually early termination. Furthermore, criticism of the treatment of the case, detailed in the *Record's* editorial, is incidental.

Tubal pregnancies may terminate: (1) in the death of the embryo and gradual resorption of the ovum, before rupture of the sac; (2) the sac may rupture, but the egg may remain within, and act as a tampon; (3) the cyst may rupture into the *ligamentum latum*, with the formation of a hæmatoma; (4) the sac may rupture into the peritoneal cavity, with the formation of a retro-uterine hæmatocele; (5) the sac may rupture into the peritoneal cavity, and the life of the woman may be threatened by free hæmorrhage, or the resulting peritonitis; (6) the ectopic pregnancy may persist until the expiration of the full period of utero-gestation. It is impossible, in the present state of medical knowledge, to make any positive statement as to the relative frequency of these terminations. Until within a comparatively recent period of time, only those cases were designated tubal pregnancies, in which the diagnosis was made by an autopsy. It is highly probable that ectopic gestation is of more frequent occurrence than the older systematic writers would lead one to believe. It is also probable that termination by recovery is not an uncommon event. These assertions receive some support from the experience of Professor Karl Schroeder:

¹"I myself see so frequently cases of tubal pregnancy, in which the diagnosis is positive, pursuing a favorable course, that I consider recovery as the regular termination."

The second, third, fourth and fifth modes of termination are alone pertinent to the present discussion.

(2.) *The sac may rupture, but the egg may remain within, and act as a tampon.* Such cases, with favorable results to the mothers, have been observed by *Wiedersperg*² and *Virchow*.

Operative interference in such cases is so obviously contraindicated, that it is unnecessary to enter upon any comment upon that subject.

(3.) *The cyst may rupture into the ligamentum latum, with the formation of a hæmatoma.*

This termination of tubal pregnancy has been observed, up to the present time, with comparative infrequency.³ There can be no doubt, however, as to its actual occurrence. The sac ruptures into the broad ligament, the embryo escapes, and an extraperitoneal hæmatoma arises. The embryo may go on to full development in this region; usually it dies and undergoes reductive metamorphosis, while hæmorrhage is checked by the pressure of the folds of the broad ligament.

Schuchardt⁴ has demonstrated the possibility of this mode of termination by his celebrated case, published in *Virchow's Archives*. J. Veit⁵ has observed the same occurrence.

Primary laparotomy is not indicated by this termination, for the reason that the natural history of the condition shows that hæmorrhage is usually controlled by the relations of the parts, and ultimately complete resorption of coagula and embryo occurs. Exceptional cases, however, may indicate operative procedure for the arrest of hæmorrhage or removal of the embryo.

(4.) *The sac may rupture and the fetus escape into the peritoneal cavity, with the formation of a retro-uterine hæmatocele.*

Ollivier, Leclerc, Schroeder, Vignès, Gallard, Karl Braun, Veit, Chiari, and others, have observed this mode of termination. There can be no doubt as to its occurrence.

As to the frequency of its occurrence, opinions and statistics widely differ. Gallard⁶ makes the statement that hæmatoceles, arising independently of trauma, are almost always due to the rupture of the cyst of extra-uterine pregnancy. Schroeder⁷ says: "This etiology of the hæmorrhage (retro-uterine hæmatocele) is decidedly of very frequent occurrence, even if the tubal pregnancy is seldom diagnosed."

Veit⁸ has very recently collected 146 cases of hæmatocele, of which 40, or 28 per cent., are referred to this mode of origin. He is convinced that 28 per cent. is a low estimate of the frequency of occurrence

¹Karl Schroeder's *Lehrbuch d. Geburtshilfe*, Bonn, 1884, p. 422.

of this etiological factor. It is highly probable, if not positively determined, that the rupture of the cyst of ectopic pregnancy is a more frequent cause of retro-uterine hæmatocele than the standard American and English text-books are disposed to admit.

The course and results of retro-uterine hæmatocele, caused by the rupture of the cyst of extra-uterine pregnancy, have been the subjects of recent study. The extravasated blood is collected in the recto-uterine peritoneal pouch, encysted, and, together with the product of conception, may be resorbed after a very variable interval. Hæmorrhage in these cases is arrested by the diminution in the force and frequency of the heart's action, the process of thrombosis, and the equalization of blood pressure within the arteries and the extravasation. (Schroeder.) Death¹ from anæmia, in the 40 cases collected by Veit, occurred but three times. No one who is at all familiar with the literature of the subject, more particularly with Leopold's experiments upon the lower animals, can entertain any doubt as to the possibility of complete resorption of the embryo. Schroeder has seen, in an autopsy on a woman, dying from a ruptured tubal pregnancy, all the peritoneal lymphatic vessels filled with red blood. Fatal peritonitis, acute or chronic, like fatal hæmorrhage, is a relatively rare termination. Schroeder, Veit and Voisin have expressed themselves very positively in favor of the view that, after rupture of the cyst of tubal pregnancy, with escape of the product of conception and the formation of a retro-uterine hæmatocele, recovery is the rule, and death the exception.

The prognosis is the same as in cases of hæmatocele from other causes. Hæmorrhage is seldom the cause of death. Peritonitis is a prognostic element of more serious import. Of the 40 cases collected by Veit, 11 died of peritonitis, at intervals of from a few days to several months.

Remarkable unanimity of opinion, as regards the treatment of retro-uterine hæmatocele, from whatever cause, exists at the present time. Schroeder, Veit, Karl Braun, Spiegelberg, Barnes, Emmet and Thomas advise the expectant plan of treatment. Absolute rest in bed in the horizontal position, or with the hips elevated, and the thighs slightly flexed upon the abdomen, the local application of cold,—ice-bags to the abdomen, bits of ice in the vagina, cold water rectal irrigation, catheterization of the bladder, in case of retention of urine, the exhibition of opium and chloral hydrate, are points of treatment, to which it is scarcely necessary to call attention in this connection.

Surgical interference, at an early stage, is seldom, if ever, indicated for reasons detailed in the foregoing brief sketch of the natural course and results of the condition.

Surgical interference, at a later stage, is considered justifiable under two indications: (1) persistence of the tumor in its original volume through weeks, without any diminution or alteration, with the occurrence of pains, which confine the patient to her bed

for a considerable period of time; (2) the occurrence of suppuration or ichorous ulceration within the tumor. (Bandl, Billroth's Handbook.)

Even under these indications, laparotomy is not regarded as the operation of election. Dr. A. Martin astonished the members of the *Naturforscherversammlung*, in Salzburg, by the communication, that he had performed laparotomy three times, on account of abdominal, blood tumors. The three patients died. Baumgärtner, since the reading of Dr. Martin's paper, has performed laparotomy, on account of a peri-uterine blood tumor, once. The patient made an excellent recovery. With these statistics, laparotomy has roused no degree of enthusiasm. Operators of the present day limit their interference to the various modifications of the methods, originally suggested and practiced by Nélaton, that is, vaginal puncture, or incision.

(5.) *The sac may rupture into the peritoneal cavity, and the life of the woman may be threatened by free hæmorrhage, or the resulting peritonitis.*

Free hæmorrhage into the peritoneal cavity and consecutive peritonitis have been regarded, for so long a period of time, as the exclusive mode of termination of tubal pregnancy, that no evidence is required to establish the fact of occurrence. Again, opinions and statistics differ widely as to the relative frequency of this mode of termination. The tendency of modern investigation is in favor of the view that free hæmorrhage into the peritoneal cavity and resulting peritonitis are unusual occurrences. ¹Fatal hæmorrhage is very seldom observed, according to the observation of J. Veit, when rational expectant treatment has been practiced. Cases terminating by recovery either do not come under observation, or doubt as to the accuracy of the diagnosis is entertained. On the other hand, cases terminating by death from hæmorrhage or peritonitis are almost always subjected to post-mortem examinations. Very naturally, in the course of time, the fallacious induction—that death from hæmorrhage or peritonitis is the rule—has been made.

It is highly probable that many of the cases, recently reported in American and foreign journals, of favorable termination of tubal pregnancy before rupture of the cyst, as the result of the passage of the electric current, have resulted favorably, not from the death and resorption of the embryo within the sac, but from rupture of the cyst, death and escape of the embryo in the modes just indicated. The effect of an electric current upon smooth muscular fibre is to produce a contraction. When the number of sances, the currents employed, and the symptoms following, are taken into consideration, it is difficult to escape the conviction that in some cases, at least, the favorable result ought to be ascribed to rupture of the cyst. The question of treatment, when the patient's life is threatened by free hæmorrhage into the peritoneal cavity, or by peritonitis, is difficult and important.

Wiltshire, Lawson Tait, Knowsley Thornton, and our editorial friend of the *New York Medical Record*,

¹Die Eileiterschwangerschaft, von Dr. J. Veit, Stuttgart, 1884, p. 15.

¹Die Eileiterschwangerschaft, von Dr. J. Veit, Stuttgart, 1884, p. 65.

see in this condition an absolute indication for *immediate laparotomy*. There are others—and they may be justly designated “surgical leaders of the day,”—who do not recognize this absolute indication for immediate operative procedure.

The prognosis of laparotomy, after rupture of the cyst, is by no means as favorable as in tubal pregnancy before rupture.

The reasons for gloomy prognosis are evident.

The operation must be performed upon a woman in a condition of more or less profound shock. The state of acute anæmia exercises an unfavorable influence. Ether is dangerous, from the possibility of dislodgment of a thrombus and renewal of hæmorrhage. Chloroform must be used with extreme caution, on account of the enfeebled heart. The blood poured out into the peritoneal cavity is mechanically removed, instead of undergoing resorption. The *technical* difficulties of the operation are great. The anatomical relations of the parts are very different from those in cases of consecutive or secondary hæmorrhage, after extirpation of tumors by abdominal section. It is difficult, even on post-mortem examination, to differentiate between tissues and organs. *In viva*, the complications are still more intricate, as all who have had experience will testify. The choice of time, of place, and of operator, is out of the question. Abdominal section must be made without qualified assistants, and without attention to the principles of antiseptic surgery. If the patient is removed to a hospital, she may die on the way. If she survives transport, the assumption of spontaneous recovery is justifiable.

“Is, therefore,” says Veit, “the prognosis of the operative procedure gloomy *per se*, the prognosis of the tubal pregnancy remains the same; indeed, it grows better with every hour the patient lives after rupture, so that of laparotomy and arrest of hæmorrhage there really can be no serious talk.” Finally, Veit, after a careful study of the literature of the subject, has been unable to find *one recorded case*, in which the patient’s life was saved by the operation.

Under the expectant plan of treatment, is included a variety of expedients. Absolute rest in bed, in the horizontal position, the free exhibition of opium, compression of the abdominal aorta by sand-bags, shot-bags, ice-bags, tourniquet, or the band, rectal irrigation with ice-water, are the more important methods by which hæmorrhage may be controlled and the process of thrombosis favored. It is not necessary to add that all cardiac stimulants and counter-irritants must be proscribed.

If, notwithstanding this therapy, symptoms of internal hæmorrhage persist, abdominal section may be resorted to as the only procedure, that offers hope.

It may not be amiss to note the “surgical leaders of the day,” who defend the line of treatment thus briefly sketched:

Karl Braun, Karl Schroeder, J. Veit, August Martin, Sir Spencer Wells, T. Gaillard Thomas, and Thomas Addis Emmet, all advise the expectant plan of treatment, until it has proved futile.

2330 Indiana Avenue, Dec. 1, 1884.

SPECIALTIES, AND THEIR RELATION TO THE MEDICAL PROFESSION.

BY L. DUNCAN BULKLEY, A.M., M.D.,

Attending Physician for Skin and Venereal Diseases at the New York Hospital, Out-Patient Department, etc.

Read before the American Academy of Medicine, August, 1884.

The title chosen for this paper is purposely a little ambiguous and possibly a trifle ungrammatical; but it was desired to express by means of the title certain aspects of the subject of specialism in medicine which are worthy of consideration, and which are better indicated by this title than by one worded differently. The topic is not “*specialists* and their relation to the members of the medical profession,” but the broader one of specialism, or the concentration of thought and work in one direction, however it is accomplished. Nor is the topic “*specialties* and their relation to the *science of medicine*,” but is broader even than this, and looks toward the relations which those who are practicing and advancing medicine should bear toward the development of its science and art, by developing the separate or special portions of that science and art.

The thoughts to be presented in regard to specialties in medicine may be grouped under several quite distinct heads:

1. Specialties—what they are.
2. Why they exist.
3. The relations they bear to the progress of medicine.
4. The relations they bear to general medical practice.
5. Specialists, or those limiting their practice to a single branch of medicine, or class of diseases.
6. The education necessary for the proper practice of a specialty.
7. The future of medical specialism.

First, as to what medical specialties really are. A specialty is defined by Webster to be “that which is the special or particular mark of any person or business: that for which a person is distinguished, or which he makes an object of special attention.” A specialty in medicine is some particular branch of the science or art, or even some individual disease, to which especial attention has been given, or with which, from any circumstance, a medical man is exceptionally well acquainted. In the broadest sense, every one practicing medicine is more or less of a specialist, for it is impossible to have knowledge and experience so evenly acquired that they should not be relatively greater in one or more directions. This is certainly so in every other branch of science. Now, the step from having special knowledge and experience in any one direction to making advances in this line, is not, or should not be, very great, and with this increased interest in and study of a branch, the further step into concentrating more and more of energy and thought upon the special subject which has become of interest, is most natural and fitting. Thus it is that specialties have grown in medicine in

earlier times; thus it is that out of the general mass of those engaged in the study and practice of medicine, one and another has in times past emphasized and developed one portion and another of the vast field in which all have labored. Thus, from the conglomerate mass of diseases, individual ones have been carefully differentiated, groups and classes have been established, and the field of general medicine and surgery has been greatly cleared, and much light has shone through what was almost impenetrable darkness two hundred years ago.

This development of the science and art of medicine gives in part the answer to our second question:

2. Why do medical specialties exist? The answer to this is comparatively simple: First, It is because the entire field of medical knowledge has become so vast, and the advances in it so great, that it is an absolute impossibility for any one mind to perfectly grasp the former, or to follow and comprehend the latter; and unconsciously the choice is made by every one, whereby certain things are specially considered and certain others are slighted. It is with difficulty now that even a specialist can keep thoroughly posted in all that is accomplished in his own line of practice, and it is utterly out of the question, even if it were desirable, for him to read all that is written in his branch alone. Second, Medical specialties but follow the lead of other branches of science, which are all divided and subdivided so that no scientist pretends to grasp the whole perfectly. In the other professions the same has taken place; in the law the lines of knowledge and practice are distinct between civil and criminal law, real estate, patent-office, international, and other departments of the legal profession; in mechanics, naval, mining, mechanical, and civil engineering are all quite separate departments of work; and so on of many other professions and occupations. Third, Medical specialties exist because there is a public demand for them, and the supply follows accordingly. The public wish, and are willing to pay for, the highest attainable knowledge and skill in regard to each and everything relating to the practice of medicine, and successful dealing with diseases which have previously proved obstinate or distressing under treatment, will inevitably lead to increased confidence in the individual who gives relief, and invariably tend to enlarged opportunities in the same direction. Thus, were the entire profession at any one time to be placed on a perfect equality of knowledge in a community, a greater or less degree of special practice would unconsciously develop, and certain members would, before long, stand more prominent than others in particular lines of work.

This leads us naturally to the consideration of our third topic:

3. The relation which medical specialties bear to the progress of medicine. As we have seen, specialties are the natural and necessary outgrowth from the progress of medicine. They have not arisen from any premeditation or desire to split up the subject of medicine into many disjointed parts, but they are only the long, far-reaching roots which the parent tree of medicine has sent out to draw sustenance from the deep and hidden springs of wisdom and knowl-

edge, in order to minister to the growth and development of the trunk and branches, which in turn bear the leaves and fruit of healing. To oppose specialties is to sap the life of the entire science and art of medicine. Who can deny the gain which has resulted from the first great specialty, namely, surgery, or who can compute the lives and suffering which have been saved by those who have devoted special attention to this branch, even to the exclusion of ordinary medical practice? Subdividing this branch again, who can estimate the value of the lives which have been spared through the exertions of those who have given great attention to a single operation, ovariectomy? Who can be blind to the progress in the science and art of medicine made through the labors of those who have confined their energies to gynecology, ophthalmology, laryngology, dermatology, neurology, and other special lines of work, and who can claim that the same advances could have been made by those whose thought and practice extended over the entire, rapidly enlarging circle of medical knowledge?

It is undoubtedly true that many valuable additions to special lines of practice have been made by those engaged in general medicine, of which ovariectomy, perhaps, is the most striking example; but, on the other hand, the mass of knowledge in general regarding particular diseases has been contributed mainly by those whose opportunities gave unusual acquaintance with them.

It must never be forgotten that the existence of specialties renders it possible to give to the medical profession a large amount of enlightenment and experience in particular directions which could not otherwise be obtained. Thus, the gathering together of patients afflicted with diseases of a particular class, and the experience gained therefrom, enables the teacher to tell in a moment that which another might take a lifetime to acquire, and by the exhibition of cases, to demonstrate features of disease and methods and procedures of practice which another could learn only with the greatest difficulty, if at all, from personal experience.

We come now to consider our fourth topic:

4. The relations which medical specialties bear to general medical practice. From what has preceded it is evident that as specialism is the outgrowth of general medicine, the connection between the two is very intimate; they can no more live apart than can the tree and its root live and thrive when torn asunder; the life of the one is the life of the other.

It was remarked that every practitioner of medicine was, to a greater or less extent, a specialist, and the converse is still more certainly true, namely, that every really good specialist must be acquainted with general medicine and be able to practice the same with success; he cannot rationally and properly treat any special disease without understanding and appreciating the relations which that disease may bear to the system at large. Other things being equal, the best specialist is undoubtedly he who has the best knowledge of and experience in general medicine, and who applies the same in connection with the line of practice in which he is specially engaged.

The greatest errors and harm can come from the too exclusive concentration of thought upon a single branch of medicine without a proper appreciation of the relations which may and generally do exist between the organ of disease under treatment and other organs of the body, or the general system.

This leads us again, very naturally, to the consideration of our next subject :

5. Specialists, or those limiting their practice to a single branch of medicine or class of diseases. A specialist is defined by Ogilvie to be "a person who devotes himself to a particular branch of a profession, art, or science; a person who has studied and acquired a special knowledge of some particular subject." If the foregoing argument and reasoning are correct, a true specialist in medicine may be defined to be a "physician or surgeon who is thoroughly acquainted with general medicine, theoretically and practically, but who has devoted particular attention to, and acquired peculiar knowledge and skill in some special branch or department of medicine, or class of diseases." The proverb *poeta nascitur, non fit*—the poet is born, not made, applies equally to the specialist as to the poet: he should be born out of the womb of mother medicine, should feed on the rich milk which nourishes all her children, and should grow out of the necessities of the case, being nursed in the lap of experience, and in full process of time may develop into something useful; but to jump into the practice of a specialty, like Minerva from the head of Jupiter, fully armored and ready for the fight, can seldom be accomplished with the highest success. And yet many attempt this yearly; the idea seems very prevalent that a young man has but to secure a diploma, spend a little time in the study of one special subject in one of the larger cities here or abroad, announce himself as a specialist, write an article or two, and, *presto*, change, he is a veritable specialist, only waiting for patients.

This tendency to hasty and imperfect preparation in the matter of general medical study and general clinical experience has resulted in much harm to specialism, and much injury to the science and art of medicine, as well as to its reputation before the world. Want of proper knowledge and training leads to imperfect medical observation, undue or insufficient appreciation of concomitant or allied symptoms or features of disease, and too often to unsuccessful treatment, from a failure to judge wisely in many matters relating to the individual under treatment. While accurate diagnosis and correct pathology are most essential and vital elements in medical practice, the broad knowledge and experience belonging to the general practice of medicine best fits one to understand and treat individual cases of disease, and the specialist will have but little relative success who ignores systemic influences, and pays exclusive attention to local phenomena and local measures.

The practice of a specialty is, therefore, beset with no little difficulty, for the tendency is very strong to concentrate thought and attention too exclusively on one idea, and to see and think of only one organ of the body or class of diseases, and thus to lapse into what Lord Lytton calls "the wretched narrow-

mindedness of every one who cultivates his specialty alone." Let no one, therefore, envy the specialist, for in addition to the immense drudgery and monotony of seeing and dealing with the same diseases over and over again, and the untold labor of treating the thousands of free patients in public institutions, which give him his knowledge and skill, he has a constant struggle, if he be a true specialist, to rise above his speciality, and to maintain his proper relations to the science of medicine. Few but those who have undergone it can appreciate the labor involved in connection with these matters, to say nothing of literary work and teaching; so that no one should seriously contemplate special practice who is unprepared for long and arduous toil. It is, I think, a fact, that the health of specialists breaks down more commonly than that of those engaged in the round of general practice; certain it is that the daily weariness and exhaustion of one who has spent a day in varied occupation, out in the world, from place to place, with changing scenes every moment, cannot excel that of the busy specialist who, going round and round the treadmill, day by day, over the same ground again and again, never seems to advance much beyond the point at which he started.

It is useless for our subject to enter this matter more fully, but many specialists will be willing to agree that in many things they envy the general practitioners—in the largeness and variety presented by their field of operation, in the many warm and true friendships formed, and in their varied and healthful occupation, which a possible larger pecuniary success in a few instances in a specialty by no means counterbalances.

We come now to consider :

6. The education necessary for the proper practice of a specialty. As may be judged from what has preceded, a specialist's education should be most thorough and complete. In the first place, the academic and collegiate education is most necessary, both for the training of the mind to close study and observation, and for the knowledge of the languages, ancient and modern, which are continually required in the study and prosecution of any special branch.

In beginning the study of medicine proper, the idea of a specialty should be kept entirely out of mind, and the most thorough course of general medical study possible should be followed, with especial attention to chemistry, histology and pathology. The practical portions of study should also be closely followed, and later in the course as much as possible should be learned from clinics. If the medical man is subsequently to give his attention to one branch more exclusively, it is all the more reason that he should have the foundation and groundwork thoroughly and perfectly learned, for it is a constant lament of specialists that there is so much outside of their specialty which they would like to know, but which their subsequent press of work prevents their acquiring. It may be stated most positively that no portion of a thorough medical education is wasted in preparing one for the practice of a special branch, not even obstetrics for a laryngologist, or ophthalmology for a gynecologist; sooner or later every particle

of medical knowledge which can be acquired will be brought into requisition. Three years is all too short for laying a groundwork which may be called upon for use many years later, to solve some doubtful question in pathology or therapeutics.

On graduation, it is exceedingly important to have a period of service in some general hospital as interne, for two years if possible; this is preferably to be in a medical service, rather than in a surgical. If one is to deal with only one class of diseases in his future practice, it is all the more necessary that he should have practical and personal acquaintance with general diseases beforehand, and this hospital service, if well employed in note-taking, will be to him afterward a mine of wealth of experience from which he may draw with the greatest comfort and benefit. All who have served as internes in a hospital will appreciate this, and will recall how little they found that they knew practically on leaving the medical college and entering the hospital. It makes one shudder to think of those who have plunged into a specialty without having thus had their studies crystallize into practical shape under the fostering care of the experience acquired in hospital life. This service in a general hospital is of far more value, practically, than a residence in a special hospital devoted to the branch which is to be followed.

On leaving the general hospital a service in a special hospital is most desirable, and forms the best basis for acquiring the specialty. It is painful to an educated man visiting the centres of medical education abroad, to see how little the younger students there from other countries know of what is well known at home, and much reproach is thereby brought on our own land and institutions.

The student of a specialty should learn all that is possible here before going abroad; otherwise his judgment is warped, and correct impressions and clear knowledge cannot be obtained. Many who have been special teachers here will verify the statement that those who return from studies abroad continually express surprise, on their return, that so much is known here, and the remark is often made that if they had appreciated the fact they would not have gone abroad for study. If two or three years are to be taken for the study of a specialty, a certain, if not considerable, portion of it can be far better spent here first, and then one is able to determine the true value of what may be seen and learned abroad. Space forbids entering further on this topic, on which much might be said, as it is a most important matter, bearing strongly on our subject.

When the future specialist has completed this portion of his preparation, what course should he pursue in regard to active practice? For many reasons it is important that he should attend first to general medical practice. This should be the backbone of his life, both for the purpose of remuneration until he can secure adequate special practice, and more especially in order to accustom himself to meet and treat patients, recognizing readily their various complaints and adapting himself to their different constitutions. He will soon enough get narrowed down to the little rut or track around which he must travel day after

day, and this early experience in general practice will be looked back upon with pleasure and profit as he plods in his beaten circle in after years.

For some reasons it is desirable for a young specialist to secure a class of patients in a dispensary other than those presenting the complaints he is to treat. Indeed, the best is a general class of digestive disorders, including rheumatism and the various unclassified diseases which are often grouped together. This will enable him to get a wider and a firmer grasp on general medicine. Also, if it were possible, later, to secure an appointment as attending physician to a hospital, it is wise and beneficial to take one devoted to general diseases, and it would be well if all specialists could have such appointments in general hospitals, as they would best serve them in keeping up their practical acquaintance with general medicine.

In regard to the matter of a specialist practicing general medicine later, in connection with his specialty, or confining his practice to the latter exclusively, a few words may be said. Although theoretically, as has been shown, this is highly advantageous and proper, there are certain practical objections to it which render the latter course, now generally pursued, necessary if not desirable. First, in the large cities there is quite sufficient work for a specialist to do without going outside of his special line. Those who really get into a good practice have often all that they can do, and many are quite exhausted with this work alone. Second, the hours which the consultant is required to be in his office are such that he cannot well attend to outside parties, however much he may desire. In the cities it is necessary to have early hours for the business gentlemen, and morning and noon hours for ladies, so that with critical cases it would not be right or proper to delay the visit until after office hours, which are often prolonged, say even until two o'clock or later. Third, there is always the danger of a specialist, by his success in a single disease, making such an impression that the patient wishes his care on all occasions, and thus he may readily alienate from their regular attendants individuals who have perhaps, been referred to him in his special branch. This is an experience which every specialist has had more than once, and one is urged continually to do this by enthusiastic patients. The only safe way, so as never to give offense to physicians or patients, is to avoid the acceptance of such patients for other diseases on any account whatever, and this is made the easier if, after one has become established in special practice, he abandons all but such cases as legitimately come within his special province.

Thus, we see, the specialist should properly grow out of the general practitioner, either following throughout some previously determined course, or shaping his practice as circumstances and experience seem to direct.

We come now to our final topic, namely:

7. The future of medical specialism. Many medical men view the comparatively recent growth of specialties with more or less alarm, and fear lest, with specialists for every organ of the body and class of disease, there will soon be nothing for the

general practitioner to do, and on this ground some have opposed specialists and have failed to seek their aid, even in proper cases. This fear is quite natural, for, verily, if every case should be turned over to the various "ologists" who might possibly claim it, the family physician would indeed become but a distributor of patients without aiding his own pocket or reputation.

But, like every other principle in political economy, this one will solve itself on the basis of supply and demand. If the public want better treatment in difficult cases than they have had, and if they are willing to pay for it, it will surely be forthcoming somewhere or in some way—so that the tendency to specialism in medicine cannot be arrested, even if it were so desired. In the law the patent office lawyer gets the difficult and doubtful cases, and the celebrated criminal lawyer is retained where his services are most needed.

But there is a solution of the difficulty which is rapidly working itself out, and which daily becomes more and more apparent. By the multiplication of colleges, post-graduate courses and clinics, and by the great increase of periodical literature and of books, these very specialists are doing all in their power to enlighten the medical profession, present and future, not only as to what has been already learned, but what they are daily learning from their extended experience. They are daily, at great pains, giving to the medical profession the most careful and particular instruction, not only as to the grosser matters in their several branches, but also the more minute and special points in diagnosis and practice; they are, in fact, giving away their most precious truths, points of practice, secrets even, they are publishing widecast all that they use in their successful practice. An outsider would exclaim, that seems incredible, and yet it is a fact, and who can deny it?

Now, what is the solution of the question? Simply this, the coming medical man will be educated not only in all that his predecessors knew, but he will acquire such an additional knowledge of the various special diseases to which the body is subject, that he will be able to treat successfully a large share of the ordinary cases. No specialist now claims that all cases coming under his branch should come to him, but he seeks continually to enlighten others so that they can manage them, and he rather delights in the more difficult and obscure cases. And such must always exist, and the student of the special branch will come in to aid where the skill of the general practitioner naturally fails.

Who then is to blame at the present time if the specialist succeeds in curing cases where others have failed to give relief? Who is to blame if other similar cases come to him on the recommendation of those who are cured? Shall he refuse to give relief when asked?

The thoroughly educated and properly qualified specialist, then, has and will ever have his functions to perform in the great field of the science and practice of medicine, and his powers for good will increase, and his field of usefulness enlarge, with the

advancing world of science, and the broadening and deepening of the stream of knowledge. What a necessity, therefore, that the formation of this class of practitioners should be most zealously guarded in the future; what need is there that their general education by collegiate instruction should be strongly and well accomplished, and that their general medical education and practical knowledge of the entire science and art of medicine should be most completely and carefully planned and carried out to the letter.

It is recognized and acknowledged with regret that there are those who have entered special practice without the full and proper training here described, and that the tendency of imperfect specialism is to narrowness of mind and even to charlatanry. But is the evil much greater here than that which yearly takes place in the indecent thrusting forth by the many medical colleges of the hosts of imperfectly prepared doctors of all sorts upon the community? Surely the American Academy of Medicine has a great and noble work to do in boldly attempting to stem this tide of evil.

There are certain questions of etiquette in connection with the matter of the relations of specialties to the medical profession which it might be well to consider, did time permit; but this paper has already exceeded the limits intended, and their consideration must be deferred.

In conclusion, the matters here presented may be briefly summed up as follows:

1. The science and practice of medicine has, in company with other sciences, become so vast that no one mind is capable of fully grasping every portion of it.
2. Unconsciously its various departments have become divided up, and from natural causes certain men have become prominent in various departments.
3. These so-called specialties in medicine are so great and extensive each, that particular or exclusive attention is now devoted to them, the study and practice in each branch being sufficient to fully occupy one's time.
4. The development of these branches has greatly increased the scope and extent of medical knowledge.
5. Every medical practitioner should be more or less of a specialist, excelling in some particular direction.
6. To properly follow and develop one of these specialties, the medical man should be particularly well educated, theoretically and practically, in general medicine as well as in his special branch.
7. This tendency to specialism in medicine cannot be arrested; but the difficulty tends to solve itself, by the education of practitioners and students in these specialties, so that the majority of simpler cases shall be treated by them, while the more difficult and obscure cases will naturally fall to the specialist who refuses to treat other diseases and confines himself to the practice of a single branch.

ADDITIONAL POINTS IN THE USE OF COCAINE MURIATE.

BY W. W. SEELY, M.D., CINCINNATI, O.

The extreme scarcity of the new anæsthetic, *cocaine muriate*, has rendered it clinically impossible for any of our observers to test its advantages and disadvantages in all directions, and hence contributions from different sources are needed to complete its history.

I have had a supply from three different sources—Foucar, of New York; Parke, Davis & Co., and Wilfert, of Cincinnati.

That the drug thoroughly and completely anæsthetizes the conjunctiva and cornea, needs no further mention. In fact, I think it might be affirmed that it will anæsthetize any part it comes in contact with that will rapidly absorb it—a mucous membrane in any locality, and the broken skin, and such parts as it can be brought into contact with by the hypodermic needle, as witness the case reported by Carmalt, of New Haven, in the last number of the *JOURNAL*.

The smarting and burning of small abrasions and cuts are set aside by the cocaine in about a minute, as I have had occasion to both witness and experience. In regard to the new points I have to offer, I will state:

1st. That the effects of the drug seem to be more rapid and persistent, and are produced by a smaller amount, in the normal state of the parts than in the morbid.

This point I deduce from some cases of corneal and conjunctival inflammation experimented upon, and in a specially carefully tested case of bad superficial excoriation of the cornea as result of a burn, and in which lead wash had been used by some one. It was almost impossible to more than render pricking of the cornea tolerable, while in three other cases of my own and one by Dr. Tangemann, my assistant, the corneal opacities could be tattooed with almost no pain, if the remedy was put in every few moments.

2d. The necessity of using the drug during the operation, as its effects seem to be neutralized by the manipulations.

This would seem to have been demonstrated by the tattooing cases.

3d. As fresh surfaces are exposed, more of the drug must be used, and a few minutes must be given for its absorption, as for example in the operation for strabismus. If care is taken to instil the solution into the wound repeatedly, the operation can be robbed of about all its pain, as I have demonstrated in two cases.

It would be fair to conclude from the above that enucleation might be done with very little pain, if sufficient time is taken for the medicine to act, constantly instilling it into the wound.

4th. That the sensibility of the iris can be, to some degree at least, diminished.

From my personal experience in three iridectomies, two being made as part of the Graefe cataract opera-

tion, the other for artificial pupil, I could not say that all sensibility of the iris can be set aside. It must be borne in mind that a large portion of old persons will not complain at all of any of the steps of a cataract operation, hence it will require a large number of observations to settle this point.

In my iridectomy case, after the corneal incision, I repeatedly allowed not only a two but a four per cent. solution to enter the eye by making the wound gape and waiting ten to twelve minutes, even though the conjunctival and corneal sensibility had been gone for ten minutes before instilling into the wound, and yet the patient complained that pulling the iris gave pain. In the four cataract cases I have used it in, two were iridectomised and two not, and the operations were all absolutely painless. (I refer the reader to the statement made above in regard to extractions in old people.)

There seems to be no doubt about the drug acting as a contractor of blood-vessels. It is also feebly mydriatic in its action—the mydriasis in extreme cases lasting thirty hours. So far I have failed to find any case in which its near point was influenced, showing a paresing effect on the ciliary muscle, though, since we can scarcely have mydriasis without some paresis of accommodation, further investigations will probably show that the drug extends its influence to this muscle. The practical point in this connection is that neither the mydriasis nor paresis of accommodation are sufficient to incommode the patient. Temporarily at least the new anæsthetic has a controlling influence over pain in the eye, arising through various morbid conditions, but in how far it may be applicable in the various painful inflammations cannot be determined till it is produced in greater quantities and the price so reduced as not to render it prohibitive. Certainly if it will pass through to the iris at all—and its mydriatic effects show that it does to some degree—it should be of service in iritis. Its various properties, acting as it does as a contractor of blood-vessels, as dilator of the pupil, and as a reliever of pain, represent our ideas of a typical mydriatic, but unfortunately the fundamental property of a typical mydriatic is lacking in it, viz.: power and persistency. I have found in two or three well-marked instances that if used after the full effects of eserine have set in, it quite sets aside the pain.

In aural practice it serves a valuable purpose in passing the catheter through such nostrils as are extremely sensitive, and for reducing the sensibility of the membrani tympani and mucous membrane where perforation exists and fungous growths are to be removed or treated.

Even though the enthusiasm excited by the drug should have led us to see results not borne out by extensive use of it, and have excited expectations not to be realized, still, to be able to render painless the painful operations on the conjunctiva and cornea, to rob the various steps of lachrymal operations of a large part of their pain, to render strabismus operations bearable, must be recognized as the great ophthalmic advance of recent years.

S. E. Cor. 4th and Broadway, Cin., O., Dec. 1.

MEDICAL PROGRESS.

MATERIA MEDICA AND THERAPEUTICS.

SUNSTROKE TREATED BY RECTAL INJECTION OF IPECACUANHA.—Dr. Jos. Bancroft (*Australian Medical Gazette*), finding it difficult to administer medicines by the mouth in cases of sunstroke, as they may be drawn into the wind-pipe, and observing that cases which vomited made better recoveries than others, tried emetics, and found it easy to bring about vomiting by injecting ipecacuanha into the rectum. This he does by as soon as possible injecting into the bowels a drachm of ipecacuanha rubbed up in two ounces of water. After the injection he removes the whole of the dress from the chest and abdomen and irrigates the surface with iced water in a watering-can so long as the temperature seems to require it; but, though the skin may be cooled, the thermometer will frequently indicate a body-heat of from 105° to 108° . Vomiting generally takes place within half an hour, and it is astonishing what a quantity of fluid is at times rejected.

MALT EXTRACTS AS FOOD.—Dr. J. Milner Fothergill (*Practitioner*) writes very encouragingly of the influence of malt extracts as food. Their use is the direct outcome of the practical aspect of chemical knowledge in its bearing upon clinical medicine. The chemist observed that in the process of malting the starch of the barley underwent precisely the same change as does starch in the human mouth, viz.: a conversion of the starch into a grape-sugar under the action of a ferment (diastase). The identity of the change led to the utilization of the diastase of cereals for the needs of human infants where the digestion of starch is defective. Hence the numerous malt extracts now on the market.

By admixture with farinaceous food before being eaten, or by being taken practically simultaneously with such food, or before the stomach has become distinctly acid in the digestive act, malt extracts have been found highly useful in the conversion of the starch into grape-sugar.

In the malting process the starch of the grain is more or less converted into grape-sugar; probably some is converted into maltose, while some is less completely acted upon, but is put forward some way toward grape-sugar. In addition, however, to this amyloid metamorphosis, the albuminoids of the grain, and the mineral salts thereof, are retained in a soluble and highly digestible form in malt extracts. As a consequence, malt extracts form a most useful food where the digestion is gravely impaired, whether in infants or in adults. They constitute, indeed, a food of a highly nutritious character in small bulk, and therefore available when the stomach resents the presence of any bulk of food. He cites two cases to illustrate this, one of a middle-aged woman who was "wearing out by starvation," and had tried everything except malt extracts. She was ordered a teaspoonful of malt extract every hour, and lived *entirely* upon this for about two weeks, and then she was able to take other food in small quantity, and continued the malt

extract, feeling well satisfied with it at the end of six months of the treatment. In another case, one of cancer of the stomach, with contraction of that viscus to the size of a cricket ball apparently, and where all food was rejected more or less completely, the Cremor Hordeatus Soeflundii (cream deprived of much of its water and preserved by malt extract) was given in a small quantity, about the size of a filbert, every hour; the patient rallied, was much better, and three months later was still holding her own. Comparatively few stomachs rebel against its use.

In many cases where the digestive powers are very feeble, malt extract as a food requiring a minimum of the digestive act is very useful. It can either be taken alone or added to some warm milk. In such form it can be taken an hour, or an hour and a half, after a meal, in many cases with advantage. Especially when some food is required in the course of the night, this admixture of milk and malt extract is of service. It can be prepared at bedtime and kept near the bed in a hot water jug—the lid preventing any taint of the room—and be kept warm under a cover.

The many prepared foods for infants now sold are equally good for dyspeptics. They consist of flour which has been subjected to a high temperature. That is the main fact to remember. In its solubility in the digestive act there is all the world of difference betwixt raw uncooked flour, and flour which has been previously cooked, as prepared food, or baked flour. Such cereal matter can be added to milk, to beef tea, or made into puddings, with the greatest advantage. Farinaceous matters of this "baked" flour order are especially indicated where the digestion of starch is feeble, whether malt extracts be used therewith or not. By the combination of the two excellent results can be attained in cases of grave indigestion. Dr. Fothergill gives three illustrations in cases to support his views.

Mellins's food he looks upon as a most palatable preparation. Liebig's malted food extract is not nearly so toothsome. Malted foods differ from malt extracts in that the diastase is killed by the heat employed. As food they are about as good as malt extract; but they possess no diastasic power. Further, in cases where ordinary sugar undergoes acetous fermentation in the stomach, malt preparations are indicated; he quotes from Dr. Mitchell Bruce as saying, "Maltose is a form of sugar which does not ferment, and will not give rise to acidity and dyspepsia." Sugar, as a main source of fat, is indicated in all cases of emaciation, and in the sadly numerous cases where acidity is caused by ordinary sugar, in malt extract and malted preparations, we find a sugar of the highest utility in practice as not liable to acetous fermentation.

MEDICINE.

RENAL COMA.—Dr. Robert Laundly reports to the *Medical Times* an interesting and instructive case in which he calls particular attention to the subject of renal coma. The patient was a woman 20 years of age, anæmic, lancinating pains in the region of the spleen, bowels loose, three motions a day, vomiting;

twenty ounces of urine daily, which was highly albuminous, pus, no sugar. Was taken with a convulsion, lasting about five minutes, fourteen hours before death. This was followed by a semi-comatose state with the pulse 120 and respirations 24, deep and sighing. On auscultation the air could be heard entering freely into the thorax. She rallied somewhat after an injection into the veins of a solution of sulphate of soda, becoming conscious, but soon sank. At one time the respiration became noisy and she was slightly delirious. The urine, drawn on the day of her death, was reddish-brown in color, putrid, alkaline, $\frac{1}{3}$ column of pus, sp. gr. 1.011, gave a deep brown color with ferric chloride not diminished by heating. Albumen about $\frac{1}{3}$ column, no sugar. Microscopically there were present granular cells, squamous and pyriform epithelium, bacteria and blood corpuscles. In the post-mortem evidences the kidneys were the seat of the most pathological interest, the right kidney weighed only $1\frac{1}{4}$ ozs., pelvis dilated, medullary and cortical substances indistinguishable, measuring together only a quarter of an inch in breadth. In the left hypochondrium was a mass weighing 38 ounces of adhering duodenum, pancreas and descending colon—in which mass was a cavity the size of an orange, containing purulent fluid—inside this cyst wall was the left kidney, in a condition of sacculated dilatation. All normal kidney structure was absent. There were calculi in both kidneys, but both ureters were patent.

The peculiar interest which attaches to this case is that it presented striking analogies to that form of coma which Kussmaul described as occurring in diabetes, and which goes by his name. The characteristic symptoms of Kussmaul's coma is dyspnoea with free respiratory movements and unobstructed air passages. This has been accepted by Senator as a typical symptom. The other symptoms are rapid feeble pulse, epigastric pain; in this case the nurse said that just before the convulsions the patient complained of *pain in the stomach*, excitement, followed by coma. And lastly, a symptom to which much attention was at one time paid—the peculiar reddish-brown or Burgundy red reaction of the urine with the perchloride of iron. Kussmaul attributed these phenomena to intoxication by acetone, the urine reaction being held to indicate its presence. In a large number of experiments on animals and men, including persons suffering from diabetes, large doses of acetone and aceto-acetic acid have failed to produce any of the characteristic phenomena of this form of coma, although Penzoldt found that by retarding excretion through the lungs, intoxication, hebetude, and coma followed the introduction of large quantities of acetone into the circulation of rabbits, and he contends that when the lungs are disabled by any cause these results will follow. As regards this, Dr. S. Mackenzie found that pulmonary disease was absent, or only recent and slight, in fourteen out of nineteen cases of diabetic coma, while at Gray's Hospital, fourteen out of twenty-six cases of coma presented no visceral lesions whatever, and several cases dying with phthisis or pneumonia presented no coma.

The case related differs essentially from the classical type of uræmic coma in important details. Were there any features by which it might be distinguished from Kussmaul's coma? In the latter condition, convulsions are rare, but yet they do occur; the temperature is normal or subnormal, but so it is in uræmia, except after a convulsive attack. Lastly, the red coloration with ferric chloride did not disappear or diminish on heating. This is held to distinguish the reaction from that produced by salicylic or carbolic acid in the urine, but neither of these drugs were being used in any way about the patient. (Here, however, as a note indicates, any of the acetic, formic and sulpho-cyanogin compounds, which may occur in the urine, give this reaction).

We must, therefore, no longer regard this type of breathing as peculiar to the coma of diabetes, but as a phenomenon which may occur in connection with the terminal coma of a variety of conditions, of which the only connecting link is that there is profound disturbance of the nutrition of the tissues.

ALCOHOLIC PARALYSIS.—Prof. Charcot recently delivered a lecture on this subject at the Salpêtrière (*Gazette des Hôpitaux; Med. Times*). He gave to Magnus Huss the honor of having been the first to mention the existence of paralysis in chronic alcoholism. Lancereaux, in 1864, first described its form as resembling saturnine paralysis in the fact that the extensor muscles of the limbs were affected by preference; Leudet added to this that the paralysis was painful—affected the lower limbs, and most especially at night, with integrity of the spinal cord, and lesions of the peripheral nerves and of the muscles to which their diseased branches were distributed. Wilks and Lockhart Clarke, in 1872, noted a disease which they designated as alcoholic paraplegia, which was preceded by motor disturbances, and pains recurring in paroxysms, which the patient compared to electric shocks.

In regard to the etiology, the prior history must be sought for, as in the early periods it is very difficult to obtain an avowal, while, when the affection is constituted, it becomes associated with a certain mental condition. It is very improbable that one form of alcoholic drink rather than another will produce this effect. With that symptom of intoxication, the *nocturnal dreams*, with their nightmares and frightful visions, one of the first indications of this form of paralysis seems to consist in the appearance of *vivid pains*, which are especially felt in the lower extremities. These pains sometimes nearly resemble those which are met with in the first stage of locomotor ataxy, consisting in prickling formications, lancinating and true fulgurant pains which traverse the limbs. They soon become generalized, occupying *symmetrically* the two lower limbs by preference, and accompanied by cutaneous anæsthesia, they invade the upper extremities, and after a certain time, give place to analgesia. The sensation of cold, of heat, or of puncture is no longer felt in the limbs attacked, and contact with the ground is not perceived. It is then that motor paralysis supervenes, which is also symmetrical and affects the upper and lower extremi-

ties, especially the latter, influencing by preference certain groups of muscles, namely, the extensors. The patella-reflex is abolished. Alcohol always seems to respect the muscles of the face. There are marked vaso-motor phenomena in the diffused red or sometimes violaceous color, and the peri-malleolar doughiness which almost constantly exists, without the urine furnishing any satisfactory explanation. At other times there are local sweatings of the hands or feet which appear suddenly, and cease in the same manner, or there are alternating paleness and redness. Finally, at the end of a certain time, there are formed amidst these equine-shaped feet fibrous adhesions of the tendons and thickening of the connective tissue which surrounds the tibio-tarsal articulation, adhesions which render the restoration of the normal movements of the feet impossible. If these patients recover, a surgical operation will be necessary. The paralyzed muscles are softened and their electric excitability is notably diminished.

In regard to the mental state of these patients, it is the same with them as with the subjects of morphinism, they always, when in the early stages of their malady, still retain all their lucidity, and stoutly deny its etiology, while, when the paralysis is confirmed the memory is also lost. The progress of the paralysis is essentially chronic, the acute form being very rarely met with. Its course is progressive, and fatal if the drinking habits are not abandoned, or if the intoxication is already of too long a date. In a young man a paralysis of three months' duration disappeared under the influence of treatment by isolation, the suppression of alcohol, and hydro-therapeutics; but as he yielded to habits of drinking a relapse ensued. The diagnosis differentially in the early period from commencing locomotor ataxy is not easy. The subjects of diabetes and saturnism may also be the victims of alcoholism.

ANÆSTHESIA OF THE OPTIC NERVE.—M. Dianoux (*Bulletin de la Société Française d'Ophthalmologie; Med. Times*), finds this affection as occurring only in women, or in men who are, so far as their nervous system is concerned, women by nature. The onset is sudden, often during sleep, there are no premonitory symptoms, and there is no pain, though there is often a sense of a dull weight in the head. From the first the blindness is usually absolute, and may last an indefinite time; it rarely affects both eyes, the eyes are equally liable to be attacked. Examination of the eye yields absolutely negative results. It may undergo spontaneous cure, or it may persist for an indefinite time unmodified, or it may gradually pass into atrophy. The diagnosis is easy, the only difficulty which could arise is the weakened form of neuritis which betrays itself by a persistent discoloration of the disc. The prognosis is favorable, the cases that are most favorable are those of the longest standing where the blindness is absolute; if atrophy comes on, or if the onset is gradual, the outlook is not so good. Youth, a delicate constitution, a lymphatic temperament, uterine diseases, and hysteria constitute the best known predisposing causes. M. Dianoux regards anæsthesia of the optic nerve as

only a very slight form of the morbid process which leads to neuritis and atrophy of the disc after ischæmia. There is some circulatory disturbance followed by plastic exudation within the sheaths of the nerve, leading to a modification of the myelin which renders it a bad conductor. This exudation may be absorbed without any traces being left behind, or it may organize and compress the capillaries, leading to permanent discoloration of the disc; or if the exudation is more abundant, it may lead to œdema of the disc, and ultimately to organization of the new products "choking" the vessels and nerve fibres. By way of treatment he recommends tonics, quinine, iron, and cod liver oil, the hypodermic injection of strychnia locally, and the use of the continuous current; the uterine functions should be attended to.

CLITORIDIAN CRISES AND CRISES OF MUSCULAR FATIGUE IN THE ONSET OF LOCOMOTOR ATAXY.—Prof. Pitres, of Bordeaux, in the *Jour. de Med. de Bordeaux (Jour. de Med. et de Chir.)*, gives two interesting cases which illustrate the clitoridian crisis as first described by MM. Chuveot and Bouchard, in 1866. The first case was in a patient aged 48 years, where the disease made its appearance with relatively slight gastric crises. Twice a month, without any physical or psychical provocation, the patient felt a pleasurable sensation in the clitoris, which persisted, increasing in intensity, from a quarter of an hour to twenty minutes, and then terminated by a complete erotic spasm, with an abundant vulvo-vaginal secretion. This took place sometimes in the day, sometimes at night, and with no prodromata. The erection of the clitoris ceased soon after the ejaculation, and left behind no especial fatigue. The second patient was 32 years of age, and subject for some time to very acute pains in the head, which were taken to be neuralgic. With her, clitoridian crises were preceded by a violent beating of the heart; then the genital organs became the seat of voluptuous sensations, resembling those felt in coitus. The crisis terminated by an abundant vulvo-vaginal secretion, after which the patient remained exhausted for some minutes. These crises were reproduced four or five times a month for ten years, coming on indifferently by day or night, and unprovoked by any erotic ideas. They often attacked the patient while occupied with her household duties, or when sitting down. A year later the ataxy was definitely confirmed, and the clitoridian crises disappeared as the fulgurating pains became established in the lower limbs.

The crises of muscular fatigue have never been systematically described. Certain patients, at the onset of progressive muscular ataxy, complain of well-marked attacks of muscular fatigue, which occur suddenly, without appreciable cause, persist for several hours or days, and pass off without leaving any persistent fatigue behind. These attacks recur at variable intervals, day by day, week by week, or at longer periods. The pains which characterize them are not acute, lancinating, or shifting, like fulgurant pains. They consist in a painful sensation of lassitude and muscular fatigue, as if the patient had been subjected

to a too violent or prolonged physical exercise (fencing, riding, or swimming). This sensation has its seat in the muscles of the limbs or of the sacro-lumbar region. It is sometimes so severe as to compel energetic and vigorous subjects to lie down in the middle of the day, and to rest in the decubitus-dorsal position until the attack passes off. These crises may continue for many months or years, as the sole morbid symptom recognized by the patient. In the three cases cited by M. Pitres, they preceded the more positive signs of tabes, after the development of which they disappeared.

The practical application of the foregoing is that these crises are sufficiently marked and positive in their character as to allow of a diagnosis of progressive locomotor ataxy, in the absence even of any evidence of incoördination of movements.

ANILINE DYES.—Prof. Poincaré, of Nancy, gave to the Hygienic Congress at the Hague this year the results of his experimental researches upon the effects of the aniline colors (*L'Art Medical*). He found the following to be perfectly harmless; blue, yellow, orange, cachou, brown, Java indigo, sulpho-naphtholate of calcium, methyl blue, chrysomel, sulphonilic acid, naphthol eosine, rocelline, methyleosine, erythrosine, fluoreosine, sulpho-naphthol, and naphthionilic acid.

The following produced death: Saffron, Hoffman's violet, paratoluidine, acetanilide, violet, phthalic acid, picric acid, diphenylamine, orthotoluidine, naphthylamine, binitro-benzene, binitro-toluene, resorcinol, green.

Anthracene and ponceau gave serious disturbances, as also chrysoid, fuchsin, toluene and dimethylaniline—the latter of which sometimes produced death.

None of these substances produced the marked effect upon the temperature as described by writers. Among the non-toxic substances only one, sulphonilic acid, produced a lowering of the temperature. On the contrary, nearly all the toxic substances lowered the temperature curve, among the most marked of which were the acetanilide, violet, paratoluidine and Hoffman's violet. Emaciation was produced with but four of the non-toxic substances, and with them it was insignificant.

There was a marked analogy in the symptoms produced, the most constant of which were as follows:

(a) A great interference with movements, developing into a paresis, and even a more or less general paralysis. Paresis was absent in but two substances; orthotoluidine and toluene. The toluene produced an increase of activity in the muscular force.

(b) Convulsive tremblings most marked with ponceau, toluene and dimethylaniline.

(c) Coma, which was very marked with orthotoluidine, binitro-toluene and diphenylamine.

(d) Dyspnoea accompanied with tracheal râles with toluene and sapranine, and violent cough with Hoffman's violet and dimethylaniline.

(e) Irregularities in the heart beat, particularly with toluene.

(f) Anæsthesia which was only noticed with orthotoluidine.

Speaking generally the derivatives of toxic aniline have rarely altered in an appreciable manner the histological elements, and seem to have produced death by altering the composition of the blood and interfering with vascularization.

The principal practical conclusions are: 1. The use should be interdicted in the coloring of children's playthings, foods, wines and liquors, of such of these substances as are recognized above as toxic, particularly as they are very often combined with arsenic, lead or mercury. 2. These toxic substances may be tolerated in the coloring of tissues and papers, but on the condition that they are perfectly fixed. The rules which follow are for the guidance of workers in these dyes.

In the ensuing discussion M. Napias called attention to the activity of these dyes in a state of powder or dust, particularly *eosine*, the effects of which in workmen who manipulated this substance, he had noticed in the form of erythematous and papular eruptions, with irritations of the mucous membranes. Unfortunately those colors which are not toxic in themselves are made so by combination with lead.

M. Clonet, in confirming the preceding statements, had observed that these aniline colors were without bad effect when in a state of solution on account of the minute proportion of the coloring principle present, but when simply deposited upon the tissue and not fixed in the fibres of materials, they are absorbed in the powdered state. But, particularly regarding the action of fuchsin, he believed it to be innocuous if the aniline was pure. He, with some of his students, have taken up to 40 grammes in the course of a few days without producing any bad effects. In the case of one of his students where the urine was examined to determine if fuchsin was eliminated by the kidneys, the urine was found to be albuminous, but ceased to contain albumen on the fourth day of the experiment. A similar experience has resulted in the administration of this substance to hospital cases representing different forms of albuminuria. As to non-arsenical *grena*, it has been taken in larger doses than fuchsin by some of the students, with no other bad effect than vomiting, caused by the repugnance it provoked.

NAPHTHALINE IN DIARRHOEA AND CYSTITIS.—For the last three years Professor Rossbach, of Jena, (*Med. Press*) has employed naphthaline in all cases of diarrhoea that have come under his care. He concludes that it is of great service in all cases of chronic intestinal catarrh, with or without ulceration, attended by chronic diarrhoea, and in all cases the stools in the course of from five to fifteen days become of normal frequency and consistence. Some of the naphthaline given passes over into the urine, and the effect in the case of urinary trouble was noted to be exceedingly favorable. Pus, blood, and vibrios quickly disappear from the urine after its administration. It was given in doses of 2 to 3 gm. per day. After half a grain daily the appetite was often improved.

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 65 RANDOLPH STREET,
CHICAGO, ILLINOIS

SATURDAY, DECEMBER 13, 1884.

THE NEXT MEETING OF THE AMERICAN MEDICAL ASSOCIATION.—We hear from various sources intimations that a movement has been started to change the time of the meeting of the Association in New Orleans, which was appointed to commence on the last Tuesday in April next, to an earlier day. The reasons given for the proposed change are, that the International Cotton Exposition is to close on the 1st of May, only four days after the time appointed for the Association to meet, and that the last week in April is likely to be too warm for the comfort of the members. The first of these reasons is simply an error, as we are assured, on the very best authority, that the Exposition will not close until the first of June. We think, also, the apprehensions in regard to high temperature are without foundation. The Association held its meeting in New Orleans in 1869, commencing on the first Tuesday in May, one week later than the time appointed for the meeting next spring; and yet the weather was exceedingly pleasant and genial. We have nowhere spent a more comfortable week than in New Orleans during the first week in May, 1869. When at Washington the Association was invited by the profession of New Orleans to hold the next annual meeting in the latter city, the time agreed upon was that suggested by the representatives extending the invitation. And certainly no attempt should be made to change the time now, unless such change is asked for by the local Committee of Arrangements, on which devolves the duty of making all necessary provision for a profitable meeting of the Association. So far as we are informed, that com-

mittee desires no change in the time. On the contrary, its members would regard a change to the first week in April as very objectionable in every respect.

MEDIASTINAL TUMORS.—Tumors of the mediastina possess more of a pathological than of a clinical interest. This is particularly true of new growths which invade the heart either primarily or secondarily. Until the researches of Virchow declared their real nature, mediastinal tumors were regarded for the most part as being carcinomatous. It is now known, however, that in the majority of instances they are sarcomatous or lymphosarcomatous. Very rarely the heart may be the seat of both cancer and sarcoma, but tumors in this situation are generally secondary. So slight are the symptoms they sometimes occasion, that their presence is not even suspected and is only discovered *post-mortem*. In all cases, where the probability of their existence is entertained, a positive diagnosis is extremely difficult. As a matter of pathological interest, and to illustrate the impossibility many times of differentiating new growths from valvular or other organic disease of the heart, we give some facts communicated by P. Liborius to *Virchow's Archives*, 93, page 401, and recapitulated in *Centralblatt f. d. Med. Wiss.* Oct. 4, S. 702.

In the course of twelve years, 7,566 autopsies were made at the Marine Hospital of Kronstadt, and in but 31 cases were sarcomatous tumors discovered. Four of these implicated the heart and pericardium, as follows:

The first narrated by Dr. Liborius was the case of a vigorous, well-built sergeant of marines, aged 34 years. The first symptom referable to a mediastinal tumor was experienced seven months antecedent to his death, and consisted of a moderate pain in his left side and left arm. This pain disappeared after a few days. Three months later a physician discovered an impurity of his heart sounds. After the lapse of another month the man was seized with acute articular rheumatism which gradually subsided, leaving an obstinate cough behind. Upon his entrance into the hospital, five weeks prior to his death, he presented the following signs and symptoms: Dyspnoea, cough, cyanosis of the face and upper extremities; the cardiac impulse, in the fifth space, was weak, and the feeble heart sounds were accompanied by a systolic murmur; precordial dullness was increased transversely. Subsequently the *sputa* became bloody, dyspnoea increased; the cardiac dullness advanced to the left anterior axillary line, the left arm and lower extremities became oedematous, and the patient grew

delirious the day before his death. No diagnosis had been possible *intra vitam*. The necropsy revealed a teleangiectatic, round-celled sarcoma, as shown by the microscope, and having in places quite a luxuriant development of connective tissue. The tumor was almost as large as a man's head, and had its seat in the pericardium, by which it was nearly enveloped. Superiorly to the left, it had perforated the pericardium, to which at this point it was intimately adherent. The sac of the heart was implicated in the process to a considerable extent. The heart had been pushed to the right and compressed. Two small tumors were also found in the upper lobe of the left lung. Liborius thinks the growth originated in the pericardium, and not in the lymphatic glands nor loose areolar tissue of the mediastinum. This case is remarkable because of the almost entire absence of pressure and other signs, such as dilatation of veins, enlargement of lymphatics, etc. Circumscribed cedema was a late symptom. Indeed, the disease might easily have been mistaken for a valvular one, resulting from the acute inflammatory rheumatism. The extension of cardiac dullness to the left of the mammillary line was too rapid, we think, to be referred to dilatation of the left ventricle. It would be interesting and instructive to know the exact character and the point of maximum intensity of the systolic murmur. The case certainly carries an important lesson for diagnosticians.

In another man, thirty years of age, the autopsy revealed a myeloid sarcoma, twelve to thirteen ctm. in diameter, located in the posterior mediastinum. It had perforated the superior vena cava and likewise forced its way into the right auricle and right ventricle, having occasioned thrombosis of all veins emptying into the descending vena cava and of the right femoral vein. There were double hydrothorax, cedema pulmonum, and subcutaneous dropsy of the whole body.

In this case diagnosis must have been less difficult, since it is likely the tumor gave rise during life to a circumscribed area of dullness between the *scapule*. Cardiac murmurs probably existed and must have been interesting.

In a woman fifty years of age a spindle-celled sarcoma was found situated on the right auricle. It was as large as a man's fist; nodular, of firm consistence, and had eaten into the heart-muscle. The inner surface of the auricle was thickly studded with concretions of a nature not stated, some of them of the size of a pigeon's egg. Numerous secondary growths also existed. Here too, it would be instructive to

learn whether or not signs referable to the heart had been noticed in life.

In the fourth case, a woman seventy-six years of age, a round-celled sarcoma of considerable size existed in the posterior mediastinum, while the inner surface of the left half of the pericardium was closely studded with secondary growths, some of them as large as hazel-nuts. It is unfortunate that it is not stated whether or not in this instance the growths had given rise to pericarditis and pericardial friction sounds, since this result is said to be produced by carcinoma, not by sarcoma of the pericardium.

DR. ABRAM GROESBECK, one of the oldest and most honorable members of the profession in this city, died on the 24th of November, 1884, at the age of 74 years.

He had practiced medicine with fidelity and success half a century; was a well educated man, with all the qualities of a true gentleman, and highly esteemed by all who knew him. Appropriate notice of his death was taken at a recent meeting of the Chicago Medical Society, the proceedings of which we shall give in our next issue.

DR. J. G. THOMAS, of Savannah, Ga., a member of the General Committee on the Organization of the International Congress of 1887, who was taken severely sick before his arrival in Washington to attend the recent meeting of the Committee, died in the latter city on the 6th inst. A further notice will be given in the next issue of the JOURNAL.

DR. MAHOMED, formerly secretary of the general committee of the British Medical Association on the Collective Investigation of Disease, died in London, Nov. 22, 1884, of typhoid fever. Dr. Mahomed was an able and active worker in the profession, and his death will be greatly regretted on both sides of the Atlantic.

INTERNATIONAL MEDICAL CONGRESS.—The official proceedings of the first meeting of the General Committee on the Organization of the International Medical Congress for 1887, will be found under the head of miscellaneous matter in the present number of the JOURNAL.

MISPLACED.—In the Paris letter, published in the JOURNAL for Nov. 6, 1884, two lines that belong at the bottom of the second column of page 530 the printer has placed at the bottom of the first column of page 531; a dislocation which is well calculated to puzzle the reader.

SOCIETY PROCEEDINGS.

REPORT OF PROCEEDINGS OF THE ILLINOIS STATE BOARD OF HEALTH.

QUARTERLY MEETING, NOV. 20-21, 1884.

The regular quarterly meeting of the State Board of Health of the State of Illinois was held in the rooms of the Board in the Capitol building at Springfield, Nov. 20-21, 1884.

Present, the Hon. Newton Bateman, President of the Board, and Drs. Clark, MacKenzie, Kreider and Rauch.

After the reading and approval of the minutes of the last meeting the Board went into executive session, for the consideration of charges against certain practitioners under the Medical Practice Act.

At the evening session the Secretary presented the following

QUARTERLY REPORT.

During the quarter ended Sept. 30, 1884, there were received in the Secretary's office 1,623 communications, letters, reports, etc., and 3,472 letters, postals and other written communications were sent out. Of printed matter there were distributed 2,689 copies of the Fifth Annual Report and upwards of 200,000 copies of other printed matter—the mail and express packages sent out during the quarter aggregating 8,982 pounds' weight, or over four tons.

Among the more important written and printed documents distributed were those concerning the vaccination of school children, sent to about 12,000 school districts, through the County Superintendents:

Concerning the Sanitary Inspection of Public Buildings—especially of Almshouses, Jails and similar institutions—sent to County Commissioners, Boards of Supervisors and other officers:

Concerning the Sanitation of Railway Buildings, Grounds and Travel, sent to the General officers of thirty-three Railway Companies operating in this State:

Concerning Preventable Diseases, sent to localities in which Small-Pox, Scarlet Fever, Diphtheria or Typhoid Fever appeared.

In connection with these latter circulars, the blanks for Reports of Epidemic Diseases have been revised, and a new edition has been partly printed, together with a circular of instructions for their use.

A pamphlet of 51 octavo pages has also been prepared, printed and distributed, containing the Public Health Laws of Illinois; the Form of an Ordinance for the Protection of the Public Health, suggested for adoption by communities which have no health organization, and for substitution for existing health ordinances which have been found defective or inoperative; Rules and Regulations concerning Contagious Diseases; concerning vaccination; concerning the Sanitation of smaller Cities and Towns; and concerning the Principles and Practice of General Sanitation.

MEDICAL PRACTICE.

State certificates, entitling to practice medicine and surgery in Illinois, were issued to 105 graduates, 88 of which were granted unconditionally upon the diplomas of medical colleges in good standing; 6 upon examination in omitted branches, to graduates of colleges which had not fully complied with the schedule of minimum requirements of the Board; and 11 upon presentation of evidence of proper preliminary education, to graduates of colleges, otherwise in good standing, but which had not yet enacted a matriculation examination at the beginning of the session of 1883-84. There were also issued 8 duplicate certificates upon affidavits of the loss or destruction of the originals, and one certificate based upon length of practice in the State.

To midwives 6 certificates have been issued upon the diplomas or licenses of recognized schools of midwifery, and 3 upon satisfactory examination.

QUACKS AND DISREPUTABLES.

With the exception of those in Chicago, the fraudulent advertising quacks and disreputable specialists seem to have been pretty well weeded out of the State. For the first time since the passage of the Medical Practice Act there have been no complaints received concerning this class, except as above indicated.

After repeated attempts a grand jury was at last found which indicted eleven of the more prominent of those in Chicago during the month of July, but thus far none of the number has been convicted.

The noted quack, R. C. Flower, of Boston, Mass., has finally abandoned his efforts to secure a foothold in Chicago. By means of insidious and plausibly-worded advertisements, frequently of over a column in length, he succeeded in doing quite a thriving business for a time, and charged the most exorbitant fees. Unable to comply with the law and obtain a State certificate, and being refused an itinerant license, he was compelled to make appointments with his patients at Michigan City, in Indiana, and at Davenport, in Iowa, only venturing to stay in the State for a day or two at a time, and leaving before his arrest could be effected. Some of his dupes and victims have lodged complaint against him, and are now anxious to secure his arrest and punishment.

The suit of Frank B. Smith, one of the "K. and K. Surgeons," against the Secretary of the Board, for \$50,000 damages, alleged to have been sustained by the revocation of his certificate by the Board on charges of unprofessional and dishonorable conduct, and which suit was brought at Detroit, Mich., in the United States District Court, has been dismissed, and the plaintiff mulct in costs.

THE PUBLIC HEALTH.

Small-pox, noted as existing in isolated localities in the southern portion of the State at the date of the last report, was practically extinct at the close of the quarter, with the exception of a few cases in Marshall county, the contagion of which was introduced from Indiana. Reports of a serious epidemic of the disease in Ballard county, Ky., threatening Cairo and the line of the Illinois Central Railroad, led me to

visit the locality early in August, after communicating with the Secretary of the Kentucky State Board of Health. The precautions necessary to protect the threatened region of our own State were instituted, and these were efficiently supplemented by the action of the management of the Illinois Central, under the direction of the Superintending Surgeon, Dr. John E. Owens.

Notwithstanding the freedom of the State from this disease at the present time, and its subsidence abroad, the necessity for vaccination and re-vaccination in all localities where there are still unprotected individuals is likely to become apparent upon the approach of cold weather; and it is incumbent upon local health authorities to secure the fullest protection in season.

There has been a diminution in the prevalence of scarlet fever during the quarter, but toward its close there is noted an increase of diphtheria and of typhoid fever. The demand for the Preventable Disease circulars of the Board has, in consequence, been much greater than usual, and that on diphtheria has been reprinted, in part or whole, by many newspapers.

In response to a telegram from Dr. Salmon, the Veterinary Expert of the Department of Agriculture at Washington, I went to Peoria on the night of the 17th of August, and on the following day examined some cattle suspected of being infected with pleuropneumonia. The post-mortem examination of one of these animals confirmed the diagnosis, and since that date the disease has been detected in several other localities. Occasional cases continue to be reported, but the State Veterinarian believes the outbreak is in a fair way to be suppressed. The necessity for additional legislation on the subject of the contagious diseases of animals, already suggested from time to time in these reports, is emphasized by this outbreak.

SANITARY INSPECTION AND WORK.

The results of the efforts made in accordance with the instructions of the Board at the last quarterly meeting, to secure a general inspection and improvement of sanitary conditions, have been very gratifying. Reports from two hundred and thirty cities, towns and villages have thus far been received in reply to the circulars sent out, and an immense amount of work has already been accomplished in remedying the defects disclosed by the inspection. In many localities it is known that the reports are deferred until the completion of work already being pushed forward in anticipation of the advent of cholera next year.

I have personally inspected a number of State institutions, and find them in as good condition as could be expected, in view of obvious faulty construction or location, from a hygienic standpoint. Such suggestions of improvement as I have found it necessary to make, have been carried out as far as practicable.

Responses to the special circular concerning Railway Buildings, Grounds and Travel, have been received from sixteen companies, comprising the more important of all the roads operating in Illinois.

On the whole, there is cause for congratulation in the progress already made in this effort of the Board to secure the best attainable sanitary condition of the State as the most efficient and valuable mode of warding off the epidemic of Asiatic cholera.

It is to be wished, however, that the newspaper press, especially in the smaller cities and towns, would devote some of their space to articles urging the fundamental importance of individual sanitary effort. Without this, boards of health and health officers are, to a great extent, inadequate to cope with some of the more serious evils. A large portion of the community needs to be taught that personal cleanliness, and cleanliness of the household and premises, are among the highest results of sanitary science, and that, of themselves, they constitute the best safeguards against contagion and preventable disease.

RECOMMENDATIONS AND SUGGESTIONS.

The following recommendations and suggestions are respectfully submitted:

First—That a thorough sanitary survey of the State be inaugurated not later than the 1st of January, 1885, under the direction of the Board.

Second—That a committee of the Board be appointed to prepare revisions and amendments of the laws of the State regulating the practice of medicine, and concerning the protection of the public health. The defects of the statutes concerning both these subjects are patent, and should be remedied as speedily as practicable.

Third—That action be taken in anticipation of the forthcoming meeting of the National Conference of the State Board of Health, with reference to the subject of Asiatic cholera.

JOHN H. RAUCH, Secretary.

Upon the conclusion of the reading, on motion of Dr. Clark the report was accepted, the recommendations and suggestions were taken up for consideration, and the following action was had:

SANITARY SURVEY OF THE STATE.

Dr. Kreider submitted the following resolution, which was adopted:

Resolved, That the Secretary be authorized to prepare the necessary blanks and instructions, and to distribute the blanks to the proper authorities of counties, townships and municipalities, for a thorough and systematic sanitary survey of the State, to be begun by January 1, 1885, or as soon thereafter as practicable.

The Secretary explained that it was proposed to begin work in the southern portion of the State and to work northward as rapidly as the weather would permit, so that by the 1st of May, the sanitary condition of every dwelling, in all of its parts, of all premises, outhouses, wells, cisterns, and other belongings, should be made known, the remedy of defects be pushed, and the authority of the Board be exerted wherever necessary to supplement the efforts of local authorities in the preparation of the State to resist the threatened invasion of Asiatic cholera.

NATIONAL CONFERENCE ON ASIATIC CHOLERA,

With reference to the forthcoming meeting of the National Conference of State Boards of Health to be

held in the city of Washington, December 10th, prox., to consider the subject of Asiatic cholera, Dr. Clark offered the following preamble and resolutions which were adopted :

WHEREAS, The members of this Board, having carefully considered the able and exhaustive paper upon the Exclusion and Prevention of Asiatic Cholera in North America, prepared by the Secretary of the Board, find the argument set forth abundantly supported by incontestable facts duly cited in the text, and believe its conclusions and recommendations to be comprehensive, practical and sufficient ; and

WHEREAS, This subject is the most important of any which now demands the attention of those charged with the protection of the public health—involving as it does, the prevention of a great sacrifice of human life, of an immense money expenditure, and of serious and wide-spread injury to commerce, manufactures and all other industries—therefore, be it

Resolved, That a committee be appointed to draft a formal expression of the views of the State Board of Health of Illinois concerning the measures which should be adopted and enforced by municipalities, State and the National Government for the protection of the country against an invasion of Asiatic cholera.

Resolved, That the action of the National Conference of State Boards of Health, held at St. Louis, October 13-15, 1884, on the subject of Asiatic cholera be, and the same hereby is, approved and endorsed by this Board.

Resolved, That the Secretary of this Board be authorized to attend the forthcoming meeting of the National Conference in Washington, D. C., and present to said Conference the action of this Board as above indicated.

On the motion of Dr. MacKenzie, the Chair was authorized to appoint the committee, to consist of five members, including the President as Chairman of the committee. Drs. Haskell, Clark, MacKenzie, and Rauch, and the Hon. Newton Bateman were thereupon appointed as members of the committee.

REVISION OF THE LAWS.

On motion of Dr. Kreider, the President appointed a committee, consisting of Drs. Rauch, Haskell, Kreider, Clark and MacKenzie, to prepare revisions and amendments of the laws regulating the practice of medicine and concerning the public health, to be submitted to the next General Assembly.

During the executive session of the Board the case of Dr. Ed. S. McLeod, of Chicago, was considered. The following extract from the formal notification citing McLeod to appear before the Board, and show cause why his certificate should not be revoked for "unprofessional and dishonorable conduct" sufficiently explains this case :

"The charges against you are that you ply your vocation by means of fraudulent and deceptive advertisements, under assumed names, to-wit : under the alias of "Dr. James" and "Dr. Lucas ;" that in order to secure patients you hold out inducements

and promises and make suggestions which in themselves tend to promote crime and immorality ; that you publish and distribute, through the United States mails and otherwise, to all classes of the community, including the youth of both sexes, obscene circulars and pamphlets, for which you have already been once indicted in the United States District Court, at Chicago, when you pleaded guilty, were fined \$500 and costs, and your plates and circulars were seized and destroyed by the United States authorities : That such fraudulent, deceptive and demoralizing practices constitute "unprofessional and dishonorable conduct," within the meaning and intent of the statute, which was enacted for the protection of the people from the ignorant and unscrupulous under the guise of medical practice."

Upon mature deliberation and careful consideration of the evidence offered in support of the charges, the certificate of Dr. Ed. S. McLeod was ordered to be revoked.

After the transaction of the regular routine business, and auditing of accounts and bills amounting to \$2,876.55, the Board adjourned.

STATE MEDICINE.

STATE BOARD OF MEDICAL EXAMINERS FOR VIRGINIA.

To the Editor of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION:

The enactment of a law regulating the practice of medicine and surgery in Virginia was noticed in your columns some months ago. At the annual meeting of the Medical Society of Virginia in September last the names of two physicians from the State at large and three from each congressional district (thirty-two in all) were presented to the Governor, in accordance with the provisions of the law, and on Nov. 1 these gentlemen were duly commissioned as "Medical Examiners." In pursuance to the call of the Governor, the first meeting of these examiners was held on Saturday, Nov. 15, for the purpose of organizing and adopting some plan of examination.

It was deemed most important, in view of the number of examiners in the State, and the further fact that a candidate could select any three members of the Board whom he might prefer to conduct his examination, that some plan should be adopted which would make the examinations uniform. With this view a *blank form* for questions was adopted, which provides for six questions on chemistry, eight on anatomy, eight on physiology, four on hygiene, fifteen on materia medica and therapeutics, six on obstetrics, twenty on practice, and twenty on surgery. A clinical examination is also to be required when practicable. "Each examiner is required to ask a question for each number under each branch or subdivision, and to write out the question opposite the number ; the blanks thus filled out are to be forwarded to the President of the Board, along with the

written answers to the questions" (and such questions and answers are to be read out before the Board at the annual meeting). "The applicant is required to answer three-fourths of all the questions on each subject satisfactorily." All applicants for practice in the State of Virginia who have not taken out a license prior to Jan. 1, 1885, will be required to pass a satisfactory examination before the Board in session, or any three members thereof whom the applicant may select. The result of this examination is reported to the President, who, if the result be satisfactory, issues the applicant a license.

WM. C. DABNEY, M.D.

Charlottesville, Va., Nov. 20, 1884.

HEALTH IN MICHIGAN, NOVEMBER, 1884.

Reports to the State Board of Health, Lansing, by observers in different parts of the State, show the diseases which caused most sickness in Michigan during the month of November (4 weeks ending Nov. 29), 1884, as follows:

Diseases Arranged in Order of Greatest Prevalence.	Number of Weekly Reports Received, 172.		For Preceding Month.
	Per Cent. of Reports Stating Presence of Disease.	Per Cent. of Reports Stating Presence of Disease.	
Neuralgia.....	72	64	
Rheumatism.....	70	67	
Bronchitis.....	67	56	
Intermittent fever.....	60	72	
Consumption of lungs.....	58	60	
Tonsillitis.....	58	44	
Diarrhoea.....	46	75	
Remittent fever.....	44	52	
Influenza.....	42	37	
Typho-malarial fever.....	35	36	
Pneumonia.....	29	22	
Erysipelas.....	27	28	
Typhoid fever (Enteric).....	22	25	
Diphtheria.....	19	22	
Inflammation of bowels.....	19	22	
Scarlet fever.....	13	9	
Whooping-cough.....	13	16	
Cholera morbus.....	12	31	
Membranous croup.....	10	8	
Dysentery.....	10	44	
Cholera infantum.....	8	28	
Inflammation of brain.....	8	8	
Measles.....	6	6	
Puerperal fever.....	6	5	
Cerebro-spinal meningitis.....	4	7	
Inflammation of kidney.....	2	22	

For the month of November, 1884, compared with preceding month, the reports indicate that tonsillitis, bronchitis, neuralgia, and pneumonia increased, and that dysentery, diarrhoea, cholera infantum, inflammation of kidney, cholera morbus, intermittent fever, and remittent fever decreased in prevalence.

Compared with the average for the month of November in the six years, 1879-1884, diarrhoea was more prevalent, and diphtheria, intermittent fever, and consumption of lungs, were less prevalent in November, 1884.

For the month of November, 1884, compared with the average of corresponding months for the six years, 1879-1884, the temperature was slightly lower, the absolute humidity and the day and the night ozone were less, and the relative humidity was more,

Including reports by regular observers and others,

diphtheria was reported in Michigan in the month of November, 1884, at 40 places, namely: Adrian, Alton, Armada, Bloomingdale, Byron, Big Rapids, Constantine, Cooper, Decatur, Detroit, East Saginaw, Evangeline, Fruitland, Grand Rapids, Hastings, Howard City, Kalamazoo, Lansing, Leeland, London, Muskegon, Manistee, Mendon, Orange, Penconning, Portland, Port Huron, Portage, Pontiac, Romeo, Richmond, Smith's Creek, Schoolcraft, Vicksburg, Vernon, Vergennes, Vassar, Wyandotte, Warren, Watervliet. Scarlet fever at 22 places: Albion, Algonac, Armada, Brockway Center, Cadillac, Center Plains, Detroit, East Saginaw, Freesoil, Grand Rapids, Kalamazoo, Lansing, London, Manistee, Muskegon, North Muskegon, Pontiac, Portland, Roxand, St. Johns, Vassar, Vicksburg. Measles at six places: Detroit, Grand Rapids, Kalamazoo, Port Huron, St. Joseph, and Whitehall.

HENRY B. BAKER,

Secretary.

Lansing, Dec. 5, 1884.

FOREIGN CORRESPONDENCE.

BERLIN LETTER.

BERLIN, Nov. 18, 1884.

GYNÆCOLOGY.—Dr. Schroeder admits no one to his laparotomies without an especial invitation. The person invited is requested to bathe thoroughly before coming, and to wear a suit of clothes which has been aired, and which has not been in general use. I saw him make a gastro-hysterectomy at half-past seven on the morning of the 15th (most of the operative work is done here in the early morning). The operation lasted one hour and three-quarters, and varied in no essential particular from the routine which I have already described in the *American Journal of Obstetrics*. The actual cautery was used to the stump, and a 10 per cent. solution of carbolic acid was made use of. The stump was well protected by its flaps, so that there was no oozing, and it was then dropped into the cavity. The professor is most ably seconded by his first assistant, Dr. Hofmeir, who has already made a reputation as a clever operator. No drainage-tube was used. On the day previous I saw Dr. Schroeder amputate the cervix *very* high up, so high indeed that the operation was as severe as the suprapubic measure would have been for carcinoma. At one of the clinics a student was asked what treatment he advised in the case of a woman who had a tumor of the wall of the uterus near the ovary, and another higher up. He answered, "Extirpation." The professor said that he could not have given a more faulty answer—that change of life would relieve her in time, and one should operate only when hæmorrhage is dangerous, or when the woman herself urges the operation, stating that unless it is done she will be unable to earn her living. He has had *three* deaths from the intra-uterine injection of corrosive sublimate. The last one was only one litre of a 1-1000 solution. He says that he cannot believe with the

Americans, that extirpation of the uterus is a needless and dangerous operation. He has had only 25 per cent. of deaths in his cases, and if we do not extirpate, the woman will die anyway. Dr. Landau has given some exceptionally interesting clinics. He limits the number of medical men, so that each one has every facility for examining the cases and forming a diagnosis. Several cases of uterine hæmorrhage, just such instances as come up every day in the routine of the general practitioner, have been treated with uterine injections of *strong liq. ferri*.

In 500 cases Dr. Landau has never had but one case of uterine colic, resulting from these injections, and that occurred a short time ago when I was present. The woman was bleeding from what proved to be a small piece of retained placenta. The womb was curetted and injected. The bleeding still continuing another injection was made, and this was followed by colic. It was very amenable to treatment. Dr. Landau took this occasion to say that there was never any danger in dilating the canal when the woman was narcotized. He never uses intra-uterine injections of *ice-water*, because the effect is only temporary. He has frequently used hot water, but prefers *liq. ferri*. Dr. Martin injects water almost boiling into the uterus and then takes a stitch through the cervix to keep it in. Many cases of dislocated uteri were treated, and Dr. Landau impressed upon those present that in cases of retroversion, the uterus should be pressed to one side so as to clear the promontory of the sacrum, before it was carried up. Otherwise restoration would be impossible. He showed one case of great interest. He had operated upon a woman some years before for floating kidney containing a large abscess. There is still a fistula in the side from which urine escapes. She urinates also through the natural passages. This case is cited in his brochure, "*Die Wanderniere der Frauen*," which is the best work I know of on floating kidney. Dr. Gusserow's case of ovariectomy died within twenty-four hours. He has operated for laceration of perinæum for procidentia with partial prolapse of bladder and prolapse of vaginal walls, and has done some interesting work in the lying-in wards. He had one case of a woman with cancrroid uterus three months advanced in pregnancy.

EYE DISEASES.—Prof. Dr. Hirschberg lives and has his private hospital at 36 Karl street, where he lectures, operates, receives dispensary cases, etc. His operative hours are between 9 and 10 A.M., and only a few invited students are ever present. His public lecture is from 12 to 1, and here he has cases illustrative of his address. The poli-klinik between 1 and 3, corresponds to the dispensary service in New York. His private hours are from 3 to 4. Prof. Sweigger has his poli-klinik in Ziegel street. Both are popular, both have hosts of students. Dr. Schoeler has also a poli-klinik and gives an operative course, as does also Dr. Hertsman. Fraenkel gives an interesting *cursus* on the throat, and Leucæ on the ear. The latter lectures once a week, and is extremely practical and satisfactory.

MEDICINE.—Prof. Frerich's clinics in Charité are so crowded that one must go early to secure a seat.

Virchow says that he never makes a mistake. He makes a diagnosis rapidly, and his lectures are of the greatest possible interest. On the subject of erysipelas he said that he had used injections of carbolic acid, but with no good results, and until we shall know more of the disease we must govern our treatment by symptomatology. *Interstitial Hypertrophy* of the liver he said was always due to one of four causes: 1. Alcohol. 2. Syphilis. 3. Malaria. 4. Transmitted inflammation from the gall bladder.

Prof. Leyden said in one of his lectures on diphtheria, that the treatment may be divided into three heads: 1. The internal antiphlogistic (quine acid, of sodium, etc). 2. The nourishing (wine, egg, alcohol and milk). 3. Specific (corrosive sublimate, chlorate of potash, carbolic acid, and iron). He classed dropsies under three heads: 1. Those due to congestion. 2. Those due to Bright's disease. 3. Those due to cachexiæ.

SKIN DISEASES.—Dr. Laisar has his private hospital and poli-Klinik on Karl street, 19. He has students from all parts of the world, and as he speaks English and is very jovial he has many disciples among Americans. He showed me a photograph of a case molluscum-fibronem of a carcinomatous nature. His treatment of scabies is as follows: He has several private bath-rooms, conveniently arranged for all kinds of treatment. A tub of water is charged with a small amount of corrosive sublimate. The patient is stripped, rests quietly in the bath for ten minutes, being careful to keep all parts of the body covered with water. The nurse then washes him all over with green soap, washes it off, and then goes through the same process again. Then the entire body is covered by a paint brush with a preparation of the oil of cade in alcohol. This is washed off as far as possible with green soap, when the patient gets out of the bath, and is thoroughly dried. Then the entire body is covered with an ointment of naphthol, sulphur, green soap, and simple ointment, and the patient is told to dress, and to wear the same underclothes until termination of treatment. The latter application is extremely painful, and its effects must be carefully watched.

GENERAL MEDICAL NEWS.—Dr. August König is lecturing upon the color sense, and the effect which the combustion of various metals has upon pigmented paper. Sodium and barium in a Bunsen burner were thoroughly tested. He gave the reflection of various media. At an angle of 50° water reflects about 50 per cent. of light, at an angle of 90° it only reflects 2 per centum. Glass reflects 60 per cent. at an angle of 5° and only 20 per cent. at an angle of 90°. Metal reflects from 60 to 90 per cent. at all angles.

MEDICAL SOCIETIES.—At the meeting of the Medical Society on the evening of Nov. 12, Prof. Virchow was re-elected President, and Professors Küster, Fraenkel, Senator and Abraham were re-elected Secretaries. Dr. Falk was re-elected Librarian. The discussion on Diphtheria being resumed, Prof. Virchow said that he thought the difference between croup and diphtheria was one of symptoms, and not of membrane. He doubted if physicians

could always tell, in any given case, whether it fell under the head of the former disease or of the latter. He thought that stripping off the membrane was bad practice.

OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.—Held on Nov. 14, at the Woman's Hospital on Artillerie street, No. 13. Dr. Veit read a paper on "Tubal Pregnancy." Dr. Schröder, on "The Surgical Treatment of Pruritis Vulvæ," said that, of course, he did not intend urging it in every case. That when it depended upon irritating fluids or from parasites, operative interference was not demanded. But there were many cases which, if examined closely, would disclose little white swellings. If these are excised the pruritis disappears. He cited the following cases: 1. Upon close examination he found a small malignant growth of the clitoris. Surgical treatment cured the itching. Five years have now gone by, and the patient is still well. 2. Labia majora of left side hypertrophied. A part was excised, and the patient felt better. Shortly after the labia on the right side took on the same condition, and the same treatment was resorted to. The patient is now well. 3. Enlargement of labia minora; surgical treatment; cure. 4. Itching began at anus, extending up to mons veneris. The skin around the anus was thick and hardened from scratching. Small pieces were excised from around the anus, labia majora and mons veneris. The patient recovered entirely.

H. R. B.

BERLIN, Nov. 13.

MR. EDITOR:—The Royal Frederick William University is in full operation for its winter semester, and has more students than in former years. Quite a little excitement has just been produced by the appointment of Prof. Schweiniger as "Director of the section of skin diseases at the Royal Charité." He is Prince Bismarck's "Leibarzt," and on account of services rendered the Prince, the departments of Dermatology and Syphilis, previously held by Prof. Levin, have been separated. Some six or seven hundred students assembled about the building where Prof. Schweiniger was to have his first lecture, but he admitted only fifty, and much excitement prevailed.

N.

DOMESTIC CORRESPONDENCE.

OVARIOTOMY.

72 LAFAYETTE AVE., DETROIT, MICH., }
November 20, 1884. }

TO THE EDITOR:

Dear Sir:—As a kind of a sequel to the letter which I sent you a few days ago, as well as to other articles to which that letter was related, I beg leave to submit the following condensed statement of "*facts and figures*:"

Between January 1 and October 31, 1884, (10 months) I performed exactly twelve ovariectomies. Of these, *seven* were performed in public amphi-

theatres, namely: *four* at Ann Arbor before at least 400 students and medical men, and *three* at Harper Hospital, in this city, before promiscuous gatherings of students and medical men. Of the four done at Ann Arbor *one* was a frail old lady of 68. The tumor weighed over forty-five pounds; there were many adhesions; the peritoneal cavity was open for fifty-five minutes; many ligatures were tied, and much sponging was required. She was dismissed cured in two weeks from the day of operation. *One* was a young, vigorous and hopeful patient, a married woman seven months pregnant. The great and rapidly increasing size of the tumor, from which she suffered intensely, demanded immediate operation. The operation was an easy and rapid one—the peritoneal wound was stitched up in less than fifteen minutes. Unfortunately, however, in spite of every possible precaution labor supervened within a few hours of the operation, and under the additional strain of the miscarriage the patient sank and died in about twenty-four hours. In this, as in all the cases, the anæsthetic was administered before the patient was carried to the amphitheatre. I am quite sure that in all your long list of readers, there is not more than one who is so destitute of reason as to suppose, or pretend to suppose, that the place and surroundings in which this operation was performed could or should be held responsible for the catastrophe.

When the patient awoke from the anæsthetic she found herself in a very quiet and comfortable private room, with which she was entirely satisfied, and where every attention was paid her and every precaution taken to ensure her safety.

The *third* was a large but uncomplicated tumor in a comparatively young and healthy woman. The peritoneal cavity was open less than eight minutes by the watch. She left for her home at Three Rivers two weeks from the date of operation.

The *fourth* was a case impossible to diagnose accurately before operation, and, in fact, pretty difficult to make out, even after the abdominal cavity was opened. The patient was a married woman, 24 years old, with a baby ten months old. But for her abdominal tumor, she was in very fair health.

The history of her tumor was very indefinite and unsatisfactory, but I must not dwell on that at this time. Suffice it to say here that I found the left kidney and both ovaries cystic, and I removed them, along with much of the omentum, which was adherent to the large cystic kidney. The operation lasted more than thirty minutes; many ligatures and much sponging were necessary. This patient is still in hospital, and is to all appearance completely convalescent, and in a few days will be *dismissed cured*. The three cases operated upon at Harper Hospital, Detroit, were done on June 24, July 3, and July 14, respectively. One of these was a very feeble lady, upwards of fifty years of age, who had been in delicate health for a number of years. Within three weeks after her operation she returned to her home in Rome, N. Y., cured, at least, of her ovarian disease. The other two were younger women, but both of them were very bad cases. My professional brethren who witnessed the operations unanimously declared that

they were such cases as an operator would be justified in refusing to interfere with. Both of them recovered, although one of them spent eight weeks in the hospital. In both of these cases, the peritoneal cavity was during the operation, flooded with cyst fluids. But over and above these seven cases operated upon in public amphitheatres, I have five to record which were done in "cottages by the wayside," or at least at the homes of the patients.

Of these two were done on Jan. 17, in the city of Kalamazoo. Of these two one was a very simple and favorable case in a young lady of eighteen. The other was a very different kind of a case. The patient was a married woman aged 44; her tumor was very large, multilocular and extensively adherent. The patient was greatly emaciated, her strength was nearly exhausted and her spirits entirely so; her feet and legs were much swollen, her digestive organs greatly debilitated and irritated, and she used morphia to the extent of eight to ten grains daily. Last but not least, her home and surroundings were just about the exact reverse of what they ought to have been from a surgical standpoint. Both of these cases recovered with most gratifying rapidity. Of the three remaining cases one was done Aug. 29, at Midland City; the patient was about sixty years old and rather frail, her tumor was large and growing rapidly. The operation was a long and tedious one, owing to the presence of a mass of adhesion which resembled an enormous diaphragm which bound the tumor to the right side of the abdominal as well as the pelvic wall. It was short, very thick and extremely vascular. I took the utmost pains to guard against hæmorrhage from this peculiar structure, but there seems reason to suspect that in this I was not entirely successful.

At any rate, for twenty-four hours all went well, temperature about normal; pulse 100. No pain and no nausea,—in short, no bad symptom of any kind; but at the end of that time rapid and painless sinking supervened and she died. No post-mortem could be had, and therefore the precise cause of death is matter of surmise. Her home was a very quiet and comfortable one, and she had every possible advantage in the way of nursing and medical attendance after her operation. Two of the dozen cases still remain to be described. Of these one occurred at the village of Otisville, Mich., Oct. 16.

This patient was a married woman sixty-three years old, who had been tapped several times. She was nearly worn out mentally as well as physically. Her lower extremities were much swollen. Her tumor was very large. It weighed nearly forty-five pounds and several of the largest cysts were filled with pus and other inflammatory products.

The peritoneal cavity was open for nearly an hour. I had not enjoyed the privilege of seeing this case before the day of operation, and then my time was limited to two hours. I have not seen her since, but have the authority of her medical attendant, Dr. J. B. Laing, of Otisville, that she is now in good health. As to the surroundings of this patient, I can sum the matter up in a word: *They were in all respects as unfavorable as it is possible to imagine.*

The last of this dozen cases occurred at Manchester, Mich., on Oct. 31. The patient was a married woman, æt. 39. She had been exposed to extreme hardships for a year or two, to which she attributed the inception of her tumor.

The latter had grown within a year. She had been tapped several times. She was nearly exhausted, but still hopeful and determined upon having an operation. I never saw this patient until the day of operation and I have not seen her since. When I did see her she was "*a sight to behold*," so great was her abdominal enlargement. She measured seventy-three inches in circumference and she was unable to stand on her feet, or to lie on her back, or to turn over in bed.

Her surroundings were in all respects, if possible, worse than those of the preceding case. To have removed her, however, to any better place was, by the time I saw her, a physical impossibility even if she could have been induced to consent, which I don't think she could. The tumor with its contained semi-solid material, together with the ascitic fluid present, weighed *one hundred and three pounds*. She made a perfect and rapid recovery.

To recapitulate: In the current year up to October 31, twelve women have petitioned me to relieve them of ovarian tumors, and to do so, I had to operate either in the public clinic or at their own homes. *In every case I have consented. I have refused no one.* Of these twelve cases, seven were done in public amphitheatres, with six recoveries and one death, while five were done in their own homes, with four recoveries and one death.

No doubt a more skillful operator might have saved these two patients. *Possibly (but in my opinion not probably)* more favorable surroundings might have made all the difference. If it had been in my power I would most gladly have availed myself of the advantages of an "ideal" hospital; not only so, but I would gladly have procured for these poor women the services of a more skillful and better equipped surgeon. Unfortunately, neither of these very desirable advantages were within the reach of my patients. I had no choice but to operate myself, and when I did, I did the best I could under the circumstances, and I succeeded in saving *ten out of twelve of them*. My conscience tells me that I did what was right in the premises, and my common sense tells me that no more cruel and cold-blooded doctrine has ever been promulgated in the name of science than the one which would have compelled me to say to these poor suffering women, "You must die in your misery, lest my rate of mortality as an ovariologist might be increased."

Yours, etc.,

DONALD MACLEAN.

A NEW RECTAL SPECULUM.

BY O. ONEAL, M.D., WABASH, IND.

Finding the ordinary anal speculum so unsatisfactory, I have devised the one here represented, and which I find to admirably meet the objects I had in view. The blades are three and three-quarter inches

long, and can be dilated at the points by means of the screw. When closed, the instrument is round the entire length, the diameter at the outlet is one inch. Each blade has a slot three-fifths of an inch wide, and two and three-quarter inches long. These are closed by perfect fitting slides.

It is introduced closed, then by withdrawing one slide at a time the walls of the lower part of the rectum can be inspected. Wishing to examine higher up you can do so by means of the screw. This dilates the points of the blades, while the outlet

remains about the same. The advantage claimed for this speculum is that the smallest part of the mucous membrane can be exposed to the exclusion of all other parts. Wishing to operate upon a certain hæmorrhoidal tumor or an ulcer, the speculum is introduced so that one of the slides is directly over the tumor or ulcer, the slide is then withdrawn sufficiently to expose the part to be operated upon. All other parts are excluded.

In the injection of hæmorrhoids it is especially useful. After locating the tumor to be operated upon, the instrument is introduced with one slide over the part. Then slowly withdraw the slide until its end is about the centre of the tumor, and then introduce the hypodermic needle and inject the medicine. Then replace the slide and remove the speculum. The pain is much less than when they are injected while protruded and grasped by the sphincter.

The speculum is made and for sale by Tiemann & Co., New York.

BOOK REVIEWS.

TRANSACTIONS OF THE MICHIGAN STATE MEDICAL SOCIETY FOR THE YEAR 1884. Paper. 626 pages.

The proceedings of the Society present little that

is of general interest. The following extracts are from the publications:

Dr. Donald Maclean has in several cases successfully treated Colle's fracture according to the following principles: 1. That Colle's fracture is always complicated with severe sprain of the wrist joint. 2. That the fracture in the great majority of cases is easily reduced by forced extension of the hand on the forearm, thereby relaxing the tense posterior aponeurosis, and permitting of the lower fragment being pushed down into its natural relation to the upper fragment. 3. That when once replaced there is little, if any, tendency to redisplacement of this fracture. 4. That mechanical restraints, such as splints, are unnecessary, and therefore should not be used. 5. That the evil results which tend to flow from a bad sprain of the wrist are the chief dangers to be provided for in the after treatment. 6. This is best accomplished by constant passive movements, frictions, etc. The reader credits the above to a monograph by Dr. L. S. Pilcher.

According to Dr. Charles G. Lundy the advantages offered by the dry treatment of chronic suppurative otitis media seem to be: 1. The constant medication of the parts. 2. The continuous disinfection of the parts, and the destruction of micro-organisms. 3. The absorption of the discharges. 4. Protection from atmospheric influences.

In cases of prostatic hypertrophy and urinary obstruction Dr. A. B. Palmer recommended dilatation by hydrostatic pressure. It is effected thus: The urethra is compressed between the thumb and finger of the patient near the glands. It is then filled with urine, and by straining as in an attempt to forcibly empty the bladder the distension of the urethra is produced.

The distending pressure, if daily repeated at an early period of obstruction, will overcome this form of stricture effectually and without irritation.

Dr. Charles Shepard reports two cases of congenital absence of vagina and uterus where the health of the patient was improved and she was enabled to marry by the production of an artificial vagina.

This was accomplished by an incision between the labia and the separation of the cellular tissue between the rectum and bladder to the depth of four inches.

This opening was kept from occlusion by the use of a sound which was worn for several weeks. After recovery from the operation there was found to be a monthly discharge from the mucous membrane of these cavities.

C. E. W.

OSTEOTOMY AND OSTEOCLASIS FOR DEFORMITIES OF THE LOWER EXTREMITIES. By CHARLES T. POORE, M.D., Surgeon to St. Mary's Hospital for Children, New York, etc. New York: Appletons. 1884. Received from Jansen, McClurg & Co., Chicago. Pp. 187.

The need of established precepts is nowhere more felt at present than in the practice of the common operation of osteotomy. This book amounts to a treatise on the subject, and a full and complete one, though not as carefully compiled as could be desired.

The only other especial work on this subject in English with which it can be compared, is that of MacEwen, and to this it is much inferior in point of careful preparation and originality, but superior in being more recent. Some improvements which the author has devised in instruments and methods are of undoubted value, and he has been a constant worker in this field. The style of the work is forcible, because clear and exhaustive—nevertheless, it detracts from the merits of such a book to find in it minor blemishes and inaccuracies, of which a cursory reading will reveal a number.

As a sample of the unimportant but provoking inconsistencies which too often appear in carelessly written books, we quote two passages:

FROM P. 13.

"There was also at this time another revolution taking place in surgical practice, which has contributed more to its advance within the last ten years than any one circumstance, and this was the method of the treatment of wounds advocated by Mr. Lister. * * *

"That osteotomy has obtained its place as a safe and justifiable procedure, is due to the influence of Listerism."

FROM P. 19.

"With regard to Listerism, I am clearly of the opinion that it affords no additional safety, and I have long since abandoned it."

With the author's mental keenness, he could doubtless harmonize satisfactorily these two seemingly discordant opinions; but we submit that it is unkind to expect this of the average reader's intellect, for he omits to inform us at what stage of development the operator acquires such marvelous skill that he becomes independent of a method of procedure which only a short time before was the sole cause "that osteotomy had obtained its place as a safe and *justifiable* procedure." Herein lies a great mystery.

E. W. A.

TRANSACTIONS OF THE TEXAS STATE MEDICAL ASSOCIATION. Sixteenth Annual Session. Paper. Pp. 246.

The majority of the papers contributed to this publication are short and practical.

Dr. R. P. Talley has found the hypodermic use of bismutate of quinine and urea very beneficial, particularly in pernicious malarial fever. To avoid abscess he injects deeply, slowly emptying the syringe as the needle is withdrawn.

Dr. C. W. Trueheart reports an interesting case of the "reproduction of two and three-quarter inches of the clavicle in the human subject by grafting with periosteum and with thin laminæ of bone covered by its periosteum, taken from the dog."

One gentleman is considerably astonished at finding pediculi on the eyelids. This is a frequent source of wonder to careless students, and they are generally considerably disgusted when they find that this species is their old acquaintance *Pediculus pubis*.

C. E. W.

MISCELLANEOUS.

COMMITTEE ON ORGANIZATION OF THE NINTH INTERNATIONAL MEDICAL CONGRESS, TO BE HELD IN WASHINGTON, D. C., IN 1887.

PRELIMINARY NOTICE.

The Committee on Organization of the Ninth International Medical Congress, to be held in the United States in 1877, met in Washington, D. C., on November 29, 1884, for the determination of the general plan of the Congress, the election of Officers of the Committee, who will be nominated to fill the same offices in the Congress, and the consideration of questions of finance.

The following rules were adopted:

1. The Congress will be composed of members of the regular medical profession who shall have inscribed their names on the Register of the Congress, and shall have taken out their tickets of admission. As regards foreign members, the above conditions are the only ones which it seems, at present, expedient to impose.

The American members of the Congress shall be appointed by the American Medical Association, by regularly organized State and local medical societies, and also by such general organizations relating to special departments and purposes, as the American Academy of Medicine, the American Surgical Association, the American Gynæcological, Ophthalmological, Otological, Laryngological, Neurological, and Dermatological Societies, and the American Public Health Association; each of the foregoing Societies being entitled to appoint one delegate for every ten of their membership.

The members of all special and subordinate Committees, appointed by the General Committee, shall also be entitled to membership in the Congress, together with such other persons as may be specially designated by the Executive Committee.

All Societies entitled to representation are requested to elect their Delegates at their last regular meeting preceding the meeting of the Congress, and to furnish the Secretary-General with a certified list of the Delegates so appointed.

2. The work of the Congress is divided into eighteen Sections, as follows, viz:

1. Medical Education, Legislation and Registration, including methods of teaching and buildings, apparatus, etc., connected therewith.

- | | |
|-------------------------------|---|
| 2. Anatomy. | 12. Nervous Diseases and Psychiatry. |
| 3. Physiology. | 13. Laryngology. |
| 4. Pathology. | 14. Public and International Hygiene. |
| 5. Medicine. | 15. Collective Investigation, Nomenclature, and Vital Statistics. |
| 6. Surgery. | 16. Military and Naval Surgery and Medicine. |
| 7. Obstetrics. | 17. Experimental Therapeutics and Pharmacology. |
| 8. Gynæcology. | 18. Diseases of Children. |
| 9. Ophthalmology. | |
| 10. Otology. | |
| 11. Dermatology and Syphilis. | |

3. The General Meetings will be reserved for the transaction of the general business of the Congress

and for addresses or communications of scientific interest more general than those given in the Sections.

4. Questions which have been agreed upon for discussion in the Sections shall be introduced by members previously nominated by the Officers of the Section. The members who open discussions shall present a statement of the conclusions which they have formed as a basis for debate.

5. Notices of papers to be read in any one of the Sections, together with abstracts of the same, must be sent to the Secretary of that Section before April 30, 1887. These abstracts will be regarded as strictly confidential communications, and will not be published until the meeting of the Congress. Papers relating to questions not included in the list of subjects suggested by the Officers of the various Sections will be received. Any member, after April 30, wishing to bring forward a subject not upon the programme, must give notice of his intention to the Secretary-General at least twenty-one days before the opening of the Congress. The Officers of each Section shall decide as to the acceptance of any communication offered to their Section, and shall fix the time of its presentation. No communication will be received which has been already published or read before a Society.

6. All addresses and papers, read either at General Meetings or in the Sections, are to be immediately handed to the Secretaries. The Executive Committee, after the conclusion of the Congress, shall proceed with the publication of the Transactions, and shall have full power to decide which papers shall be published, and whether in whole or in part.

7. The official languages are English, French and German.

No speaker shall be allowed more than ten minutes, with the exception of readers of papers and those who introduce debates, who may occupy twenty minutes.

8. The Rules, Programmes, and Abstracts of Papers will be published in English, French, and German.

Each paper or address will appear in the Transactions in the language in which it was delivered by the author. The debates will be printed in English.

9. The Officers of the General Committee on Organization are a President, three (3) Vice-Presidents, a Secretary-General, and a Treasurer, and those elected to these positions will be nominated by the General Committee to hold the same offices in the Congress. All vacancies in these offices shall be filled by election.

10. There shall be an Executive Committee, to be composed of the President, Secretary-General, and Treasurer of the General Committee, and of four other members to be elected by the General Committee. The duties of the Executive Committee shall be to carry out the directions of the General Committee; to authorize such expenditures as may be necessary, and to act for the General Committee during the intervals of its sessions, reporting such action at the next meeting of the General Committee.

11. There shall be a Standing Committee on Finance, composed of five members, to be appointed by the President, subject to the approval of the Executive Committee.

12. Those who are elected as Chairmen of the several Sections shall be thereby constituted members of the General Committee.

The Officers elected are as follows:

President.—Dr. Austin Flint, Sr., of New York.

Vice-Presidents.—Dr. Alfred Stillé, of Philadelphia; Dr. Henry I. Bowditch, of Boston; Dr. R. P. Howard, of Montreal, Canada.

Secretary-General.—Dr. J. S. Billings, U. S. Army.

Treasurer.—Dr. J. M. Browne, U. S. Navy.

Members of the Executive Committee (in addition to the President, Secretary-General, and Treasurer).—Dr. I. Minis Hays, of Philadelphia; Dr. A. Jacobi, of New York; Dr. Christopher Johnston, of Baltimore; Dr. S. C. Busey, of Washington.

The Executive Committee will proceed at once to complete the work of organization.

J. S. BILLINGS,
Secretary-General.

WASHINGTON, D. C., Dec 1, 1884.

OFFICIAL NOTICE.

ANNUAL DUES from members of the Association—*Five Dollars* per annum—are payable directly to the Treasurer. Such payment entitles them to receive the JOURNAL of the Association for one year.

SUBSCRIPTIONS TO THE JOURNAL from those who are not members should be forwarded to the office of publication, Chicago.

BACK VOLUMES OF THE TRANSACTIONS may be procured, at reduced rates, by addressing the Treasurer.

THE INDEX to the 33 Volumes of Transactions will be forwarded, postpaid, on receipt of *One Dollar* by the Treasurer.

According to a resolution passed May 9, 1884, at the Washington meeting, continuous payment of Annual Dues is required, to retain permanent membership.

RICHARD J. DUNGLISON, M.D.,
Treasurer.

Lock Box 1274, Philadelphia, Pa.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, UNITED STATES ARMY, FROM NOVEMBER 29, 1884, TO DECEMBER 5, 1884.

Gray, Chas. C., Major and Surgeon, (retired) died at Geneva, N. Y., Nov. 26, 1884.)

Kneedles, Wm. L., First Lieutenant and Assistant-Surgeon, relieved from duty at Ft. A. Lincoln, D. T., and ordered to Camp Poplar River, M. T. (S. O. 140, Dept. Dak., Nov. 25, 1884.)

Pilcher, Jas. E., First Lieutenant and Assistant-Surgeon, to be relieved from duty at Camp Poplar River, M. T., and ordered to Ft. A. Lincoln, D. T. (S. O. 140, Dept. Dak. Nov. 25, 1884.)

McCaw, W. D., First Lieutenant and Assistant-Surgeon, relieved from duty at Ft. Wingate, N. M., and ordered to Ft. Lyon, Col. (S. O. 228, Dept. Mo., Nov. 26, 1884.)

RETARDATION OF THE PULSE IN MITRAL INSUFFICIENCY.

BY A. T. KEYT, M.D., CINCINNATI, O.

Read in the Section of Practice of Medicine and Materia Medica
of American Medical Association, May, 1884.

At the meeting of the Association last year, I read before this section a paper on Diminution of the Retardation of the Pulse in Aortic Insufficiency, in which were considered the reality, mechanism and diagnostic value of the phenomenon. In the present paper I wish to present the subject of augmentation of the retardation of the pulse in mitral insufficiency.

This subject in its inception and literature seems to be peculiarly my own. For although none would question the importance of a new diagnostic sign of a lesion so common and grave as mitral insufficiency, and whose diagnosis by means of the old signs is not always infallible; and although I presented to the profession some years ago demonstrations of this phenomenon of mitral regurgitation which to me were conclusive, the announcement has attracted but little attention; my observations have neither been confirmed nor disproved by others, and two writers only have noticed them. Dr. A. B. Isham, in presenting the value of the graphic method from the point of view of examinations for life insurance, accepts abnormal delay of the pulse as a valuable sign of mitral regurgitation.¹ And M. Pélix, in his inaugural thesis on retardation of the pulse, quotes largely and approvingly from my published reports.² These papers and my own contain all that has been contributed upon the subject.

Convinced myself of the truth and intrinsic value of the observation, and desiring to see the fact accepted and utilized, I have prepared this article, hoping that a new presentation of the subject may lead to new interest in the phenomenon, and stimulate personal investigation of the time-relation between the heart and pulse in real or suspected mitral insufficiency.

Evidences of the reality of the phenomenon are drawn, 1, from a consideration of the mechanism of mitral insufficiency; 2, from experiments on the schema; 3, from experimental observations on man.

Examining the question first from the point of view of the mechanism of mitral insufficiency we shall find a convincing *a priori* argument in favor of abnormal delay of the pulse as a direct effect of this lesion. Under normal conditions with mitral valve intact, the heart is a perfect organic pump, the left ventricle alternately and duly receiving and sending out blood. When the ventricle contracts, the pressure within becomes positive in relation to the arterial and auricular, which insures the prompt closure of the auriculo-ventricular valve and immediately thereupon the opening of the aortic valves and escape of blood into the aorta.

When the ventricle relaxes, the pressure becomes negative with respect to the arterial and auricular, and the blood flows freely in from the auricle, but is prevented doing so from the artery by closure of the semilunar valves. Auricular systole raises somewhat the diastolic intra-ventricular pressure, but the moment of beginning systole finds a considerable excess of pressure on the side of the artery. The time required to overcome this excess after the beginning of ventricular systole measures the duration of the ventriculo-aortic or presphygmic interval, which under the normal conditions will give a normal value.

Thus all goes smoothly on; the rhythmic succession of contraction and relaxation, of valvular opening and closure, of inflow and outflow of blood, and all the events of a cardiac cycle in harmony with each other in time and status and movement.

But when the mitral valve is permanently open the harmony is no longer preserved. The ventricle fills in diastole even more promptly and completely than in normal conditions, in consequence of falling into it of blood from the surcharged auricle; but in systole the blood is first sent backwards through the open valve into the relaxed auricle. This process fills the auricle and pulmonary veins and dams back the blood towards the lungs. The retrograde current, however, is soon arrested by meeting the direct current from the right ventricle, whose systole is synchronous with the left, and whose tricuspid valve is intact. Thus the pressure within the left ventricle and auricle (now one cavity) finally becomes positive with respect to the aortic pressure, and for the remaining part of the systole blood escapes into the aorta. From this it follows that the time and work of each

¹American Journal of the Medical Sciences, July, 1882, p. 119.

²Paris, 1882.

systole is consumed in first driving the blood backwards, and only a part of the systole is effective in driving the blood into the general arterial system. The effect of this condition of things upon the arterial pulse is to postpone the time of its appearance and lessen the volume of its wave; the cardiac systolic portion is shortened relatively to the length of the cardiac systole. If the heart maintain its vigor the pulse may still feel sharp to the fingers and its sphygmogram give a steep ascent and pointed summit; yet it quickly vanishes to the fingers, and, as shown in the trace, it lacks duration, as compared with the duration of the systole which has sent it forth. If the heart passes into irregular action there will be systoles without arterial pulsation, and pulsations presenting a great variety in form and in time. The many and grave ulterior pathological sequences I will not follow, as the immediate mechanism is all that concerns the present study.

If the above sketch of the mechanism of mitral insufficiency be truly drawn, the conclusion inevitably follows that abnormal delay of the pulse is an essential phenomenon of the lesion.

EXPERIMENTS ON THE SCHEMA IN ILLUSTRATION AND EVIDENCE.

Passing next to the results of experiment, I will first offer those obtained with the schema. It is well known that the mechanical action of the circulation can be well imitated by means of a good working schema. With such a device connected with the transmission tubes of an apparatus for simultaneous inscriptions, traces were obtained at the same time from the interior of the ventricle and interior of the aorta. The intra-ventricular pressure in diastole was maintained at 4 inches, and the intra-aortic at 20 inches (water manometer). The ventricle was compressed and decompressed in a uniform manner for all the experiments. The conditions were varied only with respect to the mitral valve. The instant of ventricular impulsion and that of the aortic wave were signaled by the ascents of the traces, and the time-difference between these ascents was easily computed by the accompanying chronogram. Experiments were first made with the mitral valve intact, representing normal conditions. Fig. 1 is a fair example of the results. Delay of the aortic wave, $\frac{1}{16}$ second.

Fig. 1.

Fig. 2.

Fig. 3.

Another series of experiments was made with a large mitral opening, of which Fig. 2 shows an average result. Aortic delay, $\frac{2}{9}$ second—more than three times as long as the result with intact valve.

A third series of experiments was made with a comparatively small mitral opening, with result shown in Fig. 3. Aortic delay, $\frac{1}{5}$ second, which is seen to be intermediate between the other two.

These results well illustrate the retarding effect of mitral insufficiency on the time of the pulse wave, and the additional significant fact that the retardation is in proportion to the size of the mitral opening. Indeed, in view of the careful manner in which the apparatus was prepared and the experiments conducted, together with the analogy in all essential points for our purpose between the schema and heart, these results may be admitted, also, as veritable demonstrations of the phenomenon and phases under consideration.

EXPERIMENTS ON MAN.

The subject remains to be further elucidated by the results of experimental observations on man.

In order to appreciate chronometric discrepancies between the heart and pulse, it is essential that the normal cardio-arterial time-relations should be well established. This has been done. The interval between the beginning of ventricular systole and the carotid pulse has been found, after a great many observations and measurements, to average about $\frac{1}{12}$ second with pulse-rate at 72. The normal range of variation with this pulse-rate may be placed between $\frac{1}{11}$ and $\frac{1}{13}$ second. It has been determined that the interval bears a relation to the pulse-rate, so that a frequency of 120 would give an interval perhaps not more than half as long as a frequency of 60 per minute. Also investigations have shown that the causes of the variations with the pulse-rate are changes in the mode of ventricular systole and variations of the arterial blood-pressure relative to the ventricular. In frequent pulsations, the systoles being quicker and the arterial pressure relatively lower, the cardio-carotid interval would be correspondingly shortened. The rule is this, the cardio-carotid interval for a pulse frequency between 60 and

120 varies inversely with the pulse-rate; so in estimating what would be a normal interval in a given case the rate of the pulse must always be taken into account.

The interval between the heart and more distant arterial points, as the radial, femoral, or posterior tibial is complicated by the element of transmission time of the pulse wave, which is also subject to variations; but the transmission interval between the aortic orifice and carotid point is so short compared with the whole cardio-carotid interval, as measured, that its variations are not appreciably apparent. Hence the importance of choosing the carotid or subclavian for observing the cardio-arterial time-interval.

The cardio-carotid interval, then, is practically the presphygmic or time elapsing between the beginning of ventricular contraction and opening of the aortic valves, and variations of delay of the carotid pulse are virtually variations in the length of the presphygmic interval.

With these data concerning the physiological

duration and variations of the cardio-carotid interval we are prepared to signal and appreciate the changes effected by conditions of disease.

Our immediate study concerns delay of the pulse in mitral insufficiency. The only clinical data we possess relating to this point have been furnished by my own researches.

My first observation was made in July, 1877, on a boy, aged 9 years, who suffered from mitral insufficiency, and subsequently dying, a post-mortem revealed in his case a pure mitral regurgitant lesion without any other valvular change. His pulse at the time of observation was 100 per minute. Simultaneous traces of his heart and carotid gave an interval of $\frac{2}{17}$ second, when about $\frac{1}{17}$ second would have been his normal interval with his pulse-rate. Also simultaneous traces of his heart and radial gave an interval of a little less than $\frac{1}{3}$ second; and the same of the heart and posterior tibial a little more than $\frac{1}{4}$ second; both the latter also abnormally long. These results are shown in figure 4.

Fig. 4.

Soon after this case I traced another; a young man aged 20 years who presented all the diagnostic signs of mitral insufficiency. Simultaneous traces were had of his heart and radial which gave an interval of $\frac{2}{9}$ second with pulse-rate at 80. If we deduct from this interval $\frac{1}{10}$ second, as an average carotid-

radial transmission time, we get a value between $\frac{1}{6}$ and $\frac{1}{7}$ second as the approximate cardio-carotid interval in this case. The normal interval with pulse at 80 would be near $\frac{1}{13}$ second. Traces shown in figure 5.

Fig. 5.

Observations from these two cases formed the basis of a paper which was published in the *Cincinnati Lancet and Clinic*, March 22, 1879. Since these cases I have continued my observations with results

which only multiply the demonstrations of the fact that the pulse is abnormally delayed in mitral regurgitation. But as demonstrations are more conclusive than mere statements of results, the simul-

taneous cardio-arterial traces (with accompanying chronogram in fifths of seconds), from a number of patients presenting diagnostic signs of mitral regurgitant lesion are here produced.

The cardio-arterial intervals in all these cases of mitral insufficiency are abnormally great; greater than those obtained from persons in health, or from those affected with any process of disease which does not involve pulse-retarding lesion of the heart or aorta. In the absence of such lesion, no series of cases with

corresponding pulse frequencies can be produced which will show such an amount of pulse-retardation.

Figures 6 and 7 are from Jennie M., aged 11 years. She had suffered with chorea and recurring rheumatism, and her heart had become seriously affected. It was enlarged, and emitted a loud murmur, which was distinguished as mitral regurgitant. Fig. 6 was taken during an acute attack, in the presence of fever, pulse-rate 140. Fig 7 was taken after subsidence of acute symptoms, pulse-rate 114.

Fig. 6.

Fig. 7.

Some months subsequently the girl experienced a new attack, with grave cardiac implication, under which she died. The post-mortem revealed pericarditis old and new, with adhesions and liquid effusion; general enlargement of the heart, especially hypertrophy of the right side; notable insufficiency of the mitral valve, the result of inflammatory thickening and contraction; the other valves normal.

Fig. 8 is from Mary M., next younger sister of Jennie, also aged 11 years at the time of observation. She became affected with chorea and sub-acute rheumatic symptoms, and when first seen her heart was notably enlarged, and there was present a distinct apex systolic murmur. She had slight fever, pulse-rate, 114. Carotid delay shows $\frac{1}{10}$ second against $\frac{1}{10}$, which would be about her normal interval.

Fig. 8.

Fig. 9.

Fig. 9 is from Emma O., who presented an apex systolic murmur, which supervened during an attack of scarlet fever, and persisted after recovery from that disease. At the time of observation, June 22,

1883, the murmur and pulse delay were the only indications of cardiac lesion. She remains well to the present time.

Fig. 10.

Fig. 16.

Fig. 17.

Fig. 18.

Fig. 19.

Fig. 20.

Figures 10 and 11 are from Mrs. E., aged 30 years. She was taken with præcordial soreness and a dry, hacking cough, and, when seen a few days afterwards, betrayed a marked apex systolic murmur. Tracings show the cardiac-carotid interval to be $\frac{1}{9}$ second with pulse-rate at 80, and the cardio-radial interval to be $\frac{1}{6}$ second.

Figures 12 and 13 are from Lizzie R., aged 24 years, hospital case, presenting apex systolic murmur. Delay as shown.

Fig. 14 is from Geo. B., aged 27 years, presenting apex systolic murmur. Delay as shown.

Fig. 15 is from J. B., aged 28 years, hospital case, with diagnosis of mitral regurgitation and cardiac hypertrophy. At the time the traces were taken he was under a febrile paroxysm. Indications and delay as shown.

Fig. 16 is from J. T., aged 50 years, a hospital patient, with cardiac enlargement and apex systolic murmur. Pulse delay and pulse-rate as shown.

Fig. 17 is from Sam. T., aged 28 years, who presented the signs of mitral insufficiency.

Fig. 18 is from J. C., a hospital case, with well-marked signs and symptoms of cardiac hypertrophy and mitral regurgitation.

Fig. 19 is from Chas C., aged 18 years, with indications of mitral insufficiency.

Fig. 20 is from a man in health, aged 54 years. The first traces were taken when the circulation was quiet, pulse 82; the second traces when the circulation was accelerated as consequence of exercise, pulse 130. In this figure the pulse delay represents the normal amount. It measures, in fractions, a little

less than $\frac{1}{13}$ second, with pulse at 82, and a little less than $\frac{1}{21}$ second with pulse at 130.

Having thus shown that the mechanism of mitral insufficiency includes increased delay of the pulse as one of its essential phenomena, and demonstrated the constant relationship between the lesion and phenomenon, both on the schema and man, I submit the proposition as proven, and the fact as true beyond a doubt.

DIAGNOSTIC VALUE.

In undue retardation of the arterial pulse on the systole of the ventricle we have a special and highly diagnostic sign in mitral insufficiency. In this lesion, when pure and effective, the sign is always present, and fails to manifest only when the lesion is so slight as to cause no functional disturbance, or when complicated with large insufficiency of the aortic valves. In the condition of harmless regurgitation through the mitral valve the retardation of the pulse remains normal, because the conditions are virtually normal; in the complication stated the retardation is abnormally diminished, for the reason that the aorta ventricle and auricle are as one cavity, with blood-pressure in equilibrium at the end of ventricular diastole, and the beginning of systole starts a current forwards into the artery as well as backwards into the auricle. Thus in mitral, complicated with free aortic insufficiency, instead of abnormal delay, there is abnormal precipitation of the pulse. These are the only exceptions to the rule, that the sign is present when the lesion is present.

What other conditions besides the prime one considered are capable of determining undue retardation

of the pulse? Slowness of ventricular contraction, and relatively high arterial pressure are known causes of prolongation of the presphygmie interval, but these causes are considered to produce only the normal extreme of prolongation.

1. There are good reasons to believe that mitral stenosis independent of insufficiency is capable of causing a delay which may exceed the normal limits. The mechanism, and experiments on the schema favor this view; besides, not long since I traced a case presenting the presystolic murmur and other clinical features of pure mitral stenosis and found the cardio-carotid interval unduly long. If this fact should become established, (of which I have no doubt) it will be found that the delay, unless in extreme narrowing, will not be as great as in mitral regurgitation, and that the sign will not manifest at all in moderate or even considerable contraction, for it would require a very small opening to prevent the ventricle from duly filling during diastole, which would be requisite to insure the production of the sign. Even admitting the fact of the relationship, the sign can have nothing like the diagnostic significance in mitral constriction that it has in mitral regurgitation.

(2.) Rarely, increased delay may be produced by a "locking" of pathologically changed aortic valves. This condition is uncommon, but may obtain when the valves are stiff and thickened, and, notably, when loaded with calcareous masses. They close with a species of locking and are forced open only after a prolonged effort of the ventricle.

(3.) It has been well established that an intervening thin-walled distensible aneurism of the ascending aorta may cause increased delay of the distal pulse, but that if the aneurism have resisting walls, even though it be large, there is no increased delay. Evidently, if the pulse could be traced on the proximal side of the pouch, which is impracticable in man, the delay would not obtain.

The conditions have now all been named in which there is a possibility of undue delay of the pulse being produced by other causes than mitral insufficiency. With the latter all are serious organic lesions of which abnormal delay of the pulse may be a common product.

The sign then, although always present in pure, effectual mitral insufficiency, is not of itself pathognomonic of this lesion, since it may be present, also, in other organic conditions. Here the stethoscope comes beautifully to the aid of the graphic instrument, and in the union of the apex systolic murmur of the one and the pulse-delay of the other, our diagnosis is perfected.

The graphic sign compared with apex systolic murmur.—Systolic murmur located at the left apex, is the physical sign above all, upon which turns the diagnosis of mitral insufficiency. Yet all know there may be free regurgitation without murmur, and insignificant harmless regurgitation with loud murmur, and that no direct relation subsists between the amount of regurgitation and the intensity of this auscultatory sign. Also is it well-known that apex systolic murmur may be distinctly present and the

mitral valve be functionally perfect. These points do not compare altogether favorably with the point we have stated as true concerning the graphic signs. The comparison is well shown by apposition.

Abnormal pulse delay.

Always present in pure, harmful, mitral regurgitation.

Always absent in harmless regurgitation.

The amount of delay directly proportional to the amount of regurgitation.

Present in other conditions besides mitral regurgitation, but these are organic and serious.

Apex systolic murmur.

Sometimes absent in very free regurgitation.

Usually present and often very loud in harmless regurgitation.

No certainty that the intensity of the murmur is directly proportional to the amount of the regurgitation, but often it is inversely so.

Present in other conditions besides mitral regurgitation, but these, if organic, are harmless.

Although the graphic sign has greatly the advantage in the comparison, its value and utility are most manifest when it is obtained and considered in connection with the auscultatory. Alone it is not competent to declare the presence of the lesion, but in association with systolic murmur at the left apex it speaks with positive import. Neither sign singly is conclusive of the lesion, but the two combined could be produced by no other. One locates the lesion, the other determines the extent of its damage.

An important point is that the diagnosis as made by the aid of the graphic sign is certain and immediate at any stage of the case, while the diagnosis as made by all other indications, exclusive of this, is not certain until confirmed by the development of pathological sequences. When, as often happens, other signs raise the question of the existence or not of harmful regurgitation, the graphic comes in with its prompt and positive decision.

RÉSUMÉ OF CONCLUSIONS.

1. Abnormal retardation of the arterial pulse, notably the carotid, on the systole of the ventricle is a real phenomenon of mitral insufficiency.

2. It is present in all cases of pure, harmful, mitral insufficiency, and is absent only in insignificant, harmless, regurgitation, or in regurgitation complicated with aortic insufficiency.

3. It measures by the amount of retardation the amount of the regurgitation.

4. It may be present in two other conditions, probably a third, all organic; hence this sign, notwithstanding its positive value, is not of itself pathognomonic.

5. In conjunction with apex systolic murmur its presence is conclusive of mitral insufficiency.

6. Compared with apex systolic murmur, this sign is more positive and appreciative, and distinguishes, which the latter does not, between harmful regurgitation and harmless conditions.

7. By the aid of this sign a positive diagnosis may be made at once in any stage of the case, and without waiting for the development of sequences and symptoms.

AMPUTATION AT THE HIP JOINT, WITH A REVIEW OF THE VARIOUS METHODS OF CONTROLLING HÆMORRHAGE.

BY C. A. WHEATON, M.D., ST. PAUL, MINN.

Read in the Section of Surgery and Anatomy of the American Medical Association, May, 1884.

MR. CHAIRMAN AND GENTLEMEN OF THE SURGICAL SECTION: You may perhaps think I display more of temerity than good judgment, in offering for your consideration an essay on this time-honored and much discussed subject, but my recent experience with two cases of Coxo-femoral amputation where the hæmorrhage was effectually controlled after the simple method recently described by Mr. Loyd in the *Lancet* of May 26, 1883, has led me to review the literature at my command of the operation since its first performance by Lacroix, of Orleans, in the year 1748. From the time of the first formal disarticulation at this joint to the middle of the present century, the hæmorrhage was controlled or sought to be, by digital compression against the pubic ramus at Poupart's ligament; by securing the crural vessels at that point, or below in Scarpa's triangle, or by the fingers of an assistant following the knife of the operator in fashioning the anterior flaps. We are told by Dr. Otis, that in 1845, "Mr. Cox advised that the arterial compressor, invented by Signoroni, of Padua, should be employed in amputations at the hip joint to control the arterial circulation at the groin without impeding the return of blood by the veins." In the year 1860 Prof. Joseph Pancoast introduced in Philadelphia the compressor for the abdominal aorta; a little later a modification of the same instrument was used in England by Professors Lister, Syme, and others, and by the French and German surgeons on the continent. Since that time innumerable devices have sprung up, having the same end in view, viz.: that of controlling the circulation through the terminal branches of the common iliac. Since its introduction the aortic compressor has been considered by many an almost indispensable adjunct to the operation. Nearly every modern surgical textbook speaks favorably of it, but a few writers, however, still cling to the older method of securing the femoral vessels by a preliminary operation. What are the objections to digital compression of the femoral as it emerges from beneath Poupart's ligament? Davy speaks of it thus, in comparing it with his ingenious device, the rectal lever: "I can only state that after a surgeon has proved, practically, how very easy it is to prolong indefinitely compression by the lever, he will not care to submit to the fatigue, uncertainty, and anxiety of digital pressure." The degree of pressure must fluctuate with the movements of the patient; in fat subjects it is difficult, extremely fatiguing, and must be at times uncertain, and withal, even though accurately and efficiently done, only one of the two avenues through which impending calamity is to be anticipated, is controlled,

for I believe all surgeons stand as much in dread of the posterior as the anterior vessels. Digital compression of the aorta may be resorted to, but except in the case of young or much emaciated subjects entails the same objections as attach to femoral compression, only greater in degree, and has the additional objection of interrupting the circulation to both limbs, and interfering in some degree with abdominal respiration.

The objections to the preliminary ligation of the femoral vessels are, first, the additional time required; second, an additional wound, and thirdly, as Dr. Ashurst suggests, "that the extensive separation of the artery from the surrounding tissues, which is unavoidable in this preliminary ligation, must expose the patient to greater risk of secondary bleeding than when the vessel is simply picked up by forceps or tenaculum after division as in other amputations." With reference to the abdominal tourniquet, to quote again from Dr. Ashurst's surgery, "although the benefits derived from the use of the aortic compressor in this operation are unquestionable, yet the pressure necessarily exercised upon the important nervous structures contained in the abdominal cavity must be at least undesirable, if not positively injurious." There is the possibility of a deviation of the artery from the mesial line sufficiently to make its control by pressure a matter of some difficulty. The interference with abdominal respiration in weakly subjects under anaesthesia may induce much additional embarrassment. The possibility of making harmful pressure; the interference with the circulation to the sound as well as the unhealthy limb; its absolute inapplicability to those cases requiring prolonged control of the circulation, such as sequestromy, excision, or the removal of extensive growths from the upper femoral region—all these objections certainly militate much against its general usefulness. Until quite recently Davy's lever was, perhaps, the most popular and efficient instrument which had been introduced to the profession for this purpose. It was easy of application; not likely to become displaced when once in position; did not interfere with the respiratory movements; the pressure was confined to the common iliac of the affected side, and was efficient without embarrassing in any way the operator. It was supposed to be entirely harmless, but unfortunately, not long since, a death occurred, caused, it is said, by peritonitis, which had resulted from the pressure of the instrument, this accident occurring when the instrument was in the hands of its inventor. While it serves its purpose so admirably in many respects, yet I think its having been the cause of a fatal issue in this individual case will be sufficient to circumscribe its general use. The hand introduced into the rectum has been used as a substitute for the lever, but in a case reported by Dr. Thorndike at the Boston City Hospital, it was found impossible to adopt this method, as the arm of the assistant was in the way of the operator.

The method of Brandis, spoken of by Esmarch in his "Surgeon's Hand-book," is but a modification of the principle of the abdominal tourniquet, and

has all of its objections without any of its advantages. In the *American Journal of Medical Sciences*, April, 1882, is given a description of a method of amputation at the hip joint by Professor Freundelenburg, "the principle of the method being the compression of the entire tissues of the flaps before the division of the large vessels, indeed, before the flaps are cut," by means of a steel skewer which is made to transfix the thigh in front of the femur, the tissues in front of the rod being compressed by a rubber tube wound in figure of eight fashion from end to end of the rod. The flap is then cut with a Lisfranc's knife, from within outward, as in the usual manner by transfixion. All vessels in this flap are now secured, and the skewer removed. The next step in this operation is the opening of the capsule and disarticulation of the femur, after which the rod is again passed through the limb behind the joint, the compressing band applied, and the posterior flap cut and cared for like the anterior. The objections and disadvantages of such a complicated and protracted operation are sufficiently obvious, and require no further consideration. Dr. Lewis Marshall, in the January number of the *American Journal of Medical Sciences*, reports four cases of amputation at the hip joint, after the manner of Mr. Furneaux Jordan. His description of it briefly is as follows: "If incision has been previously practiced, the existing incision is prolonged to about the middle of the thigh, the femur enucleated, the soft parts cut through with a circular sweep of the knife, and the femoral artery tied." Mr. Jordan, in his single case, controlled the bleeding by a tourniquet on the external iliac. In commenting upon this case, Mr. Jordan says that, "as compared with the ordinary operation of two flaps, the wound was less severe; the cut surfaces were less extensive, and in a manner further removed from the trunk; it was followed by less shock, less hæmorrhage, less opportunity for septic infection. The vessels cut were more easily dealt with. The muscles may be cut on the same level as the skin; the bone being absent, they retract so strongly that the skin readily covers them; its vitality is less endangered, and a great cellular plane is not opened. The bulk of the soft parts of the thigh, especially near the pelvis, lie at the inner side of the femur. Why put a knife through these parts? The surgeon may, if he choose, make the circular sweep before the shaft of the bone is turned out, if precautions against hæmorrhage have been very complete." It will be seen that this method described as Mr. Jordan's is a modification of the old circular amputation, as originally performed by Abernethy and subsequently by Lacanahie, was made with the additional "vertical incision over the trochanter major to facilitate disarticulation," Mr. Jordan dividing the skin, soft parts and bone at the same level, instead of cutting through the skin and retracting it before cutting through the muscles, and by dividing all the tissues at a point more remote from the body. Mr. Loyd's plan for controlling hæmorrhage in amputations at the hip joint was first put in execution at the Queen's Hospital, Birmingham, England, June 17, 1883. He thus describes it: After having emptied the limb of

its residual blood, by elevation and gentle friction toward the trunk, "a strip of black India rubber bandage, about two yards long, is to be doubled and passed between the thighs, its centre lying between the tuber ischii of the side to be operated on and the anus.

A common calico thigh roller must next be laid lengthways over the external iliac artery. The ends of the rubber are now to be firmly and steadily drawn in a direction upward and outward, one in front and one behind, to a point above the centre of the iliac crest of the same side. They must be pulled tight enough to check pulsation in the femoral artery. The front part of the band passing across the compress occludes the external iliac, and runs parallel to and above Poupart's ligament. The back half of the band runs across the great sacro sciatic notch, and by compressing the vessels through it, prevents bleeding from the branches of the internal iliac artery. The ends of the bandage thus tightened, must be held by the hand of an assistant placed just above the centre of the iliac crest, the back of the hand being against the surface of the patient's body. It is a good plan to pass the elastic over a slip of wood held in the palm of the hand, so as to diminish the pain attending the prolonged pressure of the rubber bandage. In this way an elastic tourniquet is made to encircle one of the innominate bones; checking the whole blood supply to the lower extremity. When the band is once properly adjusted the assistant has only to take care that it does not slip away from the compress or over the tuber ischii. The former is prevented by securing pad and band together by a stout safety pin, and the latter by keeping the securing hand well above the iliac crest, or even more safely by looping a tape beneath the elastic near the tuber ischii, passing behind it under the sacrum and having it held in that position. The ligature being altogether above the limb is out of the way of the surgeon, in any operation at or about the hip joint. The great trochanter is fully exposed, the hip being free upward as far as the iliac crest, and inward to the perinæum. The plan is equally applicable in amputation by transfixion, or in excision of the joint." The advantages accredited this method by Mr. Loyd, are as follows: "A minimum disturbance of the general circulation. There is no interference with abdominal respiration. There is no danger of injuring the abdominal contents. The simplicity and accuracy of its application; no previous experience being necessary to compress the vessels, there is no possibility of going wrong. The security with which the vessels are controlled, regardless of the movements of the patient or manipulations of the operator." It is applicable to all cases, and requires no special apparatus. In the light of experience furnished me by the two cases of my own, I am satisfied that this method of Mr. Loyd's is all that is claimed for it; it is simplicity itself, and as efficient as it is simple. With the Esmarch's bandage, and the roller applied as he directs, hæmorrhage is no more to be dreaded than in an amputation in any other part of the limb.

With reference to the form of amputation, too little

prominence by surgical writers, I think, has heretofore been given this modification of the circular amputation suggested (as Dr. Otis tells us in the renowned circular No. vii. of the war department) by Lacanachie in 1350. Besides affording easy access to all the vessels requiring ligation, it has the additional advantage (as pointed out by Surgeon Bouteau, U. S. A.) of permitting the examination of the femur as high as the trochanters before disarticulation, and as before quoted from Furneaux Jordan, the wound is less severe; is in a measure more remote from the trunk; the great bulk of muscles lying on the inner side of the femur are not disturbed, and from this non-interference with this mass of muscles less liability to septic infection follows; the vitality of the flaps is less endangered; the wound is as favorable for drainage as any other, and its performance even by a novice is a matter of comparative ease. In both of my cases a circular division of the limb was made, cutting through skin, muscles and bone on the same plane. The knife was applied about an inch and a half or two inches below the gluteal fold. Immediately on dividing the bone the vessels were secured. A vertical incision was next made beginning above the great trochanter and carried down the outer aspect of the thigh to intersect the circular incision. The remainder of the femur was removed as nearly as possible subperiosteally, the knife being used only in separating the muscular attachments to the trochanter and the division of the capsule. Notwithstanding the muscles were cut so near their origin, the skin afforded ample covering. There was absolutely no active hæmorrhage in either case, except from one or two small articular vessels.

The general adoption of the method of Mr. Loyd will, I believe, rob this amputation of one of its greatest dangers, and will confer an inestimable boon upon the unfortunates who are to suffer exarticulation at this joint, as well as contributing greatly to the comfort of the surgeons who are called upon to make it.

Accompanying this paper are three sketches. No. one (1) shows the method of removing the limb, Nos. two (2) and three (3) the application of the tourniquet.

EFFECTS OF MURIATE OF COCAINE ON THE ORBICULARIS PALPEBRARUM.

BY J. L. THOMPSON, M.D., INDIANAPOLIS,

OF THE CHAIR OF DISEASES OF THE EYE AND EAR, MEDICAL COLLEGE OF INDIANA.

In the report of the following cases it will be my endeavor to simply state the facts as briefly as possible, leaving the profession to judge as to the efficacy of this alkaloid in eye surgery.

In the first case a two per cent. solution was used, but in the nine following ones it was increased to four per cent. No question could be entertained as to its purity, as it came from Merck's, and its peculiar action on the orbicularis corroborated this belief.

CASE I. Machinist, æt. 34. F. B. (Emery) deeply

imbedded in the right cornea, of three days' standing. The solution was dropped into the eye every three minutes for fifteen minutes when the body was dug out with a spud. He stated that the operation did not hurt much.

CASE II. Very severe trichiasis, in which Arlt's operation for transplantation had been previously performed, and in which the tarsal margins were very much notched, and most of the ciliæ were still inverted. The proposed operation was to remove the anterior tarsal margin of each upper lid, with all of the hair bulbs. James H., æt. 33, was taken before the class at St. Vincent's Hospital. Three drops were instilled into the eyes every three minutes for twenty minutes, and besides this eight drops were twice injected subcutaneously at the outer canthus of the right eye. A narrow scalpel was thrust into the edge of the lid for the purpose of splitting it, but he kicked, bellowed and struggled so terribly that the operation had to be completed under ether.

CASE III. Removal of portion of prolapsed iris, in case of ulcerative keratitis. W. S. æt. 16 years, very strumous; has had "sore eyes almost since infancy." Three drops were put into the eye every three minutes. When the first application was made the orbicularis resisted one's efforts to open the lids, but on each renewal less resistance was experienced until it was found easy to drop them into the eye, even without touching the lids. She did not flinch when the speculum was applied, but when the iris was seized with the forceps she complained very much, but we succeeded in excising it.

CASE IV. John E. S., æt. 34, a traveling salesman. Very small chalazion at tarsal margin of left upper lid. Two drops were used in the eye every three minutes, and dropped on the outside of the lid while he occupied a recumbent position. He was told that while this would not cause the operation to be painless, it would very much mitigate it by benumbing the parts, thereby removing about three-fourths of it. When first dropped into the eye he flinched and contracted the lids greatly, but after a few additional applications, he soon suffered its use without any resistance, and in twenty minutes the pupil was widely dilated, and the eye much more widely open than the other. Knap's lid clamp was then applied, and the little growth was removed while the patient puffed and blew like a porpoise. When the operation was finished he remarked that it was a great blessing that a remedy was used which removed three-fourths of the pain, as the remaining one-fourth nearly killed him.

CASE V. Emma S., æt. 17. Strabismus convergens of over six lines, requiring operation on both internal recti. The usual 4 per cent. sol. was used every three minutes for nearly forty-five minutes until the pupils were widely dilated, and the resistance of the orbicularis most thoroughly overcome; but no sooner was the conjunctiva grasped, than she struggled and complained most terribly, and this she kept up during the whole length of the operations on both eyes, and she vomited during the following afternoon and night.

CASE VI. William W., æt. 50. This was a patient on whom an extraction for cataract had been

made six months before, from the right eye, which had been followed by irido capsulitis and closed pupil; in the left he had cataract and iridodonesis. The operation was an artificial pupil in the right, and a preliminary iridectomy in the left. When first operated on for cataract he contracted the lids so tightly when the speculum was placed in the eye, that it was removed until ether was administered and the operation finished. This was an excellent case in which to test this remedy. The drops were applied every three minutes for over twenty and until the left pupil was well dilated. After the third time of using them he became much less touchy about his eyes, and very soon they were used without any winking at all. The speculum was applied to the left without any resistance on his part, but when the conjunctiva was grasped by the fixation forceps he winced considerably, and when the iris was seized he jerked, and tore it loose from the forceps; again was it grasped and cut off while we scolded him most unmercifully for his nonsense. More drops were used on the right eye when a similar experience was again met with, and the operation was finished with De Wecker's scissors.

CASE VII. Patrick H. B., æt. 48, machinist. Removal of small piece of steel from the cornea. Two drops instilled every three minutes for fifteen, and body dug out without any difficulty. On questioning him he said that it did not hurt much; hardly as much as usual. We must remember, though, that machinists are so in the habit of having bodies removed by their fellow workmen, that these are not of the best class to test the virtues of this remedy.

CASE VIII. Re-insertion of style in nasal duct. Mrs. C., æt. 49, had submitted to the operation for stricture of the duct, and had had a style inserted without taking an anæsthetic, two months previously, and had made but little complaint during the operation; but on its removal, every ten days or two weeks, she always said it pained her on its insertion. This was doubtless owing to the peculiar curvature of the passage. The drops were used very freely for the usual length of time, and no force was exerted in replacing said style, but she experienced no difference whatever in the slight pain usual to its insertion on former occasions.

CASE IX. Removal of half of the prolapsed iris in lacerated wound of the cornea. John H., colored, æt. 52, was wounded with a brickbat two weeks before, and had been kept quiet with iced compresses and atropia locally, before I saw him. The eye was still much inflamed, and quite a chemosis was present. The cocaine was used every three minutes for twenty minutes, when the speculum was inserted. He flinched but little during this part of the operation, but when the iris was removed he complained very much.

CASE X. Enucleation of the left eye-ball for sympathetic irritation. Ellsworth C., æt. 20, lost the vision in the left sixteen years ago, from wound through cornea and ciliary body. Three weeks ago he commenced losing the sight of the right eye. He was urged to have the eye removed under the influence of the cocaine; was told that though it would

not entirely relieve pain, it would very much mitigate it. He was treated with it every three minutes for over half an hour, but he declared that he did not feel any difference in the eye, though it was noticed very early that after the use of the first few drops he ceased to contract the lids, and the medicine was applied without having to open the eye with one's fingers. He made no complaint when the speculum was adjusted, shrank a little while fixing the eye, and urged me to hurry up while the muscles were being taken up. The operation lasted two and a half minutes, and when completed he asked if the eye was out, and said that "It did not hurt half as badly as he had expected; but as he had never even had a tooth pulled, did not know how much such cases did usually hurt one." He seemed dazed during the operation, and doubtless would have acted similarly had no cocaine been used.

From the above experience it is my opinion that as an anæsthetic in eye operations this alkaloid has been exceedingly overrated, and that many of the cases which have been reported would have done almost as well had it not been administered. I have been strikingly strengthened in this opinion quite recently, for while waiting for the arrival of the medicine (which took nearly four weeks to procure) an unusual number of cataract cases presented themselves for treatment, all of which were operated on without any anæsthetic whatever, and, doubtless, had it been used in these, as was my intention, I also would have gone into ecstasy concerning its "wonderful" efficacy. I have used it in a very large number of cases where my object has been simply to get a view of the whole of the fundus of the eye, and for this purpose it seems to have no superior, as its effects pass away more rapidly than even homatropine is used; but it does not seem to sufficiently relax the accommodation to justify its use in the exact measurement of anomalies of refraction. While using it for the purpose above-mentioned, I found that its effects upon the palpebral portion of the orbicularis are much greater than are those of other mydriatics, as in a very large majority of the cases in which it is used the eye is opened much more widely. Again, its action upon the sphincter of the eyelids points to its desirability in cataract extractions, as they undoubtedly tolerate the speculum much better than when it is not used. I would also suggest its use in tonic blepharospasm. My next door neighbor, who is a throat specialist, tells me it has done wonders with the nasal mucous membrane. So, taking these things into consideration, it seems to be a valuable agent in a limited field. It is to be hoped that the newspaper puffs which it is receiving on every hand may continue, as by this means we can tell our patients that we are going to resort to that "precious" remedy concerning which they have, doubtless, read so much; then many will submit to operations without the aid of ether who would never have consented before. Faith in the remedy will have its effect on others, and by the time this has found its true position, in all human probability something else will arise to take its place.

tainities."—BACON.

"All scientific novelties are subject to inconsiderate criticism."—
PASTEUR.

Republished with appendix by the special permission of the author, by
G. Frank Lydston, M.D., Chicago, Ill.

From the facts connected with these ² affections—clinical and pathological—embracing as they do, the etiology, the history of origin, progress,³ interchange, and inter-communicability, mode of propagation, hybridity, and transmutation, we cannot avoid arriving at the conclusion that these ailments may be generated *de novo*, and from one common source, as well as by direct communion with one already suffering; or by indirect, through some secretions, excretions, or some thing, or person, that has been in contact, or communication with the sick.

That there are two forms of scarlatina is distinctly manifest—a fact thoroughly established on evidence from which there is no escape. There is—1st. That contracted from a scarlatina patient, or from some one or thing that has been in contact with him, or in communication with him. To this I give the name orthodox scarlatina. There is—2nd. That generated *de novo* from blood poisoning, such as occurs in puerperal patients, and in surgical cases (the "surgical scarlatina" of Sir James Paget) from deleterious matters absorbed or otherwise passed into the blood, and thence into the tissues of the body more or less generally; or from noxious drains, sewers, imbibition, or ingestion of pernicious articles of drink or food—such as tainted water, milk, cream, decomposing animal or vegetable substances. To this form I have given the name toxæmic, to distinguish it—as regards origin—from the orthodox. As an example of what I mean I shall give the following particulars:—

At one of the meetings of the Harveian Society the President brought forward a case which he termed

¹By unity is meant not that the poison is always the same, but that the one poison—the one *origo mali*—whatever it may be, will originate several so-called different affections.

²I had at first placed at the head of my paper only the first four diseases (keeping to the conventional word).

³"Erysipelas is a specific disease, due to the presence of some blood poison that has probably been introduced into the body from without; it is intimately allied with other blood poisons, such as are found in scarlet or puerperal fevers, or septicæmia in any of its forms: for their poisons seem to be convertible."—Bryant's *Surgery*, second edition, vol. i, p. 44.

"simulative scarlatina from eating tomatoes," in which occurred all the symptoms of scarlatina, except that there was no desquamation; and for albumen in the urine no search was made.

In passing, however, I may observe again—I have made the same remark elsewhere—that desquamation is no proof whatever of the existence of orthodox scarlatina, and its absence no disproof of orthodox scarlatina having attacked a patient; for, high temperature of the skin, arising from any causes—and they are various, setting scarlatina aside altogether—will occasion such rapid cell changes, that the surface cells will be thrown off in larger or smaller quantities, and, according to the height to which the temperature has run, will they be shed wholesale, being effete. Thus arises that process which we call desquamation. In some undoubted cases of scarlet fever there may be only slight exaltation of temperature, or so transiently may it take place that it escapes detection; or it may even be altogether absent, owing to the great and sudden depression of vitality produced by the virulent character of the virus, or by the largeness of the dose taken into the system, or the suddenness of its invasion. With this absence of high temperature desquamation will also be absent. Nor is albumen in the urine a pathognomonic sign of scarlet fever poison pervading the system. In how many conditions and affections of the body other than those demonstrating the existence of scarlatina will not albumen be found? "There is nothing unusual in the fact that inflammation of an important surface should be attended with albuminuria," says Mr. Jonathan Hutchinson. (See *Brit. Med. Journal*, May 3, 1879, page 665, under head of Discussion at Medico-Chir. Society on Report of the Committee on Croup and Diphtheria.)

Here—in the person of the patient brought before us—was undoubtedly a case of "toxæmic scarlet fever," symptoms generated, as far as could be traced, by the eating of tomatoes. No source of contagion or infection having been discovered or being discoverable, no other source of origin, these fruits were apparently the *origo mali* of certain chemico-physiological changes in the system, which were sufficient to produce a general poisonous effect that demonstrated itself in certain physical changes, phenomena or symptoms—the majority of which, or the entire in the aggregate, being such as to lead the observer to say the patient had got scarlatina.

Bearing upon this case, I would adduce an instance wherein the symptoms of scarlatina were all so marked that it is specially applicable, and fully corroborates the President's in showing that ingested materials will at times induce symptoms so closely resembling orthodox scarlatina as to be undistinguishable. And here I would ask, if distinguishable, how, then, does the attack differ from orthodox scarlatina, *i. e.*, that which has been contracted from a scarlatina patient, or some one or thing that has been in communication with him? *The difference lies only in origin!* In my case the symptoms rose from eating very high game, and though not proceeding from eating tomatoes, it is relevant—1st. Because in all points it

was one of "simulative scarlatina"—a name I was the first to use some years back, but for which I now prefer to use the term "toxæmic scarlatina;" 2nd. Because it arose from a similar, though not the same cause, ingested material; and thus, thirdly, was an answer to the query propounded,—Were the symptoms in the instance before us due to eating one of the solanaceæ order?—inasmuch as it shows that causes other than *the active¹ principle of that order* produce such symptoms, even while admitting that the active principle of the tomatoes may *per se* at any time, under any circumstances at all events, set up toxæmic scarlatina, and may in this particular patient have directly produced the symptoms and been the direct exciting source of the illness.

A second case which I would adduce bears strongly on the same; so strongly, indeed, that though having published it in 1875, I will quote it, as it also is to the point:—

1st. Because in symptoms it was identical; 2d. Was what would be termed "simulative (toxæmic) scarlatina;" and 3d. Showed that these symptoms may arise even from *animal* poisons passing into the system *in a way other than by the mouth*;—viz.: by the womb, in contradistinction, though not in opposition, to the tomatoes case.

Thus again answering the question directly by showing that the "simulative (toxæmic) scarlatina" symptoms are not *necessarily* dependent upon the ingestion of solanine, since they will be produced by animal irritants and poisons absorbed not through and from the mouth and stomach alone, but in other ways also.

I will here relate the case—a typical one, and such as has come before every medical man.

The conditions alluded to, and which are identical with scarlatina—are the same I now consider—have their origin not from orthodox scarlet fever contagium, that is, from a scarlatina-infected person, or some one or thing belonging to such a patient—there never having been any exposure to scarlatina in that way—but from the putrescing and offensive matter in utero and vagina, the resulting pyrexial action being indicative of the concealed cause, the latent mischief, that, without careful observation, might pass unobserved.

With the train of symptoms to which I refer, who practising obstetrics is not acquainted? The chilliness and shivering, the sickness, the dreadful headache, and the congested eyeballs from which the paining light must be veiled, or even shut out altogether; the sore throat, crimson with inflammation; the peculiar tongue; the hot, pungent skin, that so rapidly sends up the mercury, and is *died with the unmistakable rash*, with which there is a tinge of jaundice-yellow, here and there more noticeable; the delirium; the oppressed heart and breathing; and later on the diarrhœa. What are these symptoms to be termed? Not *simulative* scarlatina, surely, since they are not simulative at all, but are exactly the same as obtain in scarlatina contracted from a previously infected person or source—orthodox? What, then, are they?

Symptoms of what, for contradistinction's sake, I term "toxæmic scarlet fever," but assuredly as true scarlatina as the other form—the orthodox—though not generated in the same way, but generated *de novo* in the woman herself, and the outcome of the condition of blood poisoning existing, *not* from the introit of a *specific virus*, but of elements given off in utero or vagina—not, it may be, noxious when given off, but becoming so subsequently from morbid changes—and, when noxious, taken into the system; a blood-poisoning, I repeat, the result solely of the putrefying animal matter in utero or vagina, and of unhealthy changes, taking place locally first, in the generative tract and system, setting up local mischief primarily, and then developing and evolving through the entire body of the puerpera, till all the symptoms I have portrayed have made their appearance. In a scarlet-fever epidemic, such a group of symptoms happening to the lying-in would be set down to scarlet-fever poison, contracted from another affected with it, or from some one or thing belonging to, or that has been in contact with, such an infected person; for it is not yet generally accepted that scarlatina can commence *de novo* in the manner I describe. But these symptoms will be found where no previous case, or contagium, or source of origin other than what I name, has existed.

What, then, are those phenomena? I gave them the name of bastard or simulative scarlatina when I first wrote on this subject, not at that time considering them true scarlet fever; or knowing that the ailment could be so produced; or, indeed, be produced *de novo* in the ways that further researches have shown me it can. True—orthodox—scarlatina I consider to be that form contracted from a previously existing case, or from some one or thing connected with, or which has been in some way or another brought under and near the influence of the scarlatina virus existing in a previously infected patient. Bastard, or simulative scarlatina—toxæmic—I consider to be those scarlatina manifestations or appearances heretofore deemed mere resemblances—a view I also then took, but which I now know to be not resemblances, but the actual manifestations themselves of toxæmia set up otherwise than from orthodox scarlatina, differing only from the orthodox form in that they originate *de novo* from such sources of contamination as may occur in the lying-in; or from vitiated water, milk, cream, or the taking in of "high," *i.e.*, putrescing articles of diet,¹ or decomposing drinks, such even as milk which has begun to undergo deterioration, it may be simply because it has been long "drawn;"² or it may be because it

¹ Upon this Dr. Carpenter wrote very clearly in 1853, in the *Brit. and For. Medico-Chirurg. Review*. See his article, "Predisposing Causes of Epidemics."

² The following remarks will explain what I mean when I say that even milk undergoing deterioration will produce scarlet fever:—On Thursday, January 30, 1879, at the meeting of the Metropolitan Counties Branch of the British Medical Association, Mr. Gay, in a paper on "Milk as Food for Man," said:—"In the absence of any positive knowledge as to the source of the various exanthemata—measles, scarlatina and the like, characterized by fever, and without doubt related to some form or forms of blood poisoning, disorders that abounded mostly after dentition, and when milk was often the predominating, if not the sole article of food, was it unreasonable that we should turn with suspicion to those *unwholesome ingredients of decaying milk* for their explanation?" He continues—"Milk when once exposed to the air and rest, underwent a series of chemical changes through the influence of external and internal agencies which

¹ Belladonna, it is well known, produces scarlatinous efflorescence, etc., etc.

has been allowed "to stand" in a place, and under circumstances of temperature,¹ etc., which would permit or hasten unwholesome changes,² the milk being at the time not unpleasant to the ordinary taste, nor even at all perhaps perceptibly altered in flavor.³ I now recognize these symptoms, arising from causes other than the infection or contagion derived from a previously infected person or thing, to be as true scarlatina, and capable of becoming in its evolutions and its transmigrations from one to another, as infectious and contagious as the other form. In confirmation of this view I would name that Sir Wm. Gull has stated his belief that diphtheria may "*commence locally*, forming a poison which will propagate itself;" and he has "drawn a distinction between diphtheria and diphtheria poison, regarding the disease as beginning with a poison, but *sometimes as commencing locally, and forming a poison which may propagate itself*."—(*British Med. Journal*, May 3, 1879. Page 666.) This bears me out in the contagious and infectious character of toxæmic scarlatina; and the evidence of Burdon Sanderson, which I have quoted in my former paper, to the effect that an inflammation may begin as "simple" but go on progressively to what would be termed specific, also is corroborative. Again, we know that a benign may be converted into a malignant ulceration, progressively, under continued irritation.

And it will be found that scarlatina generated *de novo* from blood poisoning, or effected in any other way than that *usually accepted as being the only way* in which scarlatina is generated and propagated—viz.: from a previously scarlatina-infected person or thing

ensued in its degradation and decay, its last stage being that of a limpid fluid, mainly composed of water, salts and acids, amongst which figured the lactic, butyric, capronic, and capriolic. To this downward career it was carried by becoming the habitat of broods of vibrios of different kinds, and, according to Prof. Lister, of a certain bacterium—bacterium lactis—and by certain carpetings of its surface by oidium and other varieties of mould."

¹ "M. Fauvel, of the Paris Chemical Laboratory, has discovered an additional danger to that abominable invention, the baby's feeding bottle. Of 31 feeding bottles taken from various creches in Paris, 28 contained both animal and vegetable life, the milk remaining in all smelt badly, was acid and half coagulated: the globules were deformed, and numerous very lively bacteria, along with some vibrios, were present. On cutting open the caoutchouc tube through its length, coagulated milk, with small organisms, was met with; but a still more important fact was the presence in the nipple of a mass of vegetation of cryptogamic nature. Some of these bottles had been washed and were ready for use."

² The lactic fermentation has relations to a small oval bacterium, which hence has been called by Lister, bacterium lactis.

³ These deleterious, if not absolutely poisonous changes, in a fluid introduced into the system and taken up into the blood, show how milk and cream, and substances or fluids with which they are mixed and combined, can and will prove a source of originating blood-poison which, in different periods of life—cycles of age—and under different circumstances, will declare itself in symptoms at one time, or in one person, or of one or other of so-called different AFFECTIONS; at another time in the same person in a different form or set of symptoms, or at the same time in different people in the different manifestations to which have been given specific names—scarlet fever, typhoid, puerperal fever, diphtheria, erysipelas, etc.—for the purpose of distinction and of conveying to others what we mean, and which I look upon as phases of the evolution of the one poison.

I would call to mind how often the puerperal woman is dosed with gruel made with milk—that has in many cases been "standing" for some hours, and it may be in the puerperal room itself, wherein the atmosphere is not always, by ignorant people, kept the sweetest,—on the supposition that milk creates milk; how the children, and husband, and household often partake of the same milk; and how vitiated (as shown in Mr. Gay's paper) even good milk becomes by "standing," how much more by standing in the atmosphere of the lying-in chamber; and how readily this one fluid becomes an originating virus, a one *origo mali* in a house-hold, or circle of people poisoned with it, amongst whom there would be from this one source a differentiation and divergence of results, of phenomena of the poisonous action, of symptoms directly consequent, so that one or more would be said to be suffering from scarlatina, others from typhoid and diphtheria, or one of the other generally supposed specific and distinct ailments of which I write, the lying-in mother being attacked with what would be termed puerperal fever: all the differentiations resulting not from a difference in the poison, but of the persons brought under its influence.

—is infectious and contagious alike with the other form. I do not now consider *that* to be bastard or simulative scarlatina which I formerly described as such, but look upon it as true, *generated differently, propagated similarly*. I was first led to these conclusions by a case of auto-genetic poisoning, which was under my care in 1875, in which scarlet fever symptoms obtained, but which, recognized to be wholly the consequence of a morbid condition of the uterine system and its excretions, in fact, begotten and conceived *in utero* from putrescent matters therein, I treated accordingly, by grasping the soft spongy uncontracted uterus with my hands, compressing it, expelling thereby the retained and offensive clots, washing out the vagina and uterus by means of Higginson's syringe—Condy and warm water being used every two hours till the lochia became quite inodorous. Had I, however, seen the patient for the first time when those scarlatina symptoms were fully developed, and had I overlooked her puerperal state and the condition of the uterine system, I might have erred in supposing I had to deal with scarlatina from a previously infected person or thing, have overlooked the *de novo* origin of the case—the latent uterine mischief—have neglected the ablutions and cleansing processes, have treated the ailment in the orthodox fashion as being contracted from previous scarlatina infection, and no doubt have lost my patient. But being alive to the puerperal facts and bearings to which I have drawn attention, I at once proceeded as I have described, and the correctness of the diagnosis was evinced by the immediate improvement in the lady, commencing as it did from the very time I got rid of the offensive clots and washed away the noisome lochia. Within twelve months I had three cases of puerperal blood-poisoning, in which not alone was scarlatina rash well marked, but also the other symptoms of scarlet fever. I had learned from my first case valuable knowledge by which I have profited, and these later patients I accordingly treated as suffering from toxæmic scarlatina. Some time ago I had, in consultation with Dr. Joliffe, of Shepherd's Bush, a case of typhoid fever, in which relapse occurred while convalescence was advancing and desquamation—as truly marked as in what would be termed a typical case of scarlatina—was actually taking place. In the same house where lay this sick mother some of the youngest members of the family had previously been affected with scarlatina, others having suffered from what is termed scarlatina throat, while others again were at the time complaining of the same, the cause of the outbreaks being, as far as could be discovered, the defective drains, which allowed regurgitation of noisome smells and vapors into the house.

Since 1875, when I first entered upon the study of this question—the unity of poison and differentiation of resultant phenomena which we call symptoms—not because of any difference in the poison which

The experiments of Pasteur on chicken cholera are well-known. In hope of diminishing the infective power of this organism, he grew it in oxygen for a long time, and the found not only that it produced a modified disease, but that this attack in most cases protected the animal from the effect of the organisms in their most virulent state!—*Brit. Med. Journal*, December 31, 1881. Page 1062.

may be the *origo mali* of so-called various diseases, but differentiations dependent upon the media through which the poison passes, or upon which it falls, the evolutions and developments of that one poison being marked by new phases, new manifestations to which rightly we should not apply the expression separate diseases, but rather call them simply what they are, the various expressions of the evolutions of that unity of origin whatever it may be, which has set them all agoing—since, I repeat, I first entered upon the study of this question, my researches have made clear to me what before I had not recognized; and out of much mistiness, obscurity, and chaos of facts, ideas and thoughts, clearness and definiteness have evolved in my mind, so that what was to me—as to every observer in a new path—at first vague, indefinite, unshaped, has become certain and embodied in realities. What at one time I feared to be incapable of proof has come to be more and more provable, till at length it has become proved; what at one time from former teaching and consequent prejudice seemed to me to be false, has gradually opened out to me as true, till it has come to be established in my mind as a great truth.

34 St. George's Square, London, S. W.

APPENDIX.

It is with great pleasure that I embrace the opportunity of presenting through the medium of the *JOURNAL* the theory of "the unity of poison," advanced by Dr. Griffith, who has courteously permitted me to republish his views, as they have appeared from time to time in the columns of the *Glasgow Medical Journal* and *Midland Medical Miscellany*. The author has kindly consented to allow me to comment upon the views expressed in the foregoing pages, and I shall therefore make such comments as are suggested to me by their perusal.

While accepting, in the main, the arguments advanced by Dr. Griffith, and believing them to contain the germ of a great truth, there are some points to which I think we may take exception. In the first place (such eminent authorities as Paget notwithstanding), the propriety of dividing scarlatina into two distinct forms, such division being dependent upon a hypothetical difference in their etiology, is questionable. The occurrence of efflorescence, pyrexia, desquamation, and albuminuria, one or all, consequent upon the ingestion of tomatoes (which ordinarily are a healthful article of diet), does not constitute scarlatina, any more than pain in the side, fever and cough, one or all, constitute a pneumonia, but such scarlatinoid symptoms simply indicate that the poison, whatever it may have been, has the same physiological action as the *materies morbi* of scarlatina. The similarity of symptoms does not indicate a similarity of poison, but that there is some physiological co-relation due to the fact that the effects of both poisons are manifested through their influence upon the same portion of the economy, viz.: the sympathetic ganglia and trophic nerves. The "toxæmic scarlatina" is probably not scarlatina at all, being simply a collection of morbid phenomena due to profound disturbance of the sympathetic ganglia, by a powerful organic poison, and perhaps influenced greatly by

idiosyncrasy. Some persons cannot eat shell-fish without a severe resultant urticaria, not because shell-fish *per se* are poisonous, but because the sympathetic system in such individuals is intolerant of that particular article of diet. As Dr. Griffith states, belladonna produces an efflorescence resembling scarlatina. Quinine, copaiba and other drugs will produce an eruption, and in the case of quinine especially, usually in cases of idiosyncrasy. The specific poison of syphilis produces an eruption resembling measles, which is entirely independent of cell proliferation. This "roseola" is transitory, and produces no permanent change in the tissues affected. We could hardly accept these phenomena as evidences of their identity with measles or scarlatina. But there must be some explanation of their similarity, and that is the fact that *certain poisons act upon the system through the medium of some physiological disturbance of the sympathetic*. The medium being the same in all cases, a similarity of the resultant morbid phenomena might reasonably be expected. Perhaps, as the author states, the difference between the different series of phenomena, as developed particularly in the two forms of scarlatina, lies only in "origin," but that is often a very wide difference. The only essential difference between narcotic and uræmic coma is in their origin, yet they are not the same. It is the peculiar origin of each that constitutes the disease.

The author is quite correct when he asserts that the absence of desquamation and albuminuria is no proof that scarlatina is not present in a given case, but at the same time that fact could hardly be advanced as evidence of the unity of origin of "orthodox" scarlatina, and the systemic disturbance caused by the ingestion of tomatoes, or too high game. Even if both phenomena were quite frequently present in the so-called "toxæmic" scarlatina, they could be quite readily explained, without recourse to the theory of "unity." Desquamation might readily follow any peripheral irritation which interfered with the nutrition of the skin, and as is well known, the same factor of peripheral irritation would explain the albuminuria. As has been shown by Mihrau¹ a full hot bath will produce it. Irrespective of the cause, a vicarious strain upon the secretory structure of the kidney may be quite as effective in the production of albuminuria, as may the selective action of some poison.

While I am heartily in accord with the author in his opinion as to the co-relation of the poisons of disease in general, and especially with the explanation of such an interdependence based upon evolutionary laws, I incline to the belief that the tomato argument is not of great weight. It is hardly safe to attempt to support so radical a position, with so few cases. Again, it must be acknowledged, that it is only in a very small proportion of cases that we can trace our cases of scarlatina to their sources of contagion. In the instance of both the tomato and game cases cited by Dr. Griffith, a mere coincidence is highly probable.

¹These de Paris, 1832.

In a case of puerperal scarlatina, (even if the occurrence of a "toxæmic" form of scarlatina be admitted) it would be absolutely impossible to differentiate it from true scarlatina with a complicating septæmia, which is more than likely to occur, and which in my own estimation, is the explanation of the fatal character of scarlatina in the puerpera, whose secretions become septic as soon as the woman is attacked by the specific disease. The case of "toxæmic" puerperal scarlatina cited by the author, is an ideal picture of scarlatina in the puerpera, complicated by septæmia. I can see no logical reason for the inference that such a case of scarlatina is caused by septic infection.

If such were the case, the disease would occur more frequently in our hospitals, where septæmia is so frequently seen. Even from the evolutionary standpoint, (which in the basis of Dr. Griffith's views) it would be very difficult to explain so sudden a transformation of simple septic matter into the *materies morbi* of scarlatina, as such an occurrence in the puerpera would imply, particularly in cases of auto-sepsis. The law of evolution is certain, but it is as gradual as it is certain and irresistible. The train of symptoms referred to by the author may not be rare in London, but they are certainly rare in this country, as I think will be conceded by our physicians of extensive midwifery experience, and their rarity is still greater, if cases of indubitable contagion be excluded. As for the *de novo* origin of scarlatina, it can hardly be possible under the circumstances mentioned by Dr. Griffith.

But can scarlatina ever be developed *de novo*? I am quite ready to believe that it can; *but such development must occur by a normal and gradual process of evolution, not suddenly by autogenesis through the medium of a simple septæmia.* Scarlatina has its own peculiar and specific germ, *materies morbi*, or whatever we may choose to term it, and this cannot develop spontaneously in the true sense of the term, *but in the presence of an appropriate environment, the minute organisms (or minute particles of organic matter, if such be the term preferred) everywhere present in the atmosphere, may by a slow and certain process of evolution, undergo a transformation, and acquire new properties by virtue of which they become infectious, and capable of producing disease of a specific type.*

In the same way, organisms of a higher specific type may retrograde, and become harmless. These views may serve to explain the gradual rise and decline of intensity of epidemics. The increase and decrease of virulency of specific diseases may thus be due to imperceptible changes of environment. The propriety of this adaptation of the great truths of evolution to the explanation of the origin and natural history of disease, will of course be disputed by all who oppose evolution as a whole, but if the theory of evolution be correct, and the germ theory of disease be proven, the co-relation of the two is indisputable. *Accept evolution, and we must accept the evolutionary theory of disease.*

It is extremely doubtful whether the processes of simple fermentation and putrefaction are capable of

developing the *materies morbi* of specific disease (that of scarlatina for example) an occurrence which to Dr. Griffith, appears highly probable. Septic materials, when introduced into the stomach, are speedily shorn of much of their noxiousness, and the results of such ingesta are as a rule, chiefly local. The gastric juice is the great physiological antiseptic, and constitutes an almost impenetrable barrier to many noxious materials of an organic nature. That simple lactic fermentation is capable of developing a systemic poison of a specific character, I am hardly prepared to believe, and surely, we have very few facts to support such a theory. Fortunately for us, the gastrointestinal tract is very intolerant of many of the injurious products of fermentation and decomposition, and this intolerance results in their elimination, before they have had an opportunity to act injuriously upon the general nutrition.

In confirmation of his views the author quotes Sir Wm. Gull as stating "that diphtheria may commence locally, forming a poison which will propagate itself," he having consequently come to recognize two distinctive forms of diphtheria.

Now I am under the impression that it is a well recognized fact that diphtheria may commence locally by inoculation, and it is supposed by the majority of observers, that such commencement can occur in no other way. There is, however, no clinical distinction as far as known, between the cases resulting from inoculation, and those from constitutional infection. Gull's theory does not imply inoculation, but a spontaneous development of the diphtheritic poison. This I believe may occur, but in a manner so gradual, that it is extremely difficult to say where a simple process terminates and a specific begins. In accepting this view, however, I can see no grounds for differentiating the disease into two distinct forms. The degree of severity may differ in different cases, but the type of disease remains unaltered. Again, admitting Gull's theory as to the origin of diphtheria to be correct, it is difficult to understand how it can be adduced as evidence in favor of simple lactic fermentation developing scarlatina.

That the noxious vapors and gases of the sewer are capable of producing a variety of diseases, is well known, but it is quite generally accepted that such sewer emanations contain the distinctive germs of these different affections. There would seem to be, however, many peculiar cases which are hardly explicable upon the ground of a specific germ infection, and it is just here that an acceptance of Dr. Griffith's views is almost unavoidable, at least, in so far as his doctrine of the interdependence of the various poisons of disease and their unity of origin in certain instances, is concerned. As before stated, however, I believe that the transformation of the one original poison into a number which affect the human system by the production of various so-called specific disorders, must occur through a gradual process of evolution, and not by a sudden metamorphosis such as must occur if the author's deductions regarding the origin of his cases of scarlatina be correct.

There are many striking facts bearing out the theory of "unity of poison." The close similarity between

certain malarial fevers and typhoid, between typhoid and typhus, and the marked resemblance of a certain febrile condition attended by diarrhoea (which we are so fond of attributing to sewer gas), to typical typhoid, may be explicable from the standpoint of unity. There must be something more than professional stupidity to account for the difficulty experienced in differentiating certain diseases, and which almost brings the diagnosis down to the level of guess work. What peculiar combination of circumstances relating to the atmosphere, constitutional condition or hygienic surroundings of the people, determines the prevailing epidemic influence in any given locality, is unknown, and probably will always remain so.

The possibility of the spontaneous origin of specific disease has ever been a source of controversy, but that such an origin is demonstrable will, I think, be evident to anyone who carefully studies some of the more recent epidemics. The late epidemics of typhus fever in New York are excellent examples, and the preponderance of evidence would seem to show that the epidemic of cholera now declining in France, was due to local causes, and consequent spontaneous development of the disease. It is only by a recognition of the *de novo* origin of diseases of a specific type that modern sanitation can accomplish its object.

A very interesting instance was recently reported in the *N. Y. Med. Record*, by Dr. L. J. W. Lee,¹ which would appear to be strong evidence in favor of the theory of unity. In this instance, among ten cases of disease in one house, variola, varicella, measles, typhoid, and remittent fever were said to be represented. As might be imagined, the theory of unity of poison is not an easy one to support by actual demonstration, *e. g.*, it would be difficult to prove in any given instance, that the emanations from the sewer, did not contain germs derived directly from cases of specific disease.

The theory of unity as I understand it is in nowise opposed to the germ theory, and the same may be said of the theory of the spontaneous origin of specific disease. Each may take as its point of departure, the harmless organisms universally a component of the atmosphere. These organisms, from causes not at present definitely known, but unquestionably by a gradual process of evolution and adaptation to environment, become metamorphosed into poisonous germs, which, when introduced in the human system, will produce disease. An example of this is quoted by Dr. Griffith,² from Paget.³ In this instance, occurring on board a vessel at sea, a sailor wounded his hand with a beef bone, (the condition of the bone is not stated, and there is reason to surmise that it may have been poisonous from decomposition), the injury being followed by fatal cellulitis with axillary suppuration. Subsequently, cellular or erysipelatous inflammation in various forms, ran through the whole ship's company, and terminated in an epidemic of mumps. The whole

course of disease was over a month, the ship being at sea the whole time, and during the greater part of it, in the severe cold of a southern winter. Here, the first case in the presence of the crowd poison always present on board ship, afforded a laboratory for the formation of an intensely infectious poison, which in consequence of the intimate relations existing between the members of the ship's company, had no obstacle to its dissemination. Whether the parotitis was the genuine "mumps" or not is questionable. It may have been, in a mild form, the same inflammation of the parotid, which is liable to occur in pyæmia, septic peritonitis (so-called), and other toxæmiæ. A case is cited by Dr. Griffith from his own experience, which, although interesting, is open to the same objections offered to some of his other evidences in favor of "unity of poison." In this case a patient convalescing from typhoid fever suddenly developed symptoms of scarlatina. Cases of true scarlatina, or of scarlatinal sore throat, were present at the time, or had been present in the house. "The cause of the outbreaks was, as far as could be determined, the defective drains." Now, these causes probably did result from the same cause as far as the sewer exhalations were concerned, but, unfortunately, sewer gas is a compound and decidedly complex substance, and in this case, as in others, may have contained the germs of several specific and distinct diseases. I wish that it were possible to accept such evidences of "unity of poison" as indubitable, as it would greatly simplify our studies of etiology. As I have already remarked, I believe it extremely difficult to support the theory by actual demonstration, but, nevertheless, the known facts and powerful evidences of the theory of evolution in general, associated with our knowledge of the germ origin of disease, render the theory of "unity of poison" one of the most logical explanations of the causation and differentiation of disease, yet advanced. I believe, however, that the common origin of the poisons of disease is not a poison, but a harmless microscopic organism.

MEDICAL PROGRESS.

OBSTETRICS AND GYNÆCOLOGY.

MASSAGE IN GYNÆCOLOGY.—Dr. Prochownik has recently read a paper on this subject at the *Versammlung Deutscher Naturforscher und Aerzte* at Magdeburg, a translation of which is given in the *Medical Chronicle*. He refers to the doubt and reserve with which this reintroduction of massage into therapeutics was received, and acknowledges that its results were certainly for a time exaggerated, and that in consequence it fell into the hands of the humbler sort of practitioners and of quack specialists. But already the results of massage in surgery, and even in gynæcology, in the hands of some of the operators by profession, have been so striking that the subject urgently challenges an experimental investigation. As one who has freely used it for two and a quarter

¹Influence of diathesis upon contagion. *N. Y. Med. Rec.* Vol. xxv, No. v, p. 84.

²*Midland Medical Miscellany*.

³Paget, *Surgical Pathology*, 3d Ed. P. 373.

years in gynæcology, he sets forth a number of exactly formulated and easily discussed propositions, viz.:

1. The employment of massage in gynæcological therapeutics aims at the acceleration of the absorption of pathological products, the stimulation of the circulation, the stretching of shrunken and cicatricial tissue, rarely the production of contraction. Parallel with these objects the following diseased conditions come under consideration as the most suitable for treatment by massage, viz.: Transudations, exudations, metritis, subinvolution with loss of tone, cicatricial stricture, and contractions with their resulting conditions, rarely neoplasms.

2. Massage should never be employed except when all other therapeutic agents have failed. Every course of treatment by massage is tedious, often lasting for months, and it is almost always painful. Patients decide more readily to submit to this when other remedies have failed.

3. Another previous condition to the practice of massage is an exact differential diagnosis, the result of careful, combined examination. We must not hesitate to make an examination under an anæsthetic, in order to make the diagnosis clear and definite.

4. Gynæcological massage divides itself into an external and an internal. External massage is very little used, but it is advisable in most courses of treatment to begin with it, if only to test the amount of sensibility. The circumscribed employment of external massage depends upon the fact that only in a small number of patients is it possible by external manipulation to produce any effect upon the organs of the true pelvis, because every kind of massage requires a certain amount of resistance for its efficiency. The employment of massage as a test of sensitiveness is suitable for most patients, but not for all; there are women who are completely intolerant of internal measures, and who cannot bear external manipulation. The mode of employing external massage is almost exclusively by friction, a process which is easier to show than to describe. For gynæcological purposes it may be conducted as follows: The palm of the hand is laid flat, and supported upon the venter of the ilium, the rami of the pubis, the surface of the sacrum, or the psoas muscles; then, while the abdominal muscles are kept as relaxed as possible, with the tips of two or more fingers the operator seeks from the front or from the side to work down upon the part or organ to be influenced, and to draw it against one of the underlying parts, or to press it down upon or against some resisting object.

5. Internal massage divides itself into *active* and *passive*. The active form consists in a process of kneading, of pulling, and pushing, by means of the two hands working together, the fingers of one being placed in the vagina (more rarely in the rectum), of the other on the abdomen. The passive form depends on the introduction of cylinders into the vagina, for the purpose of widening and of stretching the tissues. Active, or "combined massage," is that which has hitherto been most frequently practiced. It consists in kneading the affected part—that

is to say, the operator tries from the vagina and abdominal surface to take the part between the fingers, and to rub, and press, and squeeze it. With this process of kneading may be associated a form suitable for gynæcological cases, consisting in pressing and drawing the part in various directions, according to the object to be attained. It is specially efficacious in dealing with cicatricial bands, and often affords better results, with less pain, than the kneading process.

Few women can tolerate the process more than once or twice a day, for from ten to fifteen minutes each time. Apart from the pain, a marked impression is produced upon the nervous system; sexual excitement can easily be avoided, but there is a nervous excitement of quite a different character, which is often produced by gynæcological manipulations, even in the most unimpressionable women. Only the courses of treatment which are regularly and systematically carried out with as few interruptions as possible are followed by any satisfactory result; the performance of the process of active massage only twice or three times a week produces little or no effect; the only means by which active massage can be reduced to two or three sittings a week is by employing passive massage in the intervals. This is similar to that sometimes carried out in the preparation of a patient for the operation of vesico-vaginal fistula when there are cicatrices in the vagina, or in cases of vaginismus. A series of vulcanite cylinders are employed to gradually dilate the parts contracted by cicatrix or spasm.

6. Massage may be advantageously combined with baths or with other therapeutic agents, such as iodine or iodoform.

7. (a) An absolute contra-indication is every acute disease, even if it runs its course without fever, and every sub-acute disease which has been accompanied by rise of temperature in its acute stage. In cases of exudation it is a safeguard against mishaps if we make two to three months' absence of fever a condition of employing massage; in the case of hæmatocele we may make a beginning six to eight weeks from its occurrence.

(b) Conditional contra-indications are: pregnancy, suspicion of consumption, perhaps latent gonorrhœa. In the first month of pregnancy we may cautiously employ active massage upon painful cicatricial bands. In the later months passive massage may be used for cicatrices of the vagina from whatever cause. In one case, from a consumptive family, with catarrh of the apices an attack of pleurisy seemed to have been set up by the process. In ten cases undoubted latent gonorrhœa was followed by very painful joint affections, which were associated with slight fever.

Of the results obtained, from July, 1882, to July, 1884, 102 women were treated by massage. In the beginning 16 would not go on with the treatment, from the pain produced and due to the inexperience of the operator. Of the remaining 86, five were cases of new formations—three of these were cases of small intra-ligamentary tumors, two disappeared without any concomitant bad symptoms and with no return. The attempt to aid the gradual enucleation

of submucous fibroids failed in two cases. Thirteen times was massage undertaken for prolapse of the uterus. Only once, in a case of slight prolapse, was a cure effected; twice there was slight improvement. In marked prolapse or in complete procidentia, there was never any kind of improvement. Ten cases of chronic metritis and subinvolution were treated by massage, they were all of specially long duration and obstinacy, so that a complete cure in four cases and improvement in three is a very noteworthy result. Of 18 cases of exudation (including 5 cases of hæmatocele) 8 were completely cured (including 2 of hæmatocele), 2 were relieved to the extent of an entire absence of symptoms, and a less degree of improvement occurred in three. No case was met with in which fresh inflammation was set up in an old exudation, but extreme caution was used in applying massage to exudation cases.

The largest class of cases suitable for massage are the old cicatricial, contracted remnants of exudation, callous cicatricial bands upon a basis of simple inflammation, with the changes in the position of the uterus and ovaries depending upon these conditions. Out of 40 such cases, 24 were cured, and of 10 improved, 8 were in a clinical sense also cured.

It would be foolish to call these results brilliant; it would, however, be a mistake to overlook their value. If we remember that in every case other therapeutic measures had preceded, and when we think how little success we have attained in the cure of old exudations and the dissipation of obstinate cicatricial bands, we must admit that the results here obtained are sufficient to challenge a further trial of massage in gynaecology.

INFLUENCE OF AGE ON PRIMIPAROUS LABOR.—As in comparison with the views of Courtade on this subject, given on page 409 of this journal, we append the views of Kleinwächter (*Zeit. f. Geburt u. Gynäk., Practitioner*) who found his material in the records of 920 cases of primiparæ in his clinic at Innsbruck. These cases he divides into three groups, namely: (I.) 16 to 19 years of age, 111 cases; (II.) 20 to 29 years of age, 694 cases; (III.) 30 to 41 years of age, 115 cases. These groups he designated as the young, the middle-aged, and the old, respectively. From his study of these cases he draws the following conclusions: (1.) Accidental complications, which have nothing to do with pregnancy, occur least often in the youngest primiparæ and most frequently in the old. (2.) Ailments attributable to pregnancy are observed most frequently in the old and next most frequently in the young. (3.) Hæmorrhages in the course of pregnancy occur most frequently in the young and least frequently in the old. (4.) The duration of labor is most frequently abnormally protracted in the old; in this respect the young stand next to the old. (5.) Inefficient pains, on account of which the duration of labor is abnormally protracted, are least often observed in primiparæ in the bloom of their sexual life, *i. e.*, from 20 to 29, and most frequently in the old. (6.) Therefore forceps must be used most frequently in the old and least often in the middle-aged. (7.) The lengthening of the labor

of primiparæ with the increase of age occurs chiefly in the first stage; the second stage is scarcely affected by differences of age; the third stage is not at all affected. (8.) The mortality per cent. after forceps operations on primiparæ rises parallel with the increase in age. (9.) The older the primipara, the greater is the danger of perineal laceration. (10.) The older the primipara, the more likely a post-partum hæmorrhage, although the frequency of hæmorrhage is by no means so great as hitherto supposed. (11.) With increase of age increases the disposition of primiparæ to affections of the kidneys. (12.) The frequency of œdema without kidney disease also increases with the age. (13.) The older the primipara, the less the danger of mastitis, and the less also the likelihood of her ability to suckle. (14.) The old most frequently, the middle-aged least frequently, sicken and die of puerperal fever; the same is true of puerperal mania. (15.) The morbidity and mortality per cent. is highest in the old and lowest in those from 20 to 29 years of age. (16.) Spontaneous premature labor occurs very frequently in old primiparæ, and least often in the middle-aged. (17.) With increase of age the frequency of abnormal positions of the fœtus increases. (18.) The older the primipara is, the more likely is she to bear a boy, except those from 20 to 21 years of age, who bear more girls than boys. (19.) Analogous to the discovery made by Hecker and confirmed by Wernich, that first-born children are heavier and longer the older the mothers are, is the fact that the umbilical cord of the first-born of old mothers falls off the earliest, and that of the first-born of the youngest mothers the latest. (20.) The liability to twin pregnancy in primiparæ increases with their age. (21.) With increase of age in primiparæ the frequency of bearing deformed children diminishes. (22.) The mortality per cent. of first-born children increases with the mothers' age; among the oldest primiparæ the fœtal mortality reaches a not inconsiderable height.

MEDICINE.

EXPERIMENTS ON CHRONIC DRUNKENNESS.—During the last three years MM. Dujardin-Beaumetz and Andigé have worked at this subject with a perseverance which has justly gained the approval of men of science in all countries. The animals chosen for experimenting upon were pigs, for these reasons, that it is so easy to make them partake of alcoholic substances in their foods, and also that their digestive organs are very similar to those of human beings. Eighteen of these animals, aged 4 months, were submitted to the same *regime* at Grenille. They were given daily to each kilogramme of their food, weighed out as follows, 1–2 grammes of any one of the following spirits: Ethylic alcohol at 100°, potato spirit ten times rectified at 49°, potato spirit purified by charcoal at 46°, distillery grains at 92°, potatoes at 73°, grains at 37°, beetroot at 34°, spirit of beetroot rectified at 92°, and trade amylic acid at 90°. As long as the dose did not exceed one gramme

there were no difficulties of digestion, but when $1\frac{1}{2}$ to 2 grammes were given the pigs lost their appetite, and their organs became impaired. Thus, it was necessary to suspend the treatment occasionally, to prevent serious results. The symptoms were found to be exactly similar to those of human beings suffering from chronic drunkenness. As regards the digestive functions, there were—loss of appetite, bilious or shiny vomiting, and bloody-mucus diarrhoea. There was also observed anomalous redness of stomachic mucus, occasionally congestion of the intestines, and once or twice violent ecchymoses comparable to the spots to be seen on the intestinal mucus of dogs dying of acute alcohol. These gastro-intestinal anatomical symptoms were much less marked than the functional troubles. The bilious secretion was also abnormal, as was proved by the yellow color of the conjunctivæ and urine, but in the autopsy the congestion of the liver and the friability of the parenchyma were only observed during the complete absence of interstitial hepatitis and acidity. The urine was little changed, only presenting a bilious appearance. The renal tissue was greasy, but this is very common among pigs. Nearly all the pigs suffered from a cough, and at the autopsy the lungs were shown to be congested, and sometimes in an apoplectic condition; the former was caused by the elimination of alcohol by the air tubules, and by the cold during the experiments. The organs of circulation were unaltered. The modifications of the nervous system were shown by drunkenness, the animals falling into a torpor soon after digesting the alcohol, but the ordinary excitement was not visible. After a time trembling was noticed, and want of strength in the limbs. The experiments, however, did not interfere with the fattening of the animals, but their sale for food was prohibited, as there existed in the flesh interstitial hæmorrhage of the muscular parenchyma.—*The Medical Press*.

THE DIFFERENTIAL DIAGNOSIS OF AMBLYOPIA.—M. Danir (*Bulletin de la Société Française d'Ophthalmologie; Med. Times*) finds that in the normal state, and in amblyopia without any lesion, a luminous impression is produced on the eye by the closure of an electric current of less intensity than one-tenth of a milli-ampère, whilst in cases where the optic nerve is undergoing atrophy, a current of much greater intensity is needed to produce the same minimum luminous impression. It was especially in respect of prognosis that he found this test the most useful. When, in a case of amblyopia, whether the disc was pale or not, the electrical reaction was normal, he found that the sight was eventually recovered; and, on the other hand, when the electrical reaction was diminished, then the prognosis as to recovery of sight was unfavorable. The *modus operandi* is simple. The positive pole is placed on the forehead, midway between the eyes, and maintained there by an india-rubber band; the negative pole, which is olive-shaped, is made to touch the upper and outer part of the eyeball. The circuit is then completed, and a sufficiently strong current passed to produce a very evident luminous

impression, in order that there may be no mistake, and the patient may understand what it is that he is to be on the lookout for. When this has been explained to him, the strength of the current is very gradually diminished until only at the closure of the current there is perceived the very faintest spark, which is not recognized at the opening. In health it is, as has been already stated, only necessary to employ a current of the intensity of one-tenth of a milli-ampère to obtain this, and this serves as the standard whereby to measure various degrees of impairment. In optic atrophy, sclerosis of the optic nerves, atrophy after neuritis, after embolism or hæmorrhage, the electric spark is only produced by a stronger current. In amblyopia from alcohol or tobacco the electrical reaction is normal, as it also is in congenital amblyopia and in some cases of hysterical amblyopia.

SURGERY.

ECHINOCOCCUS OF THE NECK.—Dr. Lindpainter, of Munich, reports a case of the above in the late *Festschrift des Ärztlichen Verein, (The Medical Press.)* The patient had noticed an enlargement of the neck, principally on the left side, from his earliest youth. About ten years ago, after forced yawning it increased rapidly in size, so that a considerable tumor developed behind the sterno-cleido-mastoid muscle, which caused difficulty of breathing, and was diagnosed by various physicians as struma. On August 20, 1882, Dr. Lindpainter was called to perform the operation of tracheotomy on account of the difficulty in breathing. He found on the left side of the neck a tumor the size of a man's fist, reaching from the clavicle to the ear. The trachea was forced over to the right, and flexed, so that respiration was exceedingly difficult, and the œsophagus was also so much compressed that fluids even could only be swallowed with difficulty. Dr. Lindpainter took the tumor for a solid struma, calling for tracheotomy, but upon examining more closely he discovered in a small spot above the clavicle distinct fluctuation. After puncture and the evacuation of about three ccm. of clear watery fluid, fluctuation was noted in another part; he punctured this also, and let out about 5 ccm. of similar fluid, after which the trachea straightened itself, and the breathing at once became easy. Examination of the escaped fluid showed the presence of hooklets, and the only further question was the extirpation of the echinococcus. He determined upon incision and drainage. He accordingly incised and inserted a drain on September 2, and in the beginning of December, as no more cysts by that time appeared, the drainage-tube was removed, and in a day or two the wound healed, and at the date of the report the neck appeared quite well.

SATURDAY, DECEMBER 20, 1884.

THE USEFULNESS OF THE NOSE IN DIAGNOSIS.—Probably every physician sees times in his examination of patients, when he devoutly wishes he had no olfactory nerves, or, since to be deprived of the sense of smell would at the same time also deprive him of the possibility of certain keen enjoyments, he prays for that happy condition of the farmer, who, when asked by a young theologian, if he objected to his saying grace at the table, replied, "Oh, no! say what you have a mind to, you can't turn my stomach." Unpleasant as the possession of a nose often is, there are occasions when its delicate appreciation of odors is fortunate. Nay, furthermore, it seems sometimes serviceable in guiding a physician to a correct diagnosis. All are familiar with the fetor of the air expired in cases of pulmonary gangrene. Likewise, the breath of patients suffering from chronic copper and lead poisoning has a foul, strongly suggestive smell.

A peculiar smell of the breath in other diseases has been repeatedly noted by trustworthy observers. Thus, a urinous odor has been detected in the breath of patients suffering from retention of urea in the system from renal disease. The act of coition is stated by a German whose name we cannot recall, to impart a very characteristic odor to the breath. It is needless to allude to disordered stomachs and constipated bowels, bronchorrhœa, decayed teeth, nasal catarrh, and numberless other conditions familiar to every physician, as productive of a foul breath that often leads to a diagnosis upon the very entrance of a patient into the consulting office.

The fetor of uterine cancer is so proverbial that its very mention seems superfluous. *Apropos* of this offensive smell, Dr. Middleton Goldsmith, of Rutland, Vt., in a contribution to the *New York Medical Record*, Nov. 29, 1884, entitled, "Some New Facts and Considerations in the Diagnosis of Cancer of the Stomach and Cancer of the Pancreas," cites a case in which the eructations emitted a fetor identical with that of carcinoma uteri. Gastric symptoms usually met with in cancer of the stomach were not marked, though a pronounced cachexia was present. The autopsy revealed an encephaloid cancer involving almost the entire stomach. Upon being accidentally torn into, the organ emitted an overpowering stench identical with that having distinguished the eructations in life. Dr. Goldsmith says this fetor is not invariably present, but that, when it obtains, it may be regarded as pathognomonic of gastric cancer. The fact is well worth remembering.

Peculiar odors do not proceed exclusively from mucous membranes, the skin sometimes emits an unnatural smell in disease.

A pungent mice-like odor is said to be characteristic of typhus.

A sour smell is sometimes perceived to proceed from persons ill with acute articular rheumatism. We do not recall any reference in medical literature, to a singular odor of the perspiration sometimes encountered in phthisical patients. But we recollect vividly two instances in which we were struck by this peculiarity. The first case was that of a man who had a very extensive consolidation of both apices.

The odor did not impress us specially, until a few minutes afterward upon approaching another patient, already stripped for examination, when the same odor met us, surrounding the man like a cloud. At once, without considering the rashness of the statement, we exclaimed to those about, this is a case of chronic consolidation of the lungs. Luckily the examination sustained the diagnosis. In these instances, the odor could not have been due to the medicines taken, as these were devoid of special scent. Whether there be anything in this or not, peculiar odors associated with some diseases are so well established as to render the nose of the diagnostician anything but superfluous.

SECTION of Practice of Medicine and Materia Medica of the American Medical Association:

The Chairman of this Section earnestly requests all who intend to present papers in it during the coming meeting in New Orleans, to forward the titles and

table of contents of such papers to Dr. H. D. Didama, Chairman, Syracuse, N. Y., or to Dr. Garland, Secretary, Hotel Aubery, Boston, Mass., as early as possible, that they may aid the Committee of Arrangements in having the full programme printed and ready for the use of members who may attend the meeting in New Orleans.

The same thing is desirable in reference to all who expect to read or present papers in any of the Sections of the Association.

The Chairman or Secretary of the Section to which the paper would belong should be notified of the title and contents of the paper as early as possible; and the officers of all the Sections should report to the Chairman of the Committee of Arrangements at least one month before the time of the annual meeting. We urge attention to this now, because heretofore the Chairman of the Committee of Arrangements has been embarrassed and delayed every year, in making up and printing the programme of work for the annual meeting, on account of the neglect of writers to give proper and timely notice of their intention to present papers.

CHOLERA BACILLI.—The statements in regard to the effects of this micro-organism are as variable or contradictory as ever.

While Dr. E. Van Ermengen in his communication to the Microscopical Society of Belgium claims to have successfully inoculated dogs, rabbits and guinea-pigs with the cultivated comma-bacilli, Dr. Klein has swallowed liberal doses of bacilli in pure culture, and Dr. Bochefontaine, chief of Vulpian's laboratory, has himself taken a drachm of the intestinal discharge from a cholera patient in the form of pills, both without any effect.

LIST OF PERMANENT MEMBERS OF THE AMERICAN MEDICAL ASSOCIATION.—A by-law or standing rule of the Association requires that a full list of the Permanent Members shall be published in the Transactions every third year. In complying with this rule it will be necessary to occupy the next number of the JOURNAL, which will be the closing one of the third volume, almost wholly with the said list of members, the Librarian's Annual Catalogue of additions to the Library, and the title page with full index of the volume.

COCAINE HYDROCHLORATE.—Under the head of Foreign Correspondence will be found an interesting letter on this and other preparations derived from the coca leaves.

THE CHOLERA appears to have entirely disappeared from France with the exception of Toulon, and the disease lingers in only a few places in Italy.

A NATIONAL BOARD OF HEALTH.—Our readers will remember that a National Conference of State Boards of Health was held in St. Louis during the recent meeting of the American Public Health Association in that city, in which measures were taken to influence the action of Congress in favor of the reëstablishment of a National Board of Health. The members of the Conference appointed to further this object were to reassemble in Washington soon after the opening of the present session of Congress. We are informed that there were present at this last Conference delegates from twenty-five States, and forty principal cities of the United States and Canada. The result has been the preparation of the following bill and its presentation to the Committee on Public Health, by whom it is expected the same will be brought before the two houses of Congress. The bill is as follows:

A BILL.

To amend an Act entitled "An act to prevent the introduction of contagious and infectious diseases into the United States and to establish a National Board of Health."

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, That an Act entitled, "An act to prevent the introduction of contagious and infectious diseases into the United States and to establish a National Board of Health," approved March 3, 1879, be so amended as to provide that there shall be established a National Board of Health, to consist of one member from each State Board of Health now established, or which may be hereafter established in the United States, to be appointed by the President and confirmed by the Senate, whose compensation when actually engaged in the performance of duty under this act, shall be ten dollars per diem each, and reasonable expenses. This board shall meet in Washington within ninety days after the passage of this Act, and shall meet in Washington annually, and in case of emergency upon the call of its chairman and secretary, or upon the extraordinary call of the President of the United States, as hereinafter provided.

The officers of this board shall be a chairman and secretary. The Secretary shall be the executive officer of and ex officio a member of the board, and shall devote his entire time to the duties of the office, and may be removed for cause, at any regular meeting of the board, two-thirds of the full board voting therefor, and shall receive such salary as may be determined by the board. The chairman with six other members, representing the various geographical divisions of the country, shall constitute the executive committee of the board, to be elected at the first meeting of the board, and at each annual meeting thereafter, and said committee shall, and is hereby authorized to exercise such powers as may from time to time be conferred upon it by the board.

SEC. 2. The duties of this board shall be, and it is hereby authorized and given power to make or cause

to be made, such investigations at any place within the United States, or at any foreign port or place, and to collect information upon all matters relating to the public health, and to frame such rules and regulations as may be necessary for the government of the quarantine service of the United States; and all the power and authority now provided by law, or which may be provided by law, for the control and protection of the public health of the United States, shall be and are hereby vested in said board, except as to the special authority vested in the President of the United States under the provisions of this act. The rules and regulations of this board shall severally be executed, under the direction of this board, through such Departments of the Government, or other officers, as the law may prescribe or the President may designate.

This board shall coöperate with, and so far as it lawfully may, shall aid State and local boards of health in the enforcement of the rules and regulations of such boards, to prevent the introduction of contagious and infectious diseases from foreign countries into the United States, and into one State from another.

SEC. 3. It shall be the duty of this board to make such rules and regulations as are necessary to be observed by vessels at ports of departure, where such vessels sail from any foreign port or place to any port or place in the United States to secure the best sanitary condition of such vessel, her cargo, passengers and crew, and to prepare from time to time for the consular officers of the United States, and for the medical officers serving under this act at any foreign port, and otherwise make publicly known such rules and regulations, which, when approved by the President and issued by the Department of State, and posted in the office of the consul or other representatives of the United States at such foreign ports for at least ten days, shall be enforced by the consular officers and agents of the United States.

SEC. 4. It shall be unlawful for any vessel from any foreign port or place to enter any port in the United States, except in accordance with the rules and regulations made in pursuance of this act, and of the rules and regulations made under State or municipal authority, and any such vessel which shall attempt to enter any port of the United States in violation thereof, shall be liable to process in the proper district court of the United States, and upon conviction, shall forfeit to the United States a sum to be awarded in the discretion of the court, not exceeding \$1,000, which shall be a lien upon such vessel to be recovered upon proceeding in the proper district court of the United States, in accordance with the rules and laws governing cases of seizure of vessels for violation of the revenue laws, and in all such cases the United States attorney for such district shall appear on behalf of the United States; and all such vessels shall obtain from the consular or authorized medical officer at the port of departure, a certificate in duplicate, setting forth the sanitary history of said vessel, and that it has in all respects complied with the rules and regulations of this board, made in pursuance of this act for the government of such vessels, and be-

fore granting such certificate such consular or medical officer is required to be satisfied that the statements therein made are true; and upon the request of this board, the President of the United States is hereby authorized to appoint proper medical officers, to serve in the offices of the consuls at any such foreign ports, to make the inspections and give the certificate herein required.

SEC. 5. Such vessels shall observe all rules and regulations made by this board in pursuance of this act, in regard to the inspection, disinfection and isolation of the same, upon its arrival at any port in the United States and for the treatment of persons and cargo on board, so as to prevent the introduction of contagious diseases into the United States, and it shall be unlawful for any vessel to enter such port, to land its passengers or discharge its cargo except upon a certificate from the health officer of such port, that such rules and regulations have in all respects been complied with.

SEC. 6. In the event of any sudden emergency, threatening the importation of contagious or infectious disease into the United States from any foreign country, the President of the United States is hereby authorized and required, in his discretion, to adopt and make known forthwith by public proclamation, such measures as may meet the emergency, either by suspending the introduction into the United States by land or sea, of any specified merchandise calculated to be a vehicle for the communication of contagion, or by prohibiting the entry into the ports of the United States of vessels coming from infected countries or having contagious or infectious disease on board. And in case the President shall at any time exercise the authority hereby conferred upon him, he shall, at or before the time of issuing such proclamation as aforesaid, convene the National Board of Health, to meet at Washington in special session within ten days from the date of such notice of convention, and the said board shall thereupon advise such measures as it may deem sufficient to meet the emergency; and upon the taking effect of such measures, with the approval of the President of the United States as herein provided, the President's proclamation aforesaid shall cease to have effect. It shall be the duty of this Board at all times to give prompt attention to any question in sanitary science which may be submitted to it by the President.

SEC. 7. It shall be the duty of the Department of State, to obtain from the consular officers at foreign ports or places, all available information in regard to the sanitary condition of such ports and places, and to transmit the same to this board; and it shall be the duty of this board to obtain from the State and municipal health authorities throughout the United States, and from all other available sources, weekly reports of the sanitary condition of ports and places within the United States, and reports and other matters relating to climatic and other conditions affecting the public health, and it shall prepare, publish and transmit to State and other authorities, and other proper persons, weekly abstracts of such reports, consular reports, and other useful information relating to the public health; and it shall make to the President,

for transmission to Congress, an annual report of its transactions, with such recommendations as it may deem important to the public health; and the necessary printing of the board shall be done at the Government Printing Office, upon the requisition of the secretary of such board, in the same manner and subject to the same provisions as other public printing for the several Departments of the Government.

SEC. 8. The President of the United States is authorized, when requested by this board, and when the same can be done without prejudice to the public service, to detail officers from the several Departments of the Government, for temporary duty, to act under the direction of this board in carrying out the provisions of this act, and such officers shall receive no additional compensation, except for actual and necessary expenses incurred in the performance of such duties.

SEC. 9. To meet the expenses incurred in carrying out the provisions of this act, the sum of \$500,000, or so much thereof as may be necessary, is hereby appropriated, to be disbursed under the direction of the board; and the board shall have authority to appoint such disbursing agents as it deems necessary, who shall give bond as in other cases, for the faithful performance of their duties.

SEC. 10. All acts and parts of acts in conflict with any of the provisions of this act shall be, and are hereby, repealed.

Assuming that there should be some responsible and efficient national health organization, as an aid to the Government in preventing the introduction and spread of infectious and contagious diseases, it becomes a very important question whether such organization should consist of a National Board composed of one member from each State in the Union, as proposed in the above bill, or of a regular Government Bureau of Health, with a single responsible medical man at its head, on the same basis as the Bureau of Education, or of Agriculture, as was advocated by Dr. D. J. Roberts in his address as Chairman of the Section of Hygiene and State Medicine of the American Medical Association at its meeting in May last. We trust the whole subject will receive a full and impartial consideration both by Congress and the medical profession.

SOCIETY PROCEEDINGS.

CHICAGO MEDICAL SOCIETY.

At the semi-monthly meeting held on the evening of December 1, 1884, the regular order of scientific and other important business was upon motion, temporarily suspended, and the following appropriate remarks and resolutions of respect relative to the death of Dr. Abram Groesbeck, an old and well-known physician and Fellow of the Society whose demise occurred November 25, 1884, at the age of 74

years, 7 months and 15 days, were introduced by Dr. R. C. Hamill and unanimously adopted.

LISTON H. MONTGOMERY, M.D.,
Secretary.

MR. PRESIDENT AND FELLOW MEMBERS OF THE CHICAGO MEDICAL SOCIETY:—I arise to offer a tribute of respect to the memory of a beloved member of this Society, who in the Providence of God, has been suddenly summoned from our midst to appear at the council chamber of the Great Physician.

Death has made many reprisals from the ranks of our profession in these last years. Some who had just entered the portals of professional life, with bright prospects of eminent success in full view, have been cut off in the very flower of their days—others in the vigor and maturity of their years manfully bearing their part in the battle of life have fallen in full clad armor in the front ranks—but he to whom I call your attention to-night, had more than filled his cycle of three score years and ten, and a half century of that time has been devoted to professional services at the bedside of the sick and suffering.

"The leaves of the oak and willow shall fade,
Be scattered around and together be laid;
And the young and the old, and the low and the high,
Shall moulder to dust and together shall lie."

* * * * *
"The hand of the King that the sceptre hath borne,
The brow of the Priest that the mitre had worn;
The eye of the Sage and the heart of the brave,
Are hidden and lost in the depth of the grave."

Dr. Abram Groesbeck was no common man, but a learned and scientific Doctor of Medicine, and a man of decided character, as Fellows present, who have had a more intimate association with him than has been my fortune, in the remarks that are to follow, I am sure will take great pleasure in declaring.

He lived a life of usefulness, and the world is better for such living—he died in the fullness of his years, his intellect unclouded and his love for the literature of the profession as ardent as in the vigor of his days, an honor to the cause to which the energies of a well spent life had been devoted, respected by his fellow practitioners, revered and affectionately beloved by the families who for so many years have enjoyed the benefits of his professional skill.

WHEREAS, This Association is called to mourn the loss of one of its beloved members, who, for more than a quarter of a century, has lived the life of an honorable and successful physician in our city;

Resolved, That we contemplate with great pleasure the well-rounded character of Dr. Abram Groesbeck, who has so faithfully filled the measure of a true American physician, and commend his example as a Christian and a physician to those of our number who are entering upon the arduous and responsible duties of our profession. We regret that we are called upon to part with him forever—that we shall meet him no more at the bedside of suffering—in the social circle or in the busy walks of daily life.

Resolved, That whilst we regret to note upon the records of our Society the demise of our greatly respected fellow, yet it is with pleasure we contemplate the fact, that up to the final summons, his men-

tal faculties remained in full strength, and that he was able to contemplate with perfect calmness the approaching catastrophe, saying in that prompt and decisive manner so characteristic of him: "I have accomplished my mission here, and it is better to go now, than suffer the pains and aches incident to extreme age."

Resolved, That we admire the learned and gentlemanly physician, and cherish the example he left us as a rich inheritance, and claim the privilege of dropping a tear of sincere sympathy with the bereaved family, in this, the day of their sorrow.

Resolved, That a copy of these resolutions be sent to the family of the deceased by the Secretary of this Society.

Dr. John Bartlett spoke as follows:

Mr. President: I desire to say a few words in memoriam of the friend and fellow from whom death has just separated us.

Dr. Abram Groesbeck was born at Albany, N. Y., May 24, 1810. He began his medical studies in his native city, becoming a Licentiate of the New York State Medical Society in 1831, and graduating at Albany in 1849. He settled in Chicago in 1856, and continued to practice medicine actively till a few years since, retiring only when he was no longer able to see to write a prescription. It was a circumstance which rendered the very last days of his life happier than "loosed from his environment" in part, as he was by impairment of sight and hearing, and other infirmities, he yet had a few patients to visit. For some years past symptoms of angina pectoris had developed, and two months since he had a violent attack, from which, however, he recovered, and he was in his usual health till the 24th ult., when he was taken without pain with Cheyne-Stoke's respiration, the period of apnoea alternating with rapid breathing each minute. Meanwhile the action of the heart grew feebler for eighteen hours, when unconsciousness supervened, soon followed by death. Dr. Groesbeck was fully aware of his condition, and yet he spoke cheerily to all, not omitting jocosely to rally the profession upon its want of understanding of, and lack of cure for, his ailment. The doctor expressed himself as prepared and willing to depart this life, declaring that his work was done.

He was a member of the Episcopal Church.

Dr. Groesbeck had a tall and graceful figure and a fine face. His features strikingly resembled those of the late Dr. Gross. In manner he was a gentleman of the old school—genial, courteous, amiable. He was of a kindly spirit and benevolent disposition, his most prominent characteristic being sacrifice of self for the advantage of others.

Dr. Groesbeck was endowed with a superior intellect. He received a classical education which led to an appreciation of good literature and the cultivation of excellent taste for the best writers, ancient and modern. His familiarity with the classics he retained in a remarkable degree. It was one of his amusements to confound a friend by leaving his compliments and message on his slate in the language of Celsus. He retained also his knowledge of the

French. Even in the last months of his life he selected for reading such writings as those of Tacitus; and only recently he planned to have read to him again the *Æneid* of Virgil. It gave him great pleasure to exalt the matter and style of the ancients, and to credit them with knowledge, philosophy and rhetorical skill. He liked to dwell among the old moderns, and read with deep interest such works as Pepy's Diary. On one occasion he insisted on leading a medical friend into the Public Library, that he might there read how the physician of one of his favorite old diarists successfully prescribed, hundreds of years ago, milk diet as a cure for diseases of the kidney. Of late years the doctor had been more interested in religious works, as in "Sceptical Fallacies," by W. J. Hall; and in the volume of Henry Drummond, "Natural Law in the Spiritual World." The latter production he pronounced remarkable.

"One of the saddest reflections of my later years," said recently one of the ablest of Chicago's medical men, "is that the many minor means and arts which experience has given me for the cure of disease and the relief of suffering will perish with me." Dr. Groesbeck was an old and skillful practitioner, and yet, so far as I am aware, he has left no record of his experience. It occurs to me as proper here to note a few of the views, which memory now recalls, held by him as the sum of his experience in certain departments of practice. However opposed the views of the doctor may prove to those commonly promulgated by the professional teacher, it is well to grant due weight to the opinions of so experienced and sagacious a practitioner. The doctor was by nature sceptical, and he was ever on his guard lest he might lend credence to some view not thoroughly established. While interested in theory, he was, preferring methods of true empiricism, loth to acknowledge its value. To the enthusiastic germ theorist who might occupy his attention with ingenious possibilities as to the cause of disease, he was ever ready with his chilling query, "*cui bono?*" Long before the German cry "*Fort mit der spray*," was heard over the land, Dr. Groesbeck, when invited to witness an ovariectomy, satirically inquired, "Are they to *play* with the spray?" Dr. Groesbeck often declared himself a disciple of Dr. Todd of London, and for years past had treated pneumonia not as a phlegmasia, but as a form of fever; in some cases giving a bottle of wine in twenty-four hours with apparent advantage. Even the statistical information, furnished since the death of Dr. Todd, adverse to his ideas as to the value of the stimulant treatment, did not change the opinion or practice of Dr. Groesbeck.

Dr. Groesbeck had ever before him in the practice of his profession the strong influence of the mind over the body of the sick. He deemed it a part of the skill of the physician to protect his patient from anxieties and fear. His manner and converse in the sick-room, therefore, were such as to inspire hope and courage in those under his care. It may be stated that Dr. Groesbeck deemed it in practice the part of wisdom to avoid suggesting a consultation; and this, on the ground that it diminished the confidence of the patient in his attendant, and with confidence

shaken, no small part of the power of treatment for good he believed to be lost.

For a number of years past the doctor was afflicted with a degree of deafness precluding anything like satisfactory auscultation. It was remarkable how little this circumstance lessened his confidence in diagnosing diseases of the chest. He trusted entirely to acute observation, and shrewd interpretation of the ordinary symptoms.

The doctor looked upon the placenta blocking the os uteri or vagina after labor as a natural and most useful tampon, and he regarded too early an interference with it as a mischievous interruption of nature in her efforts to close and occlude the uterine vessels. Naturally he agreed with Braithwaite, that in certain conditions of hæmorrhage after labor, the uterus being contracted, to tampon was good practice; and he went so far as to suggest that probably in such cases the re-introduced placenta might be the best plug that the accoucheur could employ. The doctor had for nearly forty years of his practice an unusual number of cases of post-partum hæmorrhage. He had meantime conducted the third stage of labor according to the standard precepts of the day. Of late years he had fewer cases of hæmorrhage, and he referred the change in his experience to a change in his practice. As an almost invariable rule he had during the first decades of his work given ergot immediately after the birth of the child. It was following a discontinuance of this practice that the comparative freedom from post-partum bleeding occurred.

In placenta prævia centralis Dr. Groesbeck believed that perforation of placenta gave as good results as the passing of the hand between it and the uterus, and he regarded the former method as easier, and more speedy than the latter. When under any circumstances turning had been resorted to, Dr. Groesbeck delivered promptly, impressing on the child the necessary turns, and never waiting for nature to do so. In breech presentations the doctor thought it better practice to break the wedge as soon as the os was sufficiently dilated, bringing down both feet and delivering at once.

The doctor was an advocate of the rather frequent use of the forceps, using the old model Bedford for higher operations. When the head was lower in the pelvis he used the short forceps, always speaking highly of their convenience and efficiency. It should be remarked, however, that in the selection of the short instrument, Dr. Groesbeck rejected those in the construction of which the maker, in shortening the handles, shortened also the cephalic curve.

Dr. Groesbeck fully endorsed the views of the anatomy of the cervix uteri gravidi held by Braune, Bandl, Barnes and others. He believed that the placenta prævia was located below the os internum.

The doctor was possessed of an unusual degree of candor and was entirely void of professional pretense. He often admitted his shortcomings; thus, he did not hesitate to state that the mechanism of labor as regards the mutations of the foetal head in passing the parturient canal were to him inexplicable. He declared that he was generally unable to determine the position of the head, and that the reputed

"planes and spines" effecting changes in it were to him a "terra incognita."

His favorite obstetrical work was "The Principles of Midwifery, by John Burns." In the preference here indicated our colleague complimented his own judgment as well as the classical production of the Glasgow professor.

The doctor had a keen appreciation of the ways and means which tact and experience teach as aids to success in practice. In a knowledge of the subtle methods by which a physician may ingratiate himself with the people, magnify his importance, and obtain and retain practice, Dr. Groesbeck was not second to the author of "The Physician Himself." But while he was prodigal of advice in such matters to others, he took, in his own conduct, little heed of his own wisdom.

After he had been in the profession half a century he felt less confident that he would in any case do all that was possible for a patient than he had felt fifty years before. He on one occasion expressed surprise at the recollection of the nonchalant unconcern with which as a novice he had undertaken the management of an adherent placenta or placenta prævia.

As to the profession as a business, Dr. Groesbeck held an opinion contrary to that of the great mass of practitioners. He always insisted that the practice of medicine was upon the whole as easy and as pleasant a mode of earning a livelihood as any of which he had knowledge.

Dr. Groesbeck felt a fatherly interest in the younger members of the profession, and never tired of stimulating their thought and enlarging their knowledge by the narration of instructive cases and the enunciation of cardinal precepts.

Mr. President: From the shores of the mystical river we call to our vanishing friend the final word of mortals: Vale! Vale! An adieu laden with uncertainty, yet buoyant with hope. As we turn from the dark waters to the duties yet before us, let us pause to inscribe our index memorabilium with the honorable name of Abram Groesbeck.

FOREIGN CORRESPONDENCE.

COCAINE.

WIESBADEN, GERMANY, Dec. 1, 1884.

Mr. Editor:

E. Merck, the celebrated pharmacist of Darmstadt, has kindly furnished me with the following items in regard to the now famous remedy—cocaine.

The chemical formula according to Lossen is: $C_{17}H_{24}NO_4$. Cocaine is the alkaloid contained in the coca leaves (*Erythoxylon Coca Lam*) which was first isolated by Niemann. In 1862, Lossen discovered a second principle contained in the same leaves, viz.: hygein, which is of a volatile nature, and has received but little investigation so far; it seems to have a weak and hardly characteristic action. The leaves further contain ecgonin, coca tannin and a peculiar wax.

The coca crystals belong to the monocline system, melt at $98^{\circ}C.$, easily soluble in alcohol, more easily

in ether, but only dissolve in 704 parts water. The cocaine *salts*, however, are easily soluble in water.

The first reports of the internal use of coca leaves are handed down from the sixteenth century (Dr. Monardes, Seville, 1569). Its first appearance in Europe dates from 1749—it was described by Jussieu, and was named erythoxylon coca by Lamarck. Tschudi, Markham, Poppig and others who travelled in South America, found that the natives were in the habit of chewing coca leaves as a remedy for or preventive against the effects of extraordinary exertions. It seems, however, that the Indians chewed the leaves, together with the ashes of chenopodium. Quinea, the alkali in these ashes, probably eliminated the tannin from the coca leaves, leaving free the alkaloid.

Cocaine is believed to be the really active principle of the coca leaves. At first, on apparently good grounds, it was believed that this alkaloid possessed a property analogous to caffeine, theine and theobromine, viz.: the checking of waste in the body, but Merck declares it impossible to absolutely confirm this theory. Only the other day I saw it in the same list with guarana, caffeine, theine, etc., but was not considered to be as powerful as caffeine!

Cocaine has in small doses an exhilarating effect on the nerve centres, and it takes but a very small dose to produce toxic effects, especially in cold-blooded animals, but fortunately the effects of the drug do not seem to be cumulative. Schroff, who first experimented with cocaine in 1862, observed that 0.05 grm. given internally to rabbits caused great variation in the pulse and respiration, also temporary mydriasis; the same dose, subcutaneously, caused death in convulsions of an epileptic form, also mydriasis in a strong degree, which disappeared at once after death. In frogs 0.001 grm. produced complete loss of motion, preceded by excitement, while a dose of 0.002 grm. proved fatal.

According to Fronmüller, in 1863, a dose of 0.03–0.33 grm. given internally did not have any important effect upon human beings, simply causing sleep in some, accelerated and then retarded pulse and respiration in others. In a case of attempted suicide 1.5 grams produced no serious injury. Explanatory of this Mr. Merck suggests that the so-called cocaine of that time may not have been really pure cocaine. The preparation with which experiments have been and are being made on this side is Merck's cocaine murias sol. and the dose is 0.05 grm.; however, as much as 0.5 grm. of this solution has been administered subcutaneously. The effects of a subcutaneous injection are first a feeling of warmth, then an insensibility to feeling in the neighborhood of the part, and finally a reddening of the skin. In thirty minutes' time these all disappear.

Dr. Aschenbrandt has found in cocaine an admirable restorative from the exhaustion of diarrhoea, as stated in No. 50 of the *Deutsche Medicin. Wochenschr.*, 1883. Prof. Dr. E. V. Fleischel, of Vienna, has proved, to his own satisfaction at least, that cocaine subcutaneously administered is a valuable aid in preventing and curing the morphia habit. (I myself have had excellent results from it with tobacco

chewers who were anxious to break the habit.) In America, W. H. Bently observed the good effects of cocaine in overcoming the taste for morphia. Dr. Freud, of the Vienna General Hospital, reports a case of the morphia habit cured within ten days by the use of 0.1 grm. injected subcutaneously three times daily. His theory is that morphia and cocaine are antagonistic. Dr. Freud likewise credits this alkaloid with aphrodisiac properties.

According to the experiments collected by Merck, the therapeutical value of cocaine may be thus described: Cocaine is a stimulant which quickly increases and serves to sustain, in a harmless manner, the physical powers of the body; it is much more strengthening than alcohol—hence its value on all occasions of extraordinary bodily exertion—in doses of 0.05 grm. at intervals. Whether the powers of the mind can likewise be increased and strengthened is still unknown, as also whether the activity of the nerve centres can be permanently increased. Some good results have been obtained in the treatment of melancholia by the subcutaneous method. It is valuable as a stomachic, particularly after a debauch in eating or drinking. It is credited with the permanent cure of atonic indigestion. The various cachexias, phthisis, exhausting fevers, mercurial poisoning, etc., are said to be averted by its use. Its value in dipsomania is not so well established as in the morphia habit, though there are many satisfactory experiments in that direction. As is well known, cocaine paralyzes the sensation of the mucous membrane when brought in contact with the membrane; hence its possible future in diseases of the throat, and in operations about the mouth and throat. (I have not seen any account of experiments of others, but I am making some observations and trials in regard to the use of the drug subcutaneously in perineorrhaphy and trachelorrhaphy. It will be a happy day for surgeons if these minor operations can be done without ether.)

Of its ophthalmological value enough has already been said.

Cocaine citras is used by dentists to anæsthetize the dental nerves. Mr. Merck tells me that this salt can be readily kneaded into pills, which may be wrapped in wadding, moistened and placed in the hollow of the tooth, when lo! the tooth can then be cleaned and filled without pain. If this be true, the man who discovered it is worthy of a high place among the benefactors of the race.

Merck's preparations include the pure cocaine alkaloid, also the salts, viz.: Hydrochlorate, salicylate, hydrobromate, tartrate and citrate. The experiments mentioned above have been made with the hydrochlorate in about 0.05 gramme doses. Von Hoffmann, of Baden-Baden, recommends the salicylate for ophthalmological use, but Merck observes that it still remains to be seen which salt is the best for the eye. Finally, cocaine is not a simple substance. When treated with concentrated hydrochloric acid, it splits up into ecgonin, benzoic acid, and methyl alcohol. Mr. Merck informs me that he hopes to be able ere long to report on the physiological action of ecgonin.

That your readers may possibly be as much interested in this subject as I am, is my only apology for thus intruding upon your valuable space.

Very sincerely yours,

SARAH HACKETT STEVENSON, M.D.

BOOK REVIEWS.

COURIER REVIEW CALL BOOK. J. H. Chambers & Co., Chicago, St. Louis and Atlanta.

PHYSICIANS' POCKET DAY BOOK. By C. H. LEONARD, Detroit.

THE 1885 MEDICAL RECORD VISITING LIST. Wm. Wood & Co., N. Y.

THE PHYSICIAN'S VISITING LIST. P. Blakiston, Son & Co., Philadelphia.

The character of these books is too well known to need comment. They are all excellent for the purpose for which they were intended. They are well bound, and in every way convenient.

MISCELLANEOUS.

COMFORTS FOR TRAVELLING INVALIDS.

An article on Winter Health Resorts, in the *Practitioner*, contains some valuable hints to invalids, to relieve the discomforts found by them abroad in travelling and at hotels. One of the discomforts of the long railway journey which is required in order to reach most health resorts, is the constant vibration and the fatigue it occasions. This may be, to a considerable extent, avoided by the proper use of air cushions. It is well for an invalid to be provided with two or more of these. The one to be used for sitting on may be either round or square, and may be either with or without a depression in the centre. Air cushions of a horseshoe shape and furnished at the ends with tapes so that they can be opened out, and again tied together, are most useful. One of them tied round the loins supports the back, and another just like a collar round the neck supports the head, so that in whatever position it is put, sideways, backwards, or forwards, it always rests against the cushion.

Another comfort to invalids travelling, is an India rubber bag for hot water with a flannel case. Indeed it is well to have two of these if the invalid be very delicate. If any sudden chill is felt, or if any pain in the chest or elsewhere should come on, relief is often obtained by the application of a hot-water bottle which takes the place of a poultice. The invalid's friend can easily get these bottles filled with hot water by giving a small gratuity to the guard of the train, and asking him to fill them when stopping at a station. Stoppages occur on the French lines at least every two hours, and the water retains its heat quite long enough to make it useful between the stoppages. Another thing which is a great comfort is an eider-down coverlet, which should be both long and broad.

It is useful, not only during travelling by land or by sea, but during a stay at the health resorts. One would imagine that an eider-down quilt would be bulky and inconvenient to travel with, but this is not the case. In most "hold-alls" there is a large pocket, and the eider-down quilt can be readily rolled up and put into this pocket. When the straps are once around it, it can, from its softness, be easily pressed into a small bulk.

Two other things that the invalid should not be without are a small etna, with can or kettle, to boil water, and a small package of tea, also beef-tea in a portable form, with a small box of biscuits. Even when such things are to be had at a hotel, the prices put upon them are sometimes so exorbitant that the invalid would hardly care to order them, however much he might desire them.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY DURING THE WEEK ENDING DECEMBER 13, 1884.

Craig, T. C., Passed Assistant Surgeon. Detached from Alliance and placed on waiting orders. Dec. 6, 1884.

Curtis, L. W., Assistant Surgeon. To the Naval Hospital, Chelsea. Dec. 9, 1884.

Gaines, J. H., Passed Assistant Surgeon. Present duty continued.

Green, E. H., Passed Assistant Surgeon. Special duty at Museum of Hygiene, Washington. Dec. 11, 1884.

Murray, J. M., Passed Assistant Surgeon. Detached from Naval Hospital, Chelsea, to the Flagship Hartford. Dec. 9, 1884.

Wolverton, T., Surgeon. To the Shenandoah. Dec. 6, 1884.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, UNITED STATES ARMY, FROM DECEMBER 6, 1884, TO DECEMBER 12, 1884.

Hammond, John F., Colonel and Surgeon, retired from active service, by operation of law, on Dec. 7, 1884, under provision of Act of Congress approved June 30, 1882. (S. O. 287, A. G. O., Dec. 8, 1884.)

Irwin, B. J. D., Major and Surgeon, granted one month's leave of absence. (S. O. 112, Dept. Arizona, Nov. 28, 1884.)

McKee, J. C., Major and Surgeon. Leave of absence still further extended one month. (S. O. 288, A. G. O., December 9, 1884.)

O'Reilly, Robt. M., Captain and Assistant Surgeon, assigned to duty as attending Surgeon, Washington City, D. C., to date from October 20, 1884. (S. O. 284, A. G. O., December 4, 1884.)

Porter, Joseph Y., Captain and Assistant Surgeon, sick leave of absence extended four months on surgeon's certificate of disability. (S. O. 286, A. G. O., Dec. 6, 1884.)

Kane, John J., Captain and Assistant Surgeon, from Dept. East to Willets Point, New York. (S. O. 286, A. G. O., December 6, 1884.)

Banister, J. M., Captain and Assistant Surgeon. (Ft. Adams, R. I.) Granted one month's leave of absence on surgeon's certificate of disability. (S. O. 251, Dept. East, December 9, 1884.)

Barrows, C. C., First Lieutenant and Assistant Surgeon, in addition to other duties, to take charge of Medical Division Office, Dept. Arizona, during absence of Surgeon B. J. D. Irwin. (S. O. 112, Dept. Arizona, Nov. 28, 1884.)

Gray, Chas. C., Major (retired.) Died at Geneva, N. Y., Nov. 22, 1884, instead of Nov. 26, as heretofore announced. (Circular Orders A. G. O. December 8, 1884.)

REPORT OF LIBRARIAN.

ANNUAL REPORT OF THE LIBRARIAN OF THE AMERICAN MEDICAL ASSOCIATION AT THE ANNUAL MEETING IN WASHINGTON, MAY, 1884.

[By. C. H. A. Kleinschmidt, M. D., Washington, D. C.]

CATALOGUE OF ADDITIONS BY DONATIONS, EXCHANGES AND SUBSCRIPTION TO THE LIBRARY OF THE AMERICAN MEDICAL ASSOCIATION, FROM MAY 1, 1883, TO MAY 1, 1884.

- Aitken* (Wm.)—Handbook of Therapeutics. New York, 1882.
Allen (Nathan.)—The Laws of Human Increase. Studies of the Laws of Life The Prevention of Insanity. Claims of the Sick Poor. Influence of Medical Men.
Anderson (M. F.) The Phosphates in Nutrition.
Army Engineer Department (United States).—The Fortifications of To-day. Washington, 1883. Donor, Engineer Bureau.
Army Medical Department (United States).—Medical and Surgical History of the War of the Rebellion, Part III, vol. II, Surgical History, 4to. 986 pp. Illustrated.
Index Catalogue of the Library of the Surgeon-General's Office.—Authors and Subjects. Vol. IV. Donor, Surgeon-General's Office.
Ashby (T. A.)—A Contribution to the Study of Neglected Lacerations of the Cervix Uteri and Perinaeum. Donor, Author.
Atlee (J. L.)—A Case of Strangulated Hernia. Donor, Author.
Atlee (L. W.)—A Case of Congenital Cyst of the Back of the Head. Donor, Author.
Atlee (W. F.)—The History of a Case of Abdominal Cystic Tumor. A Case of Ovariectomy. A Case of Fungosities of the Bladder.
Baldwin (W. O.)—Tribute to the late James Marion Sims, M.D., LL.D.
Beilstein (F.)—Lessons in Quantitative Chemical Analysis. Translated by C. O. Curtman. 1883.
Belfield (W. T.)—On the Relations of Micro-Organisms to Disease. Reprint. Donor, Author.
Billings (J. S.)—Medical Biography. Reprint. Donor, Author.
Biography. (Ashford F. A.)—Mémorial of. Donor, Washington Obstetrical and Gynaecological Society.
Biography. (Hakes, H.)—By G. B. Kulp. Donor, Author.
Boeckeler (C. F. W.) Iodoform in Dental Surgery. Reprint. Donor, Author.
Borck (E.)—Diagnosis of Ovarian Tumors. Lectures. Donor, Author.
Brownson (W. G.)—The Country Doctor. Reprint. Donor, Author.
Bruen.—(E. T.) Pocket Book of Physical Diagnosis.
Burnett (C. H. and O. C. A.)—Clinical History of a Case of Recurrent Dropsy of the Left Middle Ear. Reprint. Donor, Author.
Buscy (S. C.)—Influence of Constant Use of High-heeled French Shoes upon the Female Form, etc. Reprint. Washington Malaria and the Catching of Cold. Reprint. Craniotomy upon the Living Foetus is not Justifiable. First Annual Address of the President delivered before the Washington Obstetrical and Gynaecological Society. Reprint. Donor, Author.

DOMESTIC CORRESPONDENCE.

OVIARTOTOMY.

Dec. 1, 1884.

TO THE EDITOR OF THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.

I have been much interested in the article entitled, "Unilocular Ovarian Cyst Weighing 95 pounds Successfully Removed, by Geo. E. Ranney, M.D., of Lansing, Mich."

I was not alone interested in the history of the case, from the great size of the tumor, but more especially from the fact that about one month ago the same case was reported, in the *Medical Age*, of Detroit, as being "the largest ovarian tumor ever removed in the State of Michigan," and that Dr. Edward W. Jenks, of Detroit, was the remover thereof, and that Dr. Ranney "assisted." As Dr. Ranney did not furnish this information to the *Age*, I am much interested in the *how* and the *whatfor* of this dual report? Did this patient really have two 95-pound tumors? so that Dr. Jenks could cut away one, and Dr. Ranney the other(?) Yet, Dr. Ranney says it was an "unilocular" cyst, in his title, that he cut away. Evidently, from the facts before the profession now, some one needs to read, and draw a lesson, from Luke xiv, 7-12.

H.
